The tests described above are called presumptive tests as other strains of bacilli can give similar reactions to *B. anthracis*. The demonstration of virulence constitutes the principle point of difference between typical stains of *B. anthracis* and those of other anthrax-like organisms. Traditionally, the guinea pig has been the model used to demonstrate virulence. The animal is injected with the sample, and if it dies, the cause of death is confirmed by isolation of *B. anthracis* from blood. Although this traditional technique is sensitive, it is likely to be replaced by more sensitive *in vitro* tests.

Virulent isolates of *B. anthracis* produce both a capsule and exotoxins. Detection of capsule formation is relatively simple. Capsule-forming organisms when grown on medium containing bicarbonate and in the presence of CO_2 produce colonies that are raised and mucoid in appearance, whereas noncapsule forming organisms produce flat, dull colonies. In addition, the presence of the capsule can be confirmed by McFadyean stain.

Detection of active toxin production is not as straightforward and requires either an animal system, a tissue culture assay using toxin-sensitive cell lines, or an immunological technique, such as an enzyme-linked immunosorbent assay. An alternative approach is to employ PCR to detect the presence of the genes encoding these virulence factors.

Control and Prevention

Most countries have regulations concerning the handling and disposal of infected food animals and their products. The World Health Organization has produced detailed comprehensive and practical guidelines on anthrax detailing the best practices on all aspects of the disease. In many areas where anthrax is endemic, particularly Africa, the problem is not the lack of regulations but rather the will and the means to enforce them in the face of local customs.

In essence, the control of anthrax requires the well-supervised disposal of infected animals carcasses, the application of biocides to reduce spore numbers below an infectious dose, immediate vaccination, and/or prophylactic treatment of other members of the affected herd or at-risk individuals. Although the recommendations in most countries is that anthrax carcasses should be buried or burnt, the legacy of contaminated land from past burials capable of infecting animals many years later shows that incineration is the only truly satisfactory option. Mobile incinerators are available but complete destruction of a bovine carcass can take more than 24 h and is relatively costly. Some countries prefer rendering, although the problem of limiting environmental contamination of land and equipment during transportation to the rendering plant has to be addressed.

The decontamination of anthrax spore-contaminated soil is a vital step in breaking the infection cycle as direct animal-to-animal transmission is extremely rare. To date, decontamination modalities for anthrax spores have centered on the application of toxic biocides (formaldehyde; chlorine releasing agents, such chlorine dioxide; and hydrogen peroxide), or γ-radiation. Although effective, these approaches suffer from the fact that they damage the environment and are extremely expensive to deploy when treating large areas. For this reason, mass livestock vaccination is usually instigated once cases of anthrax have been identified. Although effective, the duration of protection is thought to be approximately a year, thus necessitating the need for repeated immunization. Consideration is being given to the development of suitable oral vaccines for this purpose, although numerous obstacles must be overcome before satisfying concerns over safety, environmental contamination, and efficacy.

Importance to the Food Industry

The number of reported cases of foodborne illness involving *B. anthracis* is extremely small compared with other traditional

foodborne pathogens. To date, there has never been a documented case in USA. In countries with well-developed veterinary and public health systems, infected animals will be identified and removed from the food chain. In countries where such systems are not in place, there is potential for contaminated animals and their products to be processed and consumed. A survey of animals in a slaughterhouse in eastern Nigeria revealed that 5% of cattle and 3.3% of sheep tested positive for anthrax. These infected animals not only pose a risk to the people consuming the meat, but are also an occupational risk to workers exposed to the carcasses. In the same survey, it was found that 13% of butchers/skinners had acquired cutaneous anthrax, whereas a retrospective survey of human anthrax cases in Eastern Turkey between 1990 and 2007 found that 95.2% of 426 infections had a history of contact with animal products. Indeed, slaughterhouse waste in the form of offal for animal feed, and slurry discharged into the environment, represents a further source of potential infection. A study of uncut anthrax-contaminated slaughterhouse waste showed that viable anthrax could still be recovered after the offal had been heat treated for 30 min at 130 °C. The use of bone charcoal by the food industry in the production of sugar products presents an avenue for anthrax contamination. The bones are normally obtained from areas of the world in which anthrax is endemic and on occasions *B. anthracis* has been isolated. For this reason, the bones must be sterilized, usually by γ-irradiation, before use.

Owing to the scarcity of the disease, there are few published records of human infection. As one would expect, the cases that have been reported originate mainly from Africa, the Middle East, and Central and South Asia. Figures for human anthrax in China showed that of 593 recorded cases, 384 were linked to the dismembering and processing of infected animals and 192 cases were due to the consumption of contaminated meat. In neighboring Korea, sporadic outbreaks of human anthrax have been reported. From 1992 to 1995, three outbreaks occurred, a total of 43 cases, all linked to the consumption of contaminated beef or bovine brain and liver. An outbreak in India was centered on an infected sheep; of the five individuals who skinned and cut up its meat for human consumption, four developed fatal anthrax meningitis. Another person who wrapped the meat in a cloth and carried it home on his head developed a malignant pustule on his forehead and went on to develop meningitis. It is noteworthy that a large number of people who cooked or ate the cooked meat of the dead sheep remained well.

Research Needs

Anthrax is primarily a disease of food animals in economically disadvantaged regions of the world. History has shown that the incidence of the disease can be controlled by the introduction and adherence to effective veterinary and public measures. Research is needed to develop practices, which will achieve these aims at minimal cost to these communities.

Bacillus cereus and Other Pathogenic *Bacillus* Species

PE Granum, L Stenfors Arnesen, and C From, Norwegian School of Veterinary Science, Oslo, Norway

Glossary

Emetic toxin Compound that results in vomiting.
Enterotoxin Toxin (protein) that causes diarrhea.
Hepatocytes Cells of the main tissue of the liver.
Necrotic enteritis Inflammation of the intestine, with cell death.
Non-ribosomal synthesis Synthesis of peptides from enzymes and not through normal ribosomal protein synthesis.
Polymerase chain reaction (PCR) A genetic tool to detect specific genes.

Introduction

There are several *Bacillus* species that have been responsible for foodborne illness (Table 1), although the only one that is frequently involved is *Bacillus cereus*. Six species are closely related and grouped together in the *B. cereus* group, among them is *Bacillus anthracis*. All these species can probably cause foodborne illness and will, in most cases, not be distinguished in routine food laboratories, apart from *B. anthracis*, which is usually not hemolytic and is sensitive to penicillin. It has also been suggested that these species are so closely related that they should be considered as one species. In this article, the *B. cereus* group (apart from *B. anthracis*) will mostly be handled as one species, although *Bacillus thuringiensis* and *Bacillus weihenstephanensis* will partly be dealt with separately.

The other *Bacillus* species that might cause foodborne illness are all isolated from soil and foods and include mainly species in the *Bacillus subtilis*-group (*B. subtilis*, *Bacillus mojavensis*, *Bacillus licheniformis*, and *Bacillus pumilus*). However, in contrast to the members of the *B. cereus* group, only a small number of isolates of these species have the ability to produce toxins that can result in foodborne illness (Table 1).

As an agent of foodborne illness, *B. cereus* is of growing concern although it does not usually cause the type of disease leading to news headlines. However, outbreaks of both the emetic and the diarrheal type of foodborne illness have caused deaths during recent years. As non-reportable diseases, the true number of cases and outbreaks is unknown, but large outbreaks have been reported for several countries. The fact that it is usually a relatively mild and short lasting disease (less than 24 h) may at least partly account for the high underreporting in official statistics.

Bacillus cereus is a Gram-positive, spore-forming, motile, aerobic rod that also grows well anaerobically. It is a common soil saprophyte and is easily spread to many types of foods, especially of plant origin, but is also frequently isolated from meat, eggs, and dairy products. *Bacillus cereus* and other members of the *B. cereus* group can cause two different types of foodborne illness: the diarrheal type and the emetic type. The diarrheal type of foodborne illness is probably caused by enterotoxins, produced by *B. cereus* during vegetative growth in the small intestine. At least three different enterotoxins are suspected to be involved. In contrast, the emetic toxin is preformed during the growth of emetic *B. cereus* strains in the food. For both types of foodborne illness, the food involved has usually been heat-treated, and surviving spores are the source of the foodborne illness. *Bacillus cereus* is not a competitive microorganism, but grows well after cooking and cooling (less than 42–50 °C). The heat treatment will cause spore germination, and in the absence of competing flora, *B. cereus* grows well. Invasion by psychrotolerant strains from the *B. cereus* group in the dairy industry has led to increasing surveillance of *B. cereus* in recent years.

The closely related *B. thuringiensis* can produce enterotoxins and has been shown to cause foodborne illness symptoms when given to human volunteers. Furthermore, foodborne illness outbreaks involving *B. thuringiensis* have been reported. The extensive use of this organism as a protective agent against insect attacks on crops may contribute to the increasing problems with organisms of the *B. cereus* group observed in the food industry. Standard confirmation procedures for *B. cereus* does not differentiate between the two species, if at all possible from heat-treated food products, because *B. thuringiensis* will frequently loose the insecticidal plasmids when grown above 30 °C. Thus, investigation of the true number of foodborne illness cases caused by commercially used *B. thuringiensis* is difficult. To ensure safe spraying with *B. thuringiensis*, the strain in use should be unable to produce foodborne disease toxins. Already, The Health and Consumer Protection Directorate-General (European Commission) has accepted that only nontoxin producing *Bacillus* spp. should be allowed for use in animal nutrition. *Bacillus weihenstephanensis* is the psychrotolerant species within the *B. cereus* group, although a few *B. cereus* strains able to grow at temperatures as

 doi:10.1016/B978-0-12-378612-8.00087-1

Table 1 The different *Bacillus* species that have been involved in foodborne illness. The first six species belong to the *B. cereus* group and are very closely related

Species	*Illness*
B. cereus	Frequently involved in foodborne illness
B. anthracis	Has also caused foodborne illness (see Characteristics of *Bacillus cereus* Disease)
B. thuringiensis	Involved in foodborne illness
B. mycoides	Might have been involved in foodborne illness
B. weihenstephanensis	Probably not, but might have been involved in foodborne illness
B. pseudomycoides	Might have been involved in foodborne illness
B. licheniformis	Involved in foodborne illness
B. pumilus	Involved in foodborne illness
B. subtilis	Involved in foodborne illness
B. brevis	Involved in foodborne illness

low as 4 °C have been described. *Bacillus weihenstephanensis* strains seem to be non- or low-enterotoxin producing at 37 °C, and hence should be less likely to cause diarrheal disease. Recently, a few *B. weihenstephanensis* strains have been found able to produce emetic toxin.

Taxonomy of the *Bacillus cereus* Group

The aerobic endospore-forming bacteria are traditionally placed in the genus *Bacillus*. Over the past three decades, this genus has expanded to accommodate more than 260 species. Analysis of 16S ribosomal RNA sequences from numerous *Bacillus* species indicated that the genus *Bacillus* should be divided into at least five genera or rRNA groups. The species that are treated in this text (Table 1) still belong to the genus *Bacillus* in the suggested division.

Bacillus anthracis, *B. cereus*, *Bacillus mycoides*, *B. thuringiensis*, and more recently *Bacillus pseudomycoides* and *B. weihenstephanensis* comprise the *B. cereus* group. These bacteria have highly similar 16S and 23S rRNA sequences, indicating that they have recently diverged from a relatively common evolutionary line. Extensive genomic studies of *B. cereus* and *B. thuringiensis* have shown that there is no taxonomic basis for separate species status. Nevertheless, the name *B. thuringiensis* is retained for those strains that synthesize a crystalline inclusion (Cry protein) or δ-endotoxin that may be highly toxic to insects. The *cry* genes are usually located on plasmids, and loss of the relevant plasmid(s) makes the bacterium indistinguishable from *B. cereus*. It is now clear that all species of the *B. cereus* group, including *B. thuringiensis*, carry enterotoxin genes.

Foodborne Outbreaks Caused by the *Bacillus cereus* Group

Bacillus cereus is well recognized as a foodborne disease agent. Outbreaks can be divided into two types according to their symptoms. The diarrheal type is the most frequent in Europe and USA whereas the emetic type appears more prevalent in Japan. Typical foods implicated are stews, puddings, sauces, pasta, and rice dishes. When expressed as a proportion of all reported foodborne illnesses, outbreaks ascribed to *B. cereus* seem to be concentrated in Scandinavia and Canada (10–47% of total have been reported) and are less frequent in Central Europe, UK, USA, and the Far East (1–5% of total). Although these differences might partly be due to different consumer habits, they are also not comparable due to dissimilar reporting practices. Thus, in the Netherlands, in 1991, *B. cereus* was responsible for 27% of outbreaks in which the causative agent was identified. However, the incidence was only 2.8% of the total, because the majority of cases of foodborne illness were of unknown etiology. In addition, when the number of foodborne illness cases ascribed to *B. cereus* is expressed on a per head of population basis, many of the large regional differences in incidence disappear. In recent years, *B. cereus* have been reported from foodborne outbreaks and isolated from foods in South America (Brazil and Argentina), Africa (Kenya and Botswana), and Asia (Korea and Thailand). However, official statistics are not available for these continents. Examples of foods involved in outbreaks in different countries are given in Table 2.

Characteristics of *Bacillus cereus* Disease

The emetic toxin, cereulide, causes vomiting, whereas diarrhea is the main symptom of the second type of disease, caused by enterotoxins. In a very small number of cases, both types of symptoms are recorded, probably due to ingestion of preformed emetic toxin together with live *B. cereus* cells/spores, which may produce enterotoxins in the small intestine after a few hours. The question of whether or not the enterotoxin(s) can cause intoxication by preformation in foods has caused some debate. On review of the literature, it seems clear that the incubation time is a little too long for enterotoxins (more than 6 h; average 12 h), and model experiments have shown degradation of the enterotoxins on the way to the ileum. Although the enterotoxin(s) can be preformed, the number of *B. cereus* cells in the food would need to be at least two orders of magnitude higher than that necessary for causing foodborne illness, and such products would no longer be acceptable to the consumer for sensory reasons. The characteristics of *B. cereus* foodborne illness are given in Table 3.

In recent years, foodborne illness due to ingestion of *B. anthracis*-infected meat has been reported from three

Table 2 Examples of the variety of foods involved in *Bacillus cereus* foodborne illness

Type of food	*Country*	*Number of people involved*	*Type of syndrome*[a]
Barbecued chicken	Many countries	–	E, D
Cooked noodles	Spain	13	D

Vegetable purée	France	44	D
Vanilla sauce	Norway	>200	D
Wheat flour dessert	Bulgaria	–	D

[a]E, emetic syndrome; D, diarrheal syndrome.

Table 3 Characteristics of the two types of disease caused by *Bacillus cereus*

	Diarrheal syndrome	*Emetic syndrome*
Infective dose	10^5–10^8 (total)	10^5–10^8 (cells per gram food to produce enough emetic toxin)
Toxin produced	In the small intestine of the host	Preformed in foods
Type of toxin	Protein(s)	Cyclic peptide
Incubation period	8–16 h (occasionally >24 h)	0.5–6 h
Duration of illness	12–24 h (occasionally several days)	6–24 h
Symptoms	Abdominal pain, watery diarrhea (in rare occasions with bloody diarrhea) sometimes with nausea	Nausea, vomiting, and malaise (sometimes followed by diarrhea, due to additional enterotoxin production?)
Foods most frequently implicated	Meat products, soups, vegetables, puddings/sauces, and milk/milk products	Fried and cooked rice, pasta, pastry, and noodles

Table 4 Toxins involved in foodborne illness produced by *Bacillus cereus*

Toxin	*Type/size*	*Food poisoning*
Hemolysin BL (Hbl)	Protein, three components transcribed from one operon: HblC (L_2-component), HblD (L_1-component), and HblA (B-component). The proteins are between 37 and 46 kDa.	Probably
Non-hemolytic enterotoxin (Nhe)	Protein, three components transcribed from one operon: NheA, NheB, and NheC. The proteins are between 36 and 41 kDa.	Yes
Cytotoxin K (CytK)	Protein, one component, 34 kDa	Yes, three deaths
Emetic toxin (cereulide)	Cyclic peptide, 1.2 kDa	Yes, two deaths

continents (Asia, Africa, and America). Patients without anthrax symptoms developed diarrhea (sometimes bloody) with fever and rashes. However, the enterotoxins known from *B. cereus* are unlikely to have caused these symptoms, because their genes are not transcribed in *B. anthracis*. From the total genome sequence of *B. anthracis*, enterotoxin genes (*nhe*) are known to be present, but the positive regulator for enterotoxin production (see Table 4) is nonfunctional.

Infectious Dose of *Bacillus cereus* Disease

Counts ranging from 10^4 to 10^9 g^{-1} (or ml) *B. cereus* have been reported in the incriminated foods after foodborne illness, giving putative total infective doses ranging from approximately 5×10^4 to 5×10^{11} cfu. The variation in the infective dose is partly due to the differences in the amount of enterotoxin produced by different strains (at least two orders

of magnitude), and partly due to the difference in infective dose between vegetative cells and spores, as the spores survive the passage through stomach acidity. Thus, any food containing more than 10^3 *B. cereus* g^{-1} cannot be considered completely safe for consumption.

Virulence Factors/Mechanisms of Pathogenicity

Very different types of toxins cause the two types of *B. cereus* foodborne illness. The emetic toxin, causing emesis (vomiting), is a ring-formed small peptide, whereas several different enterotoxins are involved in the diarrheal disease (Table 4).

The Emetic Toxin

The emetic toxin causes emesis in some primates and also has cell toxic activities. Its structure remained mysterious for many years, as the only detection system involved living primates. The discovery that the toxin could be detected by its vacuolation activity on HEp-2 cells led to its isolation and structure determination. The emetic toxin was named cereulide, and consists of a ring structure of three repeats of four amino- and oxy-acids: [D-*O*-Leu-D-Ala-L-*O*-Val-L-Val]3. This ring structure (dodecadepsipeptide) has a molecular mass of 1.2 kDa, and is, chemically, closely related to the potassium ionophore valinomycin. It has been shown in model animals that cereulide stimulates the vagus afferent through binding to the 5-HT3 receptor. The emetic toxin is resistant to heat, pH (2–12), proteolysis, and is not antigenic. Cereulide is produced by a nonribosomal peptide synthetase, encoded by the 24 kb cereulide synthethase (*ces*) gene cluster which is located on a megaplasmid related to pXO1.

Cereulide was responsible for the death of a 17-year-old Swiss boy some years ago, due to fulminant liver failure. A large amount of *B. cereus* emetic toxin was found in the residue from the pan used to reheat the food (pasta) and in the boy's liver and bile. In 2003, a 9-year-old Belgian girl died after eating a contaminated pasta salad, and there have also been other cases of serious outcomes of cereulide intoxication. In a recent study, mice were injected with synthetic cereulide, and the development of histopathological changes was examined. At high cereulide doses, massive degeneration of hepatocytes occurred. The serum values of hepatic enzymes were highest on days 2–3 after the inoculation of cereulide, and rapidly decreased thereafter. General recovery from the pathological changes and regeneration of hepatocytes were observed after 4 weeks.

Enterotoxins

As shown in Table 4, three different enterotoxins believed to be involved in foodborne illness have been characterized to date. The three-component hemolysin (Hbl; consisting of three proteins: B, L_1, and L_2) with enterotoxin activity was the first to be fully characterized. Convincing evidence has shown that all three components are necessary for maximal enterotoxin activity. This toxin also has dermonecrotic and vascular permeability activities, and causes fluid accumulation in ligated rabbit ileal loops. Hbl has been suggested to be a primary virulence factor in *B. cereus* diarrhea. A model for the action of Hbl suggests that the components of Hbl bind to target cells independently, subsequently forming a membrane-attacking complex causing cell lysis by a colloid osmotic mechanism. Substantial heterogeneity has been observed in the components of Hbl, and strains can produce different combinations of variants of each component.

A 'non-hemolytic' three-component enterotoxin (Nhe) was more recently characterized. The three components of this toxin are different from those of Hbl, although there are similarities. Nhe enterotoxin was first purified from a *B. cereus* strain isolated in a large foodborne illness outbreak in Norway in 1995. Binary combinations of the components of this enterotoxin possess some biological activity, but not nearly as high as when all the components are present. The three components act optimally in a ratio of 10:10:1 (NheA:NheB:NheC), and make a huge pore in the epithelial cells, resulting in diarrhea.

All tested *B. cereus*/*B. thuringiensis* strains carry genes for Nhe, and approximately 60% do for Hbl. Presently, the respective importance of the two toxins in foodborne illness is unknown, but several foodborne illness isolates are not Hbl-producing. Furthermore, it has been shown that the majority of the toxicity on epithelial cells is due to Nhe, and not to Hbl.

There is significant sequence identity between the three proteins of Nhe, and between the Nhe and Hbl proteins. In spite of the similarities between the components of Hbl and Nhe, they cannot substitute for each other to give biologically active complexes.

The more recently described cytotoxin K (CytK) is similar to the β-toxin of *Clostridium perfringens* (and other related toxins) and caused the symptoms in a severe outbreak of *B. cereus* foodborne illness in France in 1998. In this outbreak, several people developed bloody diarrhea, and three died. It can reasonably be characterized as an outbreak of *B. cereus* necrotic enteritis, although it was not as severe as *C. perfringens* type-C foodborne necrotic enteritis.

Other Possible Virulence Factors

The *B. cereus* spore is more hydrophobic than any other *Bacillus* spp. spores, which makes it adhesive to several types of surfaces. Additionally, the *B. cereus* spore carries appendages or pili that might be involved in adhesion (Figure 1) and may lead to clustering together of spores. Therefore, *B. cereus* spores are not easily removed by cleaning, and they are difficult targets for disinfection. In addition to enabling spores to survive sanitation (and thus be available for contamination of foods), these properties may also aid spore adherence to epithelial cells. Experiments have shown that spores from a *B. cereus* outbreak strain can indeed adhere to Caco-2 cells in culture, and that adherence is linked to hydrophobicity and possibly to the appendages. A longer incubation period observed in this disease case would be expected, as the spore would first have to germinate.

Commercial Methods for Detection of the *Bacillus cereus* Toxins

Two commercially available immunoassays detect one component each of *B. cereus* enterotoxins Nhe and Hbl. Neither assay is quantitative. The Oxoid Bacillus cereus RPLA enterotoxin detection kit (Oxoid Ltd., Basingstoke, UK) detects the

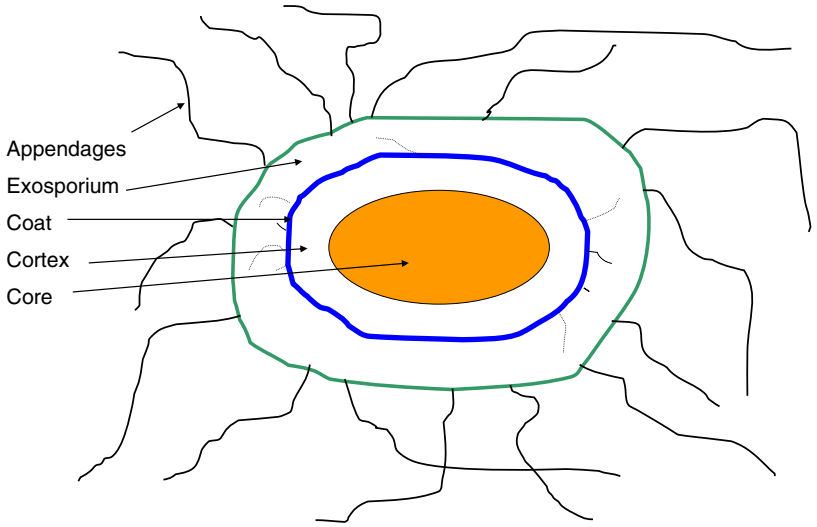

Figure 1 The *Bacillus cereus* spore with the different layers and appendages.

Table 5 Characteristics of the illness caused by the three *Bacillus* species other than *B. cereus* causing food poisoning

	Bacillus subtilis	Bacillus licheniformis	Bacillus pumilus
Foods involved	● Meat dishes with elements of vegetables ● Seafood with rice ● Bread and pastry products ● Sandwiches ● Pizzas	● Meat dishes with elements of vegetables ● Bread and pastry products ● Chicken	● Meat products ● Sandwiches ● Canned tomato juice ● Rice
Infective dose	$>10^5$	$>10^6$	$>10^6$
Incubation period	10 min–14 h	2–14 h	15 min–11 h
Duration	2–8 h	6–24 h	
Symptoms:			
● Vomiting	80%	54%	Yes
● Diarrhea	49%	92%	Yes (not all)
● Abdominal pain/cramps	27%	46%	Yes
● Other symptoms	Nausea, headaches, and flushing/sweating	Not reported	Headache, dizziness, chills, and elevated heart rate

HblC (L_2) component, whereas the Tecra Bacillus diarrheal enterotoxin visual immunoassay kit (Bioenterprises pty, Australia) mainly detects the NheA protein. Although only one toxin component is detected, a positive result from *B. cereus* culture supernatant in either assay indicates that the strain is enterotoxin positive. If the supernatant is also cytotoxic on cultured epithelial cells, the strain can be regarded as enterotoxin positive. For the third cytotoxin, CytK, there is no commercial detection method available. Unfortunately, this is also the case for detection of the emetic toxin. However, a sensitive screening assay on boar sperm has been developed for the emetic toxin, in addition to specific liquid chromatography–mass spectroscopy (LC–MS) methods.

Foodborne Disease Potential of Other *Bacillus* Species

Since the early 1970s, a number of reports have implicated *Bacillus* species other than *B. cereus* as the cause of foodborne disease, mainly involving species in the *B. subtilis* group (*B. subtilis*, *B. pumilus*, and *B. licheniformis*). Common symptoms for these foodborne illness incidents are vomiting and diarrhea and in some cases abdominal pain/cramps. Additional symptoms are headache, flushing, sweating, and dizziness. The incubation period of the incidents range from acute to 14 h, and the duration of the disease is reported from 1.5 to 24 h depending on the species involved. The implicated food vehicles in most cases are meat pasties or pies with vegetables, rice dishes, and pasta. The infective dose variation for these species is not clear, although it must be quite high (usually more than 10^6) (Table 5). Foodborne illness incidents where *B. brevis* (now *Brevibacillus brevis*) was detected in large numbers ,either alone or with *B. cereus*, from the implicated foods have also been reported. This organism was also, in one incident, isolated from the feces of a patient. The main symptoms in these episodes were vomiting and diarrhea, and the incubation times ranged from 1 to 9.5 h. In 2006, a small foodborne illness outbreak

implicating *B. pumilus* as the causative agent was reported. The incident involved three people who suffered from acute symptoms including dizziness, headache, chills, and back pain after a meal in a Chinese restaurant. Stomach cramps and diarrhea, which lasted for several days, developed later. The implicated food vehicle in this case was cooked, left-over, and reheated rice.

In the reported cases described above, no well-known foodborne pathogens were detected in the implicated foods, whereas large numbers of the suspected *Bacillus* species (more than 10^5–10^9 cfu g^{-1}) were isolated in almost pure culture in each case. The variation in symptoms and course of disease (length of the incubation time, duration) in these incidents suggests the involvement of more than one type of toxin or that the same toxin can be preformed in food and later act in the small intestine. Enterotoxins similar to those of *B. cereus* have been detected from several of the other *Bacillus* species (Table 1) using immunological- and 'polymerase chain reaction (PCR)'-based methods. However, it seems that these results were based on incorrect species identification and that the strains involved are atypical *B. cereus* strains rather than other *Bacillus* species (Table 5).

Putative Virulence Factors

Although *Bacillus* spp. other than *B. cereus* have been incriminated as foodborne illness agents, the link between toxin production in such strains and foodborne illness has not been fully established, although various toxins have been found. A sperm-toxic compound produced by *B. licheniformis* strains isolated from baby milk powder involved in the fatality of an infant has been isolated, characterized, and later identified as lichenysin A. In the incident in the Chinese restaurant described above, *B. pumilus* producing the boar sperm-toxic compound pumilacidin was isolated in nearly pure culture from the implicated food. Recently, a novel toxin produced by strains of *B. subtilis* and *B. mojavensis* isolated from cases of foodborne illness was partly characterized. This toxin, amyloisin, is non-ribosomally synthesized, heat-stable, and exhibits similar toxic properties as cereulide.

Lichenysin A and pumilacidin belong to a family of lipopeptides produced by certain *Bacillus* species. These lipopeptides are small, structurally diverse cyclic lactones, and are characterized by their high resistance to extreme heat, pH, and enzymatic challenges. The chief representative and best studied member of this group is surfactin which is produced by certain strains of *B. subtilis*. Surfactin exhibits an amazing array of different properties including strong biosurfactant, antiviral, and antimycoplasma activity. The unusual structural complexity of surfactin, especially its three-dimensional structure, probably accounts for its biological and physiochemical properties. It is produced nonribosomally by a synthetase enzyme complex, and consists of a heptapeptide part linked to the carboxyl and hydroxyl groups of a ß-hydroxy fatty acid. Because surfactin production is widely distributed among *B. subtilis*, *B. mojavensis*, *B. pumilus*, *B. licheniformis*, and *B. amyloliquefaciens* strains, a diverse collection of surfactin isoforms has been described under different names including lichenysin and pumilacidin. Lipopeptides of the surfactin family are highly bioactive and have been reported to induce voltage-independent, selective cationic channels in lipid bilayer membranes and to lyse red blood cells and other types of eukaryotic cells presumably by interacting with the cell membrane. Plasma membrane interactions such as leakage, and at higher concentrations complete membrane destruction, have been shown for surfactin as well as highly selective cell-membrane binding, depending on membrane lipid composition. The fatty acid portion of surfactin has high affinities to cholesterol and phospholipids and is found anchored in the lipid bilayer. Although both cereulide from *B. cereus* and surfactin inhibit boar sperm motility, the mechanism of interaction differs. Cereulide causes motility loss through destruction of oxidative phosphorylation in the mitochondria, while surfactin impairs the motility through destruction of the cell membrane, with subsequent mitochondrial depolarization.

Although the acute toxicity of members of the surfactin family to mammals is considered to be low, as lactones, these cyclic compounds are potentially highly bioactive. Their resistance toward heat, enzymatic degradation, and pH alterations, enables survival through food processing and passage through the gastrointestinal tract without reduction of biological activity. This might explain the intoxication symptoms reported in foodborne illness by lipopeptide-producing strains of non-cereus *Bacillus* species. An explanation for diarrhea (in some cases) may be provided by the cyclic AMP phosphodiesterase inhibitory activity reported for *B. subtilis* lipopeptides. Increased cyclic AMP levels in intestinal cells as a result of exposure to cyclic lipopeptides may lead to leakage of Cl^- and secretory diarrhea. The ability of cyclic lipopeptide-producing *Bacillus* species to establish in the intestine and to cause membrane damage of the intestinal cells (resulting in diarrhea) is yet to be proven. Whether intake of food contaminated with preformed lipopeptides of the surfactin family might lead to an intoxication of the consumer is also uncertain.

Little attention has been drawn to members of the *B. subtilis* group and their role in foodborne disease. As a result of this lack of focus on *Bacillus* species other than *B. cereus* as potential agents of foodborne illness, there has been a tendency to ignore incidents where small amounts of *B. cereus* but high amounts of other *Bacillus* species have been detected in the implicated food vehicle. Before the toxicity of *in vitro* toxic compounds produced by *Bacillus* species are tested to a greater extent in animal model feeding trials, our knowledge of the involvement of cyclic lipopeptides in non-*B. cereus* foodborne illness is limited. Until this knowledge is established, one should be cautious about ruling out *Bacillus* species outside the *B. cereus* group as possible agents of foodborne disease.

Prevention and Control of *Bacillus* Foodborne Illness

Control of *Bacillus* spp. is relatively easy in principle, though proving troublesome in the dairy industry and in the growing market of lightly processed precooked long-life products. Both product types are difficult to be kept completely free from spores of *Bacillus* spp. Growth characteristics of the four most

Table 6 Some factors determining the growth of the four most common foodborne illness *Bacillus* species

Species	*pH-range*	*Temperature range*	*Other factors*
Bacillus cereus	4.3–9.3	4–50 °C	● Growth at aw to 0.92 ● Inhibited by 0.2% sorbic acid (pH less than 5.0) ● Growth in 7% NaCl
Bacillus subtilis	5.0–8.5	10–50 °C	● Growth in 7% NaCl ● Growth with only glucose and ammonium
Bacillus licheniformis	5-?	>15–55 °C	● Growth in 7% NaCl
Bacillus pumilus	5-?	10–45 °C	● Growth in 7% NaCl

common foodborne illness *Bacillus* spp. are shown in Table 6. If foods are kept at temperatures between 6 and 60 °C for too long, spore germination and outgrowth of these species can occur. Rapid cooling and proper reheating of cooked food are essential if the food is not consumed immediately. Long-term storage must be at temperatures below 8 °C (or preferably between 4 and 6 °C to prevent growth of *B. cereus*). Low pH foods (pH less than 4.3) can be considered safe from growth of the foodborne illness *Bacillus* species.

Typical Foods

Bacillus spp. spores are commonly isolated from spices, cereals, and dried foods. For example, during the period 1960–1968, *B. cereus* was the third most common cause of foodborne illness in Hungary, and meat dishes were frequently involved, perhaps due to a preference for well-spiced meat dishes in Hungary. Several cases of *B. cereus* foodborne illness, involving many people, due to meat-containing dishes have also been reported from Norway recently.

The emetic *B. cereus* food poisoning has often been connected with consumption of rice in Chinese restaurants. The predominance of episodes involving this type of restaurants is linked to the common practice of bulk cooking of boiled rice. Portions of boiled rice are stored, usually at room temperature, overnight and *B. cereus* can multiply. The same problem may arise when other starch-rich foods (pasta, pizza) are stored for extended time at room temperature, as emetic strains are more often found in such foods.

Presently a main problem with *B. cereus* seems to be in the dairy industry, where the number of *B. cereus* cells/spores in the product is important in determining the keeping quality of milk. A defect known as bitty cream, where the creamy layer of pasteurized milk aggregates, is caused by the lecithinase activity of *B. cereus*. Furthermore, *B. cereus* is responsible for sweet curdling (without pH reduction) both in homogenized and non-homogenized low-pasteurized milk. It seems impossible to completely avoid the presence of *B. cereus* in milk, as it contaminates raw milk already at the farm, the principal source probably being soiling of the cow udders (soil has been shown to contain 10^5–10^6 spores g^{-1}). Thorough cleaning of the udder and the teats is therefore essential. Milk transport and storage at the dairy plant may result in further contamination of the raw milk from *B. cereus* spores present (adherent) in tanks or pipelines. Although vegetative bacteria

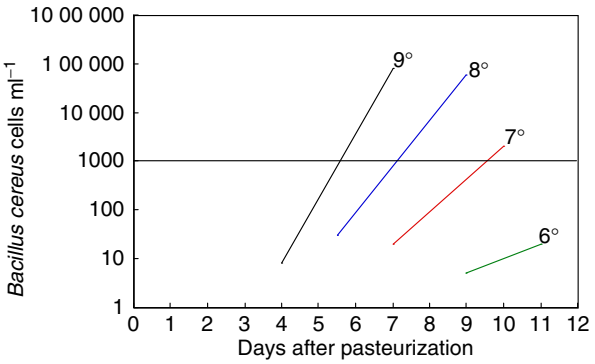

Figure 2 Growth rate of *Bacillus cereus* cells in milk stored at 9, 8, 7, and 6 °C.

are killed in the pasteurization process, the spores survive, and the pasteurization might activate some spores (heat activation), resulting in germination and possible vegetative growth.

To handle *B. cereus* problems in milk and milk products, control of the presence and outgrowth of spores, from farmer to packaging, is necessary. The temperature of storage is the most important factor in keeping *B. cereus* numbers low. Figure 2 shows the number of days required for milk to contain more than 10^3 *B. cereus* ml^{-1} at different temperatures. An increase of just 2 °C during storage, from 6 to 8 °C, increases *B. cereus* growth rates tremendously. At the dairy the milk is, in general, kept at 4 °C, and this assures a good keeping quality. However, during distribution, maintaining low temperatures can prove more challenging, and, therefore, temperatures up to 8 °C and above can occur. Furthermore, the consumer often exposes milk to higher temperatures for longer periods, for instance, at the breakfast table. As for the risk of foodborne disease, the dominating *B. cereus* group member in cooled milk products is *B. weihenstephanensis* (or cold-tolerant strains of the other members), and laboratory experiments have shown that those are usually low in enterotoxin production at human body temperature. Infant formula dried milk products should be free of pathogenic *Bacillus* species, as suggested by European Food Safety Authority (EFSA).

The strongly adhesive nature of *B. cereus* spores to different hydrophobic surfaces (such as glass and stainless steel) is a

major reason for its presence in food plants and kitchen environments. Three spore characteristics are responsible for the strong adhesion: high relative hydrophobicity, low surface charge, and surface morphology (appendages). At present the only way to overcome a spore problem, when present, is through the use of hypochlorite (0.2% at pH 7–8) or UVC light, because neither low – nor high – pH cleaning is sufficient to control the problem.

BACTERIA

Brucella

G Pappas, Institute of Continuing Medical Education of Ioannina, Ioannina, Greece

Glossary

Anthropozoonotic A disease that can be transmitted from animals to humans.

Pasteurization Process of heating food/milk to below the boiling temperature (71.7 °C (161 °F) in dairy industry settings), for a specific period of time, usually 15–20s, in order to eliminate any bacterial aggregates without irreversibly affecting the synthesis and characteristics of the product. Named after Louis Pasteur.

Background

Brucellosis is a disease attributed to bacteria of the genus *Brucella*, and is not only one of the most prevalent zoonotic infections and foodborne infections worldwide, but also a disease predating humanity and recognized since antiquity in humans: lesions similar to spondylitis caused by *Brucella* have been demonstrated in primate, prehuman, skeletons as well as in skeletons from Pompeii (dating back almost 20 centuries). The disease is also known as Malta fever, underlining its historical correlation with the island of Malta, where Sir David Bruce, a British army physician, first identified the zoonotic nature of the disease in the late 1800s and isolated the causative agent with the assistance of Themistocles Zammitt. Initially termed *Micrococcus melitensis*, and identified in goats and goat milk, the pathogen was subsequently renamed *Brucella*, as suggested by Alice Evans, a leading brucellosis researcher and Bruce's wife. *Brucella* species were recognized in later years in cows, swine, dogs, and wildlife (see subsequent article).

Characteristics

Historical knowledge refers to six *Brucella* species, of which four are able to induce human disease. Although initial molecular studies have suggested that *Brucella* is a monospecific genus, this theory has been now disputed both for scientific (less homology than projected) and practical reasons (each species largely correlates with a particular animal host). In recent years, more than six novel *Brucella* species have been characterized, expanding the ecology of the bacterium significantly. Table 1 lists currently characterized *Brucella* species, their typical animal hosts, as well as their potential for inducing human disease. There are numerous biovars for the major species, with varying epidemiology and varying molecular homology, although there is limited evidence regarding their probable varying virulence for humans.

Brucella belongs to the a2 proteobacteria, its closest relatives being predominantly plant pathogens such as *Agrobacterium* and *Ochrobacter* species, and in a more distant relationship, *Bartonella* species. *Brucella* is a small Gram-negative coccobacillus that grows slowly and, in traditional culturing methods, may require specific growth media. The recent sequencing of the complete genome of *Brucella melitensis*, *Brucella abortus*, and *Brucella suis* has allowed for a continuing effort to understand and analyze metabolism, survival, growth, and virulence characteristics: yet, little is typical to what is established for other Gram-negative pathogens, and knowledge of individual species' characteristics is constantly accumulating, making it difficult to adequately summarize this knowledge at a specific time-point.

Brucella species can grow and survive for protracted periods in the environment: survival in water for weeks has been demonstrated as well as prolonged (months) survival in soil for the novel species *Brucella microti*. In animals, the pathogen exhibits a predilection for the reproductive tract, responding to high concentrations of erythritol. Direct contact with infected raw animal tissues is a typical means of disease transmission to humans.

Foodborne brucellosis is less commonly attributed to meat consumption, and more often is the result of ingestion of unpasteurized dairy products, including milk, fresh cheese, cream/ice cream, and yoghurt. Survival of *Brucella* in dairy products is not related to fat content. Hard cheese is less effective in transmitting brucellosis, due to propionic as well as lactic fermentation taking place. Acidification processes necessary for the production of sour dairy products and, to a degree, yoghurt may also inhibit *Brucella* survival and growth. Pasteurization of milk remains the most effective means of prevention of foodborne brucellosis. Infected meat incriminated in human brucellosis is typically undercooked and is in the form of local delicacies (particularly liver/kidneys/spleen). Refrigeration does not inhibit *Brucella* survival, on the contrary, it lengthens it. Adequate cooking, however, is an efficient means of prevention of disease arising from food of animal origin.

As already stated, *Brucella* is not a typical Gram-negative pathogen, lacking virulence factors that are recognized in other Gram-negative bacteria: its lipopolysaccharide induces a vastly inferior immune response, compared with *Escherichia*

 doi:10.1016/B978-0-12-378612-8.00088-3

Table 1 *Brucella* species, their animal hosts, and their anthropozoonotic potential

Species	*Animal hosts*	*Anthropozoonotic potential*
B. melitensis	Sheep, goats, camels	Commonest cause of brucellosis worldwide
B. abortus	Cattle, buffalo, elk, yaks, camels	Major cause of brucellosis in specific countries
B. suis	Domestic pigs, wild boar, reindeer, caribou, rodents	Typically in isolated communities with a tradition in swine raising
B. canis	Canines	Increasingly recognized as human pathogen, particularly in Latin America
B. ceti	Dolphins, whales, porpoises	Isolated case reports of severe human disease
B. pinnipedialis	Seals	
B. ovis	Sheep	Not reported as human pathogen
B. neotomae	Rodents	Not reported as human pathogen
B. microti	Foxes, rodents	Not reported as human pathogen, except in experimental cases where a high degree of virulence was observed
B. inopinata	Unknown	Isolated from a single human case

coli, for example, and there are no exotoxins or endotoxins implicated in the initiation of human disease. Certain outer membrane proteins have been demonstrated as playing an important role in the intracellular survival and proliferation of *Brucella*; at present though, practically only the presence of a type-IV secretion system has been systematically acknowledged as of major importance for infection initiation.

The requisite bacterial load for transmission of *Brucella* to humans has not been adequately studied, and animal models may not allow for extrapolation due to the differences in disease pathophysiology and host–pathogen interaction observed in different animal models and for different *Brucella* species. Loads as low as of 10–100 bacteria are known to induce disease in humans, yet this may refer to airborne transmission and not to foodborne disease. It is certainly difficult to assess the bacterial load necessary for invasion through the gastrointestinal tract because the food products usually implicated, typically, carry large loads of the pathogen; moreover, the protracted incubation period of human disease usually precludes availability of the incriminated food product for evaluation of its bacterial load. There is also limited knowledge about the potential mechanisms of direct inoculation of *Brucella* through skin abrasions.

Clinical Manifestation (Disease)

The incubation period in human disease ranges from 2 to 8 weeks, the first symptoms typically observed in the fourth to fifth week after exposure. There have been no descriptions of differences in incubation period related to the means of transmission (direct contact vs. airborne exposure vs. foodborne disease).

Although characterizations such as acute, subacute, and chronic forms of the disease are often met in the literature, the definitions of these syndromes are vague, and the vast frame of clinical presentations often makes such categorizations useless. Brucellosis can be present as: (1) an acute disease with high-spiking fevers and bacteremia; (2) in a protracted form with low-grade fever, excessive malodorous perspiration (pathognomonic for the clinicians acquainted with it), malaise, myalgias and arthralgias, and evidence of reticuloendothelial system-related immune response (in the form of lymphadenopathy or hepatosplenomegaly); or (3) by manifestation of a focal complication – practically any organ and tissue of the human body can serve as the focus of brucellosis, but this is commonly observed in the osteoarticular system and the male genitourinary system (requiring a high index of suspicion by relevant specialists as orthopedics and urologists who may be the first to examine the patient). However, brucellosis has been systematically implicated in hematologic, cardiac, neurologic, respiratory, dermatologic, and even ophthalmologic complications. Complications range from benign laboratory abnormalities that rapidly regress on initiation of treatment (e.g., mild increases in liver aminontransferases with no clinical significance), to life-threatening situations as endocarditis or central nervous system involvement, and chronically debilitating, difficult-to-treat situations as spondylitis. An increased risk for abortion in pregnant females has been recorded in various patient series from the Middle East.

Eradication of *Brucella* postinfection remains one of the most scientifically puzzling and constantly resurfacing medical subjects of debate. Chronic disease can be focal, or in the form of repeated relapses without an apparent focal site of pathogen persistence, or can be vaguely described as a chronic fatigue syndrome. Brucellosis specialists are also familiar with a subgroup of chronic patients complaining of depressive symptoms in the absence of any objective diagnosis of brucellosis relapse/persistence: such behavioral and depressive symptoms have been demonstrated in chronic brucellosis since the 1940s, yet there has been limited attention to the subject in modern research. Recent advances in molecular diagnostics have allowed demonstration of bacterial load persistence in apparently healthy, successfully treated brucellosis patients, even years after the initial disease episode. The significance of such a carrier state has not been elucidated. It also remains unclear whether human-to-human transmission actually takes place apart from the occasional reports of sexual transmission. Transmission of *Brucella* through the fecal–oral route is not an issue though, in contrast to the typical foodborne pathogens arising from raw foods of animal origin.

Misdiagnosis is common when the disease appears (through patient importation by migration and international travel, or through infected food product international trade) in nonendemic areas. Misdiagnosis carries a significant risk for

a variety of reasons: (1) recognition of human disease and possible means of exposure allows for early identification of other exposed individuals (typically belonging to the same household) and early or even preemptive diagnosis and treatment initiation; (2) informing the laboratory personnel of a possible diagnosis of brucellosis allows for implementation of appropriate precautions (owing to its volatility, brucellosis remains the commonest laboratory-acquired infection worldwide, usually affecting more than one microbiologist/technician, either as an aerosol-spread infection or through multiple personnel dealing with the same culture and thus being exposed); (3) early diagnosis allows for avoidance of severe complications such as spondylitis and paravertebral abscess formation; and (4) on a purely theoretical level, because *Brucella* is a Category B potential biological weapon, it may allow for early identification of any epidemiologically unusual cluster of cases and thus early initiation of prophylactic measures for the remainder of the potentially exposed population (it should be noted here though, apart from the already stated theoretical-only risk of such a scenario, that exposure in such a case would not be through the food chain but airborne).

Epidemiology

An estimated 500 000 new cases of human brucellosis are recorded annually worldwide; one must take into account that these numbers are vastly underestimating the actual disease prevalence, because underreporting remains a major public health problem even in endemic parts of the developed world.

Novel hyperendemic areas have emerged in the past two decades, typically subject to major socioeconomic and political alterations. The disease remains prevalent in the Middle East and North Africa, in parts of Central America, and in the Indian subcontinent, although absolute data for the latter are missing (Figure 1). In the majority of the former Soviet republics of Central Asia, brucellosis has evolved into a public health emergency, with annual incidence rates exceeding 100 or even 200 per million of population. Another geographic zone where the disease has rapidly emerged/re-emerged in recent years is the Balkan Peninsular, where political regime alterations, re-designing of borders, the birth of novel countries with limited infrastructure in public health and veterinary surveillance, war, massive involuntary population movements, and loosening of border controls have all assisted in an explosion in disease incidence. This has reached a plateau in the Former Yugoslav Republic of Macedonia, is only now recognized in terms of extent in Albania, and is rapidly expanding in Bosnia-Herzegovina. This, in conjunction with the steady annual incidence rates of Greece and the hyperendemic situation observed in certain areas of Turkey, create a zone where exclusively national control efforts are doomed to be ineffective. In Western Europe, effective control through mass vaccination programs has resulted in virtual eradication of the disease in France, significant decreases in incidence in Spain and Portugal, and localization of the disease only in Sicily in Italy. In Central and Northern Europe, as well as in Canada and the USA, the disease is almost exclusively observed in association with international travel or immigration.

Populations at risk include farmers and their families, abattoir workers, veterinarians, and laboratory personnel as described above. There have been numerous reports of travel-associated clusters of brucellosis, in cases when consumption of local delicacies that may include fresh cheese or undercooked meat products, has led to delayed presentation of disease, long after return to the nonendemic homeland.

Table 2 lists some recent outbreaks of human brucellosis of potential foodborne nature.

A newly identified population at risk that is increasingly attracting interest is hunters. These may be exposed to *Brucella* through consumption of undercooked bush meat or during

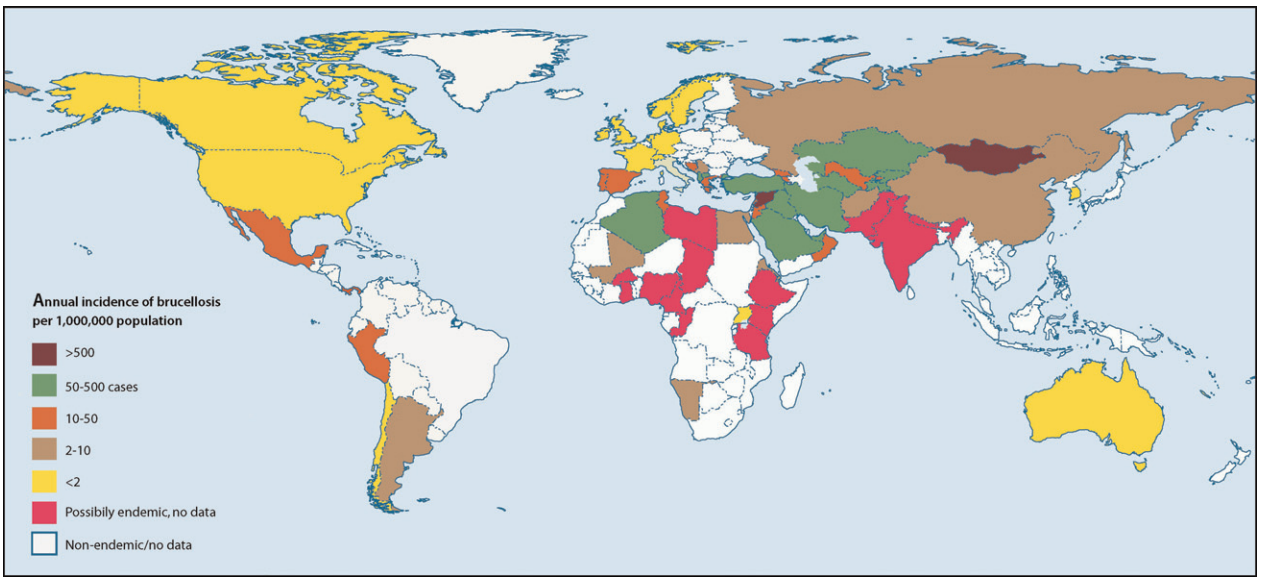

Figure 1 Global endemicity of brucellosis.

Table 2 Recent outbreaks of foodborne human brucellosis

Country, year	*Dairy/meat product implicated*	*Comments*
Thassos, Greece, 2008	Unpasteurized dairy products from infected sheep	More than 55 cases, the vast majority of which consumed unpasteurized dairy products
Elche, Spain, 2006	Unpasteurized goat milk	Observed in nine Moroccan immigrants
Treviso, Italy, 2005	Pecorino cheese from Sicily	Five cases observed in a nonendemic area
Messina, Italy, 2003	Ricotta cheese	29 cases, infected during a traditional religious ceremony which included consumption of local delicacies
Cordoba, Spain, 2002	Unpasteurized raw goat cheese	11 cases, all related to products from a particular farm

the process of skinning and meat preparation through direct contact. The recognition of brucellosis in wildlife, in animals as diverse as wild hare and elk, and the association of the disease with bush meat consumption indicate that wildlife may serve as a major reservoir of the disease. A typical example here is the demonstration of a direct relationship between elk brucellosis and bovine brucellosis in the Yellowstone area in the USA.

As Table 1 demonstrates, domesticated animals remain the principal reservoir of human pathogens. Although all anthropozoonotic species of *Brucella* can be foodborne, *B. melitensis* followed by *B. abortus* are reported as the main causes of *Brucella*-related foodborne disease cases or outbreaks worldwide. Other species may be implicated in cases associated with local food-consumption habits such as *B. suis*, mostly reported from Polynesia through pork products. However, *B. abortus*, *B. suis*, and *Brucella canis* demonstrate specific epidemiologic characteristics, which may still be understudied.

As already discussed, brucellosis is a household disease, and an index case should always prompt evaluation of the remainder of the family or other individuals exposed in common. Outbreaks are usually associated with social events which include consumption of local dairy products. On a wider scale, disease re-emergence is always associated with: weakened of the public health and veterinary surveillance infrastructure; an absence of health literacy on the subject for the population at risk; and socioeconomic factors. Elimination of infection in a herd through animal slaughtering imposes a significant economic burden for animal owners, who are often prone not to disclose the presence of the pathogen in their herd.

Analytical Methods for Organisms

The diagnosis of brucellosis should theoretically be based on the isolation of *Brucella* cultures though this is technically demanding for a variety of reasons: (1) a positive culture may take up to 4–6 weeks until detection, although the novel automated systems usually shorten this period to less than a week; (2) A proper process demands biosafety level-III practices which are not widely available (this is the reason, along with the pathogen's high volatility, that *Brucella* is so easily transmitted to laboratory workers); (3) proper process demands specialized culture media (as e.g., the Castaneda broth) and performance of subcultures; and (4) bacteremia in brucellosis, particularly in long-standing cases, is universally present – cultures of bone marrow samples have long been considered as more sensitive, but are always inconvenient for the patient. Cultures, however, allow for characterization of the incriminating pathogen to species and biovar level.

Serology remains the most widely used diagnostic approach. Serum agglutination tests give a positive result in the majority of novel cases, although, seropositivity may be observed for protracted periods irrespective of clinical response to treatment, and thus serology is not useful for follow-up. A more rapid serologic test, Rose Bengal, is widely employed worldwide, but its efficacy in diagnosis is not universally accepted and may be subject to technical inconveniencies.

Enzyme-linked immunosorbent assays (ELISAs) may be superior to classic serology in diagnosis and follow-up of disease evolution, but have been understudied in long-term follow-up. Molecular techniques have been developed in recent years and have been applied, albeit not widely, not only in diagnosing human disease and patient follow-up but also in the food industry, for an accurate detection of product infection.

Polymerase chain reaction (PCR) is an extremely sensitive diagnostic test, and real-time PCR can additionally inform on the bacterial burden of a specific product or a patient. Numerous independent researchers have systematically, in recent years, demonstrated that a positive bacterial burden can be traced by real-time PCR in apparently healthy subjects who had been successfully treated for brucellosis years, or even decades, before. This observation raises questions not only about the ability to actually eradicate the pathogen (which may survive in a latent form in a manner all too similar to tuberculosis), but also minimizes the utility of molecular techniques in the follow-up of patients. There have been contradictory results regarding the relationship between bacterial burden and potential for disease relapse in the literature.

Control and Preventive Measures

As is typical of zoonoses, brucellosis control is a multitask issue. Elimination of human disease (given that there are no effective vaccines) is largely based on elimination of animal disease, although the latter is subject to adequate veterinary practices. Veterinary surveillance for the disease and systematic animal vaccination products have assisted in minimizing brucellosis incidence in many parts of the developed world. In areas of the developing world, where inadequate veterinary infrastructure or economic issues may preclude the implementation of a widespread vaccination program, a 'test and

slaughter' policy may be more effective in minimizing animal disease incidence and spread, as well as human cases. However, the illegal animal trade has expanded in recent years and has been incriminated in the emergence and re-emergence of brucellosis in countries that were brucellosis-free or had a very low disease incidence in the past, the typical example being the Balkan Peninsula. Illegally traded animals are not subject to surveillance and vaccination, but their presence is primarily a political (regional and international) and economic issue. An adequate and sustained veterinary infrastructure allows for disease control in areas that are not neighboring endemic regions, and this is a possible explanation of the observed success in eliminating disease in Spain and France but not in Greece, the latter bordering with three of the top-20 hyperendemic countries for brucellosis worldwide. A similar explanation stands for the small, but sustained, disease incidence observed in the USA, almost exclusively in states neighboring the hyperendemic Mexico (through illegal importation of infected dairy products or illegal entry of infected humans).

Surveillance at food-chain level, however, has always been successful, particularly in the developed world, but is related to the need of industry for product reliability and the direct correlation between product quality/safety and financial returns. In the case of milk, pasteurization, or at least protracted heating of milk at 80–85 °C before consumption or further processing, is a safe approach. Fresh cheese ingested 4–6 months after production, carries small risk for brucellosis transmission. Thorough cooking of meat, even from an infected or unknown infection-status animal further minimizes the risk of foodborne brucellosis. Hygiene measures directed at herd owners, shepherds, abattoir workers, and laboratory workers relate to other modes of brucellosis transmission (direct, airborne), and should always be based on preexisting suspicion of disease. Regulatory measures relate to strict control of illegal animal movements.

Increasing awareness about the disease should be targeted at various population groups. These include not only at-risk professionals, such as the ones described in Epidemiology, but also individuals with underlying medical conditions, such as liver disease, preexisting valvular heart disease, and those with prosthetic devices who may be at risk of contracting serious disease complications. Pregnant women may exhibit increased abortion risk after contracting brucellosis (in addition to the pregnancy-related difficulties related to the administration of effective antibiotic regimens). International travelers to endemic areas should be aware of the risks of ingesting unpasteurized or undercooked local products of unknown or doubtful synthesis and origin (the traditional delicacies that are based on unpasteurized milk/milk products or raw/undercooked meat products are too numerous to mention and differ geographically); a traveler should always ensure that testing local foods does not expose him/her to any such products. Finally, it is important that policymakers understand the close proximity of disease incidence, both in animals and humans to specific socioeconomic parameters, and should thus focus on reversing these parameters.

Campylobacter

A Kvalsvig, MG Baker, and A Sears, University of Otago, Wellington, New Zealand
N French, Massey University, Auckland, New Zealand

Glossary

Bacteremia Presence of bacteria in the blood.
Broiler chickens (broilers) A male or female chicken reared and kept primarily for meat production.
Microaerobic atmosphere One which has a lower oxygen concentration than air.
Prodrome Initial phase of a disease in which the first symptoms appear; these may differ from the classic disease symptoms.
Thermophilic Requiring heat.
Vertical transmission Transmission of infection from mother to offspring.

Background

Campylobacter spp. were well described in veterinary medicine from the early twentieth century. However, it was only in the 1970s that the importance of *Campylobacter* spp. as enteric pathogens in humans was widely recognized. With increasing laboratory capacity and testing in the 1970s and 1980s, *Campylobacter* spp. quickly became recognized as one of the leading causes of bacterial enteritis in humans worldwide.

As reported incidence rates increased during the last decades of the twentieth century, there was evidence that the data were reflecting a true upward trend over and above the apparent increase that would be expected to occur with improved detection and surveillance methods.

In the twenty-first century, *Campylobacter* infection is the most commonly reported cause of bacterial gastroenteritis in many industrialized nations, and is an important cause of bacterial gastroenteritis in young children living in developing countries. It is likely that the true incidence far exceeds the number of reported cases.

Although some countries have recently noted a decline in *Campylobacter* disease incidence, there is concern that the human immunodeficiency virus (HIV) epidemic may cause a significant increase in the disease burden of *Campylobacter* in the developing world; concurrent HIV infection is known to increase both the incidence risk and severity of *Campylobacter* gastroenteritis.

The considerable disease burden of *Campylobacter* gastroenteritis is not the only public health concern related to these organisms. Recent research has highlighted the important role played by *Campylobacter* infection in the etiology of Guillain–Barré syndrome (GBS) (a serious neurological condition) and in other postinfectious conditions such as reactive arthritis.

Campylobacter infection is of particular relevance to food production given the widespread contamination of the food chain by *Campylobacter* and the many food and waterborne routes by which humans may be infected.

A number of approaches to disease prevention and control are outlined in a later section of this article, but it is clear that controlling *Campylobacter* infection is a complex and challenging task.

Characteristics of the Organisms

Campylobacter spp. belong to the family Campylobacteriaceae. They are Gram-negative rods which may be spiral-shaped, S-shaped, or curved (Figure 1). Most are motile, exhibiting a characteristic corkscrew-like motion. Motility is conferred by flagella, usually in the form of a single flagellum at one or both ends of the cell, although nonmotile species or species with multiple flagella have been described.

The genus *Campylobacter* has 18 species, but only some of these species have relevance to human health. The two species most frequently associated with human disease are *Campylobacter jejuni* and *Campylobacter coli* which together account for more than 95% of human infections; related species such as *Campylobacter laridis* and *Campylobacter upsaliensis* are more rarely reported in humans. In developed countries, C. *jejuni* is estimated to cause at least 80–90% of *Campylobacter* infections. For this reason, where *Campylobacter* organisms are discussed in relation to human health, the convention has arisen that the term *Campylobacter* is understood to refer to *C. jejuni* or *C. coli* unless otherwise indicated. This convention has been followed in the current text.

With ever-improving subtyping techniques, the variability of *Campylobacter* organisms has become increasingly apparent (see the Section on Analytical Methods). This is an important aspect of *Campylobacter* control as characterization of strains may facilitate source attribution and identification of epidemiologically-related cases during an outbreak.

Figure 1 *Campylobacter* bacteria are the number-one cause of food-related gastrointestinal illness in the US. To learn more about this pathogen, ARS scientists are sequencing multiple *Campylobacter* genomes. This scanning electron microscope image shows the characteristic spiral, or corkscrew, shape of *Campylobacter jejuni* cells and related structures. Photo by De Wood; digital colorization by Chris Pooley. *Source*: Agricultural Research Service (ARS) is the US Department of Agriculture's chief scientific research agency.

Campylobacter spp. are notable for being exacting in their growth requirements when cultured under laboratory conditions. Most species require a microaerobic atmosphere with an oxygen concentration of approximately 5%. *C. jejuni* and *C. coli* are considered to be thermophilic: they grow optimally at 42 °C and do not grow at temperatures below 30 °C.

Tolerance of the organism to heating and freezing is of great interest because of the implications this may have for control of foodborne infection. There have been numerous studies reporting *Campylobacter* survival at different temperatures; however, they show considerable variation in their findings, possibly as a result of varying temperature tolerance between strains. Despite this variability, there is some evidence that *Campylobacter* survives better under refrigeration temperatures than at room temperature. Freezing causes a significant reduction in organism counts, and the organism is rapidly inactivated at normal cooking temperatures.

The intestinal mucosa of most warm-blooded species provides appropriate conditions for growth and replication of *Campylobacter*, with poultry and other avian species thought to be the primary hosts. However, it is interesting that such a fastidious organism can also be widely distributed in the environment, where conditions are unlikely to be suitable for growth. It is now known that *Campylobacter* spp. are able to enter a viable but nonculturable (VBNC) state under adverse conditions. A detailed understanding of the survival mechanisms of *Campylobacter* in the environment may be extremely useful for disease control.

Clinical Manifestation

Clinical disease caused by *Campylobacter* is referred to as campylobacteriosis. When considering this diagnosis, it is worth remembering that the following description of the clinical manifestations of campylobacteriosis is derived from experience of laboratory-confirmed cases. In the community, where the majority of affected persons do not seek medical help, campylobacteriosis may present a different clinical picture.

Typically, symptoms of campylobacteriosis appear 2–5 days after infection with a range of 1–7 days or even longer. The mean incubation period of 3 days is longer than usual for intestinal infections, which is an important consideration when tracing exposures.

Most patients experience a rapid onset of cramping abdominal pain and diarrhea, but approximately 30% have an influenza-like prodrome with fever, headache, and myalgia, and this is believed to be associated with a more severe disease course. Nausea is common but vomiting less so. Diarrhea can be mild or may be profuse enough to cause dehydration. Approximately 15% of patients have frank blood in the stool. The abdominal pain may become continuous and severe and thus mimic other intraabdominal pathology such as appendicitis, Crohn's disease, or ulcerative colitis. Pain without diarrhea is a known variant but is uncommon.

Generally, the diarrhea starts to improve after 3–4 days, but the abdominal pain will usually persist for longer than this. Symptoms usually lasts 3–6 days, but relapses are fairly common. Patients with underlying immune deficiency such as HIV infection may have a chronic or recurrent course. However, campylobacteriosis is generally a self-limiting disease and only approximately 5–10% of cases for medical attention require hospitalization.

Fatal outcomes are rare and are usually associated with extremes of age, concurrent disease (such as malignancy), or immune deficiency. *Campylobacter*-associated bacteremia carries a high risk of death, variously reported as 4–10% in the medical literature. Deaths from delayed complications of campylobacteriosis such as myocarditis and GBS may not be attributed to the correct underlying cause, so mortality risk from this infection has probably been underestimated. For example, a cohort study conducted in Sweden found a threefold increase in the risk of death within the first month following the infection.

Following the resolution of symptoms, patients may excrete *Campylobacter* in feces for several weeks unless treated with antibiotics. However, secondary infections from this source are not common.

Both acute and postinfectious complications of campylobacteriosis have been described.

Acute Complications

Appendicitis

As previously mentioned, the abdominal pain associated with campylobacteriosis may be severe enough to mimic appendicitis. However, true appendicitis is also a known complication of this infection.

Colitis

Colitis and proctitis are common findings in campylobacteriosis patients who undergo sigmoidoscopy and rectal biopsy. It can be difficult to distinguish this from acute nonspecific inflammatory bowel disease.

Bacteremia

This is probably underreported due to the practical difficulties in culturing the organism from blood samples. It is a serious complication in patients with severe immune deficiency, because mortality risk is considerably higher.

Peritonitis

This does not appear to be a risk in otherwise healthy persons, but several cases of peritonitis have been described in patients undergoing peritoneal dialysis for renal disease.

Hepatitis

Laboratory findings suggest that a mild, subclinical degree of hepatitis is common; however clinical hepatitis is rare.

Fetal Death

Campylobacter spp. infection is a well-known cause of fetal death in animals. Although some cases have been described in humans, this complication is extremely rare.

Postinfectious Phenomena

Guillain–Barré Syndrome

GBS is an autoimmune disorder of the peripheral nervous system. *Campylobacter* infection is now recognized as the most frequent identifiable antecedent infection in GBS cases, with onset usually 1–3 weeks after the infective episode.

A number of variants have been described, but in general the condition is characterized by weakness which is usually symmetrical and which evolves over several days. It can affect any age group.

Patients typically experience an ascending paralysis with loss of movement, and approximately a third require ventilatory support during the acute phase. The condition is generally self-limiting, but symptoms may take up to 2 years to resolve and some patients are left with residual symptoms.

Treatment is mainly supportive, with the addition of intravenous immunoglobulin or plasma exchange. Reports of mortality risk vary widely, but in a setting which allows for optimal support, mortality can be as low as 5%.

Reactive Arthritis

Patients with campylobacteriosis commonly report joint pain, and reactive arthritis develops in approximately 1–5% of cases. This typically occurs approximately 10 days after the acute infection and involves one or two peripheral joints. It may be severe, but complete recovery is believed to be the usual outcome. However, this is a somewhat under-researched complication, and it is possible that long-term sequelae are more prevalent than is currently recognized.

Postinfectious Irritable Bowel Syndrome

There is an increased risk of persistent diarrhea after *Campylobacter* infection.

Myocarditis

The mechanism for heart muscle involvement is unknown. Although rare, this may be serious when it occurs.

Pathogenesis

Campylobacteriosis is a zoonosis, that is, a disease transmitted from animals to humans.

It is generally accepted that *Campylobacter* spp. do not replicate outside of animal hosts; therefore, the bacterial load will tend to diminish in the environment (at varying rates) until another suitable host is found. Multiple animal hosts or reservoirs for *Campylobacter* have been identified including birds (likely the primary natural hosts of *Campylobacter*), ruminants, pigs, rodents, and other native fauna. Insects have also been implicated as vectors for the transmission of *Campylobacter*.

Campylobacter colonization is generally asymptomatic in animals, and disease occurs only when the organism is ingested by humans, a frequent occurrence because of the widespread distribution of *Campylobacter* in the environment and the food chain.

The basic mode of *Campylobacter* transmission is by fecal–oral spread. This may occur by a relatively direct transmission route (e.g., direct contact with animal feces) or by an indirect route (e.g., through consumption of fecally contaminated food or water).

Originally, information about infectious dose levels was derived from a human volunteer study in which a dose of 800 CFU was sufficient to cause infection. However, recent work suggests that the probability of infection for naïve individuals is high even for doses of <10 CFU; the organism demonstrates a high infectivity when the number of organisms ingested is likely to be extremely low.

After ingestion, the organisms are likely to be killed by the acidic environment of the stomach, but food can act as a buffer, allowing increased survival. The use of proton pump inhibitors for gastric acid suppression increases the risk of infection.

Once the organism has reached the intestine, it actively penetrates the mucus layer and adheres to colonic epithelial cells before penetrating the mucosa. This may or may not result in gastroenteritis. Asymptomatic colonization may ensue, in which the organism survives and replicates in the intestine but does not cause disease. This is common in developing countries, where persons may experience repeated exposure to *Campylobacter*, but it is less common in the developed world where such exposures are not as frequent.

Experience with other bacterial causes of gastroenteritis suggests that the pathogenesis of campylobacteriosis is likely to be toxin related. However, to date only one *Campylobacter* toxin has been identified. It is known as cytolethal distending toxin and is produced by a variety of *Campylobacter* species. The organism is able to invade epithelial cells and induce a cytokine response, thus precipitating an inflammatory cascade and hence the typical symptoms of campylobacteriosis.

Postinfectious Phenomena

GBS is thought to arise by molecular mimicry. Ganglioside-like structures in *Campylobacter* lipo-oligosaccharides induce an immune response which cross-reacts with the ganglioside components of peripheral nerves, causing weakness and loss of function.

Immune Response

Immune deficiency (such as hypo or agammaglobulinemia, or acquired immunodeficiency syndrome (AIDS)) may lead to increased incidence, more severe disease, and a higher likelihood of chronic carriage and recurrence.

Although the role of protective immunity in campylobacteriosis is far from clear, the experience of developing countries and of persons with a high occupational exposure to *Campylobacter* suggests that chronic exposure may induce protective immunity, although this is likely to be of a short duration only.

Virulence Factors

Despite the importance of *Campylobacter* as a cause of gastrointestinal infection, surprisingly little is known about the mechanisms of *Campylobacter* virulence compared to other enteric bacteria. Research is hampered by the fact that *Campylobacter* does not usually cause diarrhea in animals; therefore it is difficult to study in animal models.

In the absence of an easily available animal model, virulence is generally assessed using *in vitro* studies investigating pathogenesis mechanisms such as adhesion, invasion, protein secretion, and toxin production at the molecular level. The results should be cautiously applied to human disease *in vivo*, but a lot of useful information has been gained from *in vitro* research.

In recent years there has been considerable progress in understanding the role of flagella in *Campylobacter* virulence. The obvious function of the flagellum is to confer motility: In mutant strains with defective flagella, the organism is unable to colonize the intestinal epithelium. However, it has now become clear that there is more to flagellar function than motility, and that *Campylobacter* organisms also utilize their flagella to export virulence proteins.

Interestingly, *Campylobacter* seems to share few of the known virulence factors of other enteric bacteria; one exception is the bacterial capsule. Capsular polysaccharides are found on the bacterial cell surface of many organisms including *Campylobacter*; they appear to influence *Campylobacter* virulence by a number of mechanisms, particularly adhesion and invasiveness.

Campylobacter appears to differ from other enteric organisms with regard to posttranslational glycosylation. *Campylobacter* has been shown to have two separate systems, known as *N*-linked and *O*-linked glycosylation, which determine virulence by influencing adhesion and invasion.

Campylobacter strains exhibit marked genetic variability and this is reflected in the wide variation in virulence between the strains. This variability may also facilitate adaptive processes such as antibiotic resistance.

Epidemiology

Incidence

Campylobacter is the most commonly reported cause of bacterial gastroenteritis in the developed world, and the global disease burden of campylobacteriosis is considerable.

The Centers for Disease Control and Prevention (CDC) report that the annual incidence in the USA is approximately 13 cases per 100 000 population, with an estimated 2.4 million persons affected each year. They estimate that there are approximately 124 fatal campylobacteriosis cases every year, and that approximately 1 in 1000 diagnosed infections lead to GBS. The healthcare costs of GBS are high because of the frequent need for ventilation or other intensive care-based supportive measures.

In 2007, the European Food Safety Authority estimated that the European Union campylobacteriosis incidence was 45.2 cases per 100 000 population (200 507 confirmed cases).

The highest reported incidence of campylobacteriosis in the developed world is seen in New Zealand, where the national notification rates reached approximately 380 cases per 100 000 population in 2006. The incidence has declined in subsequent years but remains high.

Estimating disease incidence in the developing world is more difficult because of the lack of routine surveillance data. However, estimates of 90 cases per 100 000 population have been reported in the literature, derived from case–control studies.

Surveillance data from the industrialized nations showed a clear trend of increasing incidence in the last decades of the twentieth century, which appeared to be over and above what would be normally expected from improved detection and reporting alone. The reason for this increase is unknown.

More recently, there has been a trend of decreasing incidence in some countries. This decline may be a result of prevention measures related to poultry meat which have been instituted in several countries; however, reductions have also been seen in countries without such measures (see the Section on Control/Preventive Measures).

There has also been concern that global climate change may lead to an increased incidence of campylobacteriosis. However, the relationship between climate and disease incidence is not fully understood, and it is thus difficult to model changes in disease risk with climate change. It is not necessarily the case that disease incidence would increase with climate change. For example, if ultraviolet levels were to increase significantly, this would tend to decrease *Campylobacter* survival in the environment.

Origins and Distribution of Disease

There are a number of potential sources of *Campylobacter* infection (**Figure 2**). They include:

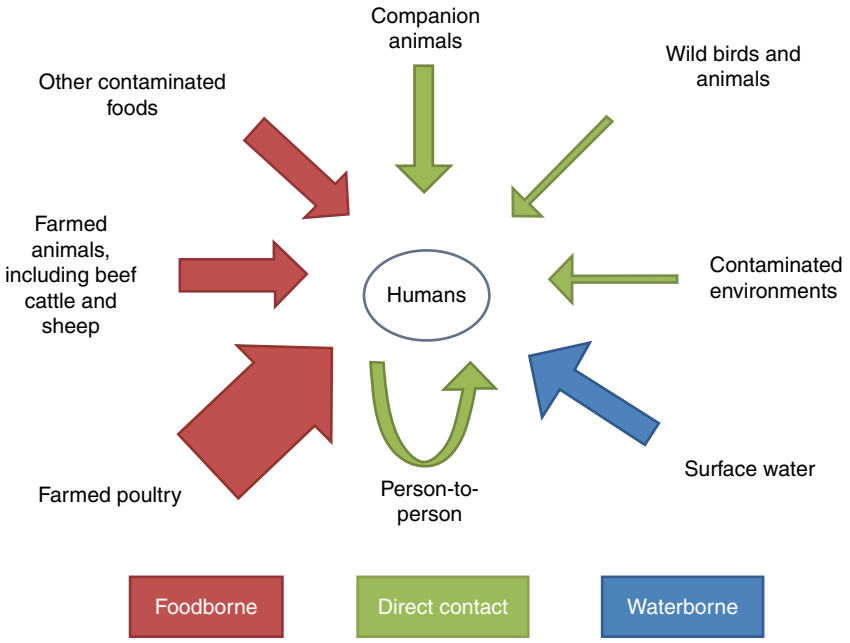

Figure 2 Most important routes for human infection by *Campylobacter jejuni*.

- Contaminated food – including consumption of undercooked food and through cross-contamination;
- Contaminated water – via drinking or recreational exposure;
- Contaminated environments – such as fecally contaminated pasture;
- Direct contact with infected animals – occupationally or domestically;
- Contact with infected humans – person-to-person transmission.

Contaminated food is thought to be the dominant source of infection in industrialized nations. Many specific foods have been identified as contributing, based on case–control studies of sporadic disease and investigations of outbreaks. However, poultry is considered the most important single source. Infection occurs after ingestion of undercooked poultry meat or by contamination of other foods with raw chicken during food transport, storage, and preparation.

Infection may occur in a variety of settings. Contact with animals may occur in the home (domestic pets) or on farms; and rural environments may also facilitate transmission via contaminated pasture, soil, or water. Foreign travel, particularly to developing countries, is also an important setting for populations in industrialized nations.

In developing nations the main drivers of infection are likely to be living conditions with close proximity to animals, and contaminated water supplies.

Campylobacter outbreaks are relatively rare compared to sporadic cases. Outbreaks tend to be small; the exceptions are outbreaks resulting from milk or waterborne infection which may affect a large number of people. Such an outbreak was reported in May 2000 in Walkerton, Canada, when municipal water supplies became contaminated and a large number of campylobacteriosis cases were reported as a result. Ingestion of unpasteurized milk on farms open to the public is a well-described source of outbreaks. Investigations continue to identify unusual modes of transmission such as a *Campylobacter* outbreak in Canada traced to the ingestion of mud by participants in a bicycle race.

Contamination of food in a retail or restaurant setting may cause small outbreaks, and a number of foods have been implicated including poultry, fresh produce, fish, and shellfish. A common mechanism of infection in restaurants is cross-contamination from raw poultry to foods waiting to be served.

Person-to-person transmission appears to be rare, and this perhaps explains the generally limited nature of *Campylobacter* outbreaks.

Factors Determining the Disease Risk in Individuals

A number of characteristics have been identified which may place individuals at a greater risk of infection.

Age

Most populations in industrialized nations show a bimodal age distribution with the highest incidence seen in young children and young adults.

It has been suggested that the peak in campylobacteriosis notifications amongst preschool children may relate to the relatively naïve immunological systems of children and infants. Other possible explanations include more frequent exposure to *Campylobacter* reservoirs (such as domestic pets), increased environmental exposure through playing outdoors, or poorer levels of hygiene. Another possibility is that higher levels of parental concern surrounding diarrheal illness in children may lead to a lower threshold for medical assessment and testing, resulting in a higher diagnosis rate among children in this age group.

In a number of epidemiological studies of *Campylobacter* prevalence, young children in rural areas have been shown to

be at a greater risk of the disease than other demographic groups (see the Section on Rurality).

The reasons for the peak in the 20–29 year age group remain unclear but may relate to factors such as increased contact with young children and their feces, particularly through nappy changing; increased occupational exposures to *Campylobacter* reservoirs; high-risk food consumption patterns (including increased consumption of food from commercial food premises); and less robust food hygiene practices.

In developing nations the age distribution of disease is somewhat different: The majority of symptomatic infections are seen in very young children, and adult disease is relatively rare.

Sex

Men have a higher rate of reported disease than women, and this has been shown to be a consistent finding across most populations and age groups.

A number of reasons for the male preponderance have been proposed, including possible underlying immunological factors (particularly as this male excess is seen in younger age groups where behavioral explanations are less likely); increased male exposure through high-risk occupations (such as farming and meat processing); differences in food and water consumption patterns (including quantity consumed and food preferences); and food hygiene practices.

Differences in healthcare-seeking behavior (and therefore, probability of diagnosis) have also been proposed as a possible reason for the reported differences between male and female campylobacteriosis rates.

Ethnicity

A number of epidemiological studies have identified variations in disease incidence between different ethnic groups living in the same geographical area. These differences may reflect a surveillance artifact with certain ethnic groups having differing healthcare seeking behavior and access to health services. Other possible explanations include differences in food preparation and providers, and travel to higher-risk countries. It is also possible that immunological factors play a part in determining variations in disease risk between well-defined ethnic groups, but to date no such factors have been identified.

Seasonality

In industrialized countries campylobacteriosis is often reported to have a higher incidence in spring and summer, whereas seasonality is generally not reported in developing countries.

The drivers behind the seasonality of campylobacteriosis remain unclear. It has been suggested that agricultural practices may play a role in campylobacteriosis seasonality, leading to increased fecal contamination of the environment during spring months. Other proposed mechanisms include differences in human behaviors (e.g., more outdoor activities possibly leading to increased *Campylobacter* exposure and greater use of barbecuing with associated consumption of undercooked meat such as chicken) and seasonal changes in human immunity.

In their analysis of *Campylobacter* seasonality in England and Wales, Louis *et al*. found a strong association with temperature, with children under the age of five experiencing the highest risk during seasonal peaks.

Campylobacter is a common contaminant of surface water. A recent study demonstrated an association between a seasonal peak of campylobacteriosis resulting from a common strain and contamination of surface water with that strain, where the association did not appear to be mediated by poultry consumption. This finding suggests that seasonality may be linked to the ability of certain strains to survive in the environment.

Overall, it is likely that the mechanisms by which seasonal variation may occur are multifactorial.

Rurality

The relationship between rurality and disease risk is not straightforward. In some populations the risk is higher in rural areas compared to urban areas, with rural children considered to have the highest risk; in others, the risk is higher for urban dwellers.

Source attribution studies from New Zealand have identified a difference in origin of infection between rural and urban areas: Rural cases are more likely to be of ruminant origin, whereas urban cases are more strongly associated with poultry. This suggests that the risks may be different for rural and urban populations: For instance, contact with animals (either directly or *via* contaminated environments) may be a significant risk in rural areas, whereas foodborne disease is likely to be relatively more important in urban areas.

Measuring Disease Burden, Incidence, and Prevalence

A degree of caution should be employed when assessing the impact of *Campylobacter* infection at a population level. Most infections are self-limiting and do not require medical attention: of those gastroenteritis cases that do, only a proportion will be investigated in such a way as to establish a proven *Campylobacter* diagnosis (**Figure 3**). In the UK, for example, a large population based study found there were cases of laboratory-confirmed *Campylobacter* infection in the community for every case recorded by the disease surveillance system, with most cases never being presented for medical attention.

Variation in disease risk is very difficult to measure because surveillance practices, self-reporting of disease, and access to

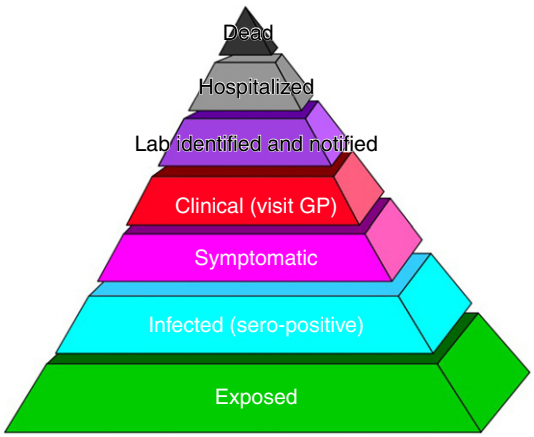

Figure 3 The pyramid or iceberg of infectious disease.

healthcare vary between regions, population groups, and individuals, and this is likely to exaggerate or mask true differences in risk. For example, campylobacteriosis as a result of foreign travel may be over-represented as a risk factor because people are more likely to seek medical advice for gastroenteritis if they have recently traveled abroad.

Analytical Methods

A range of analytical methods are used to investigate campylobacteriosis within the food safety area. These methods are concerned with: confirming illness in cases; identifying and quantifying organisms in potential sources and reservoirs; typing organisms to establish relationships between cases and with sources; investigating and identifying the sources of outbreaks; and investigating and quantifying the sources of sporadic disease. They use a mix of laboratory, epidemiological, and environmental investigation methods.

Laboratory Identification of *Campylobacter* spp. and Strains

Traditional Methods

Traditional methods of identification include direct detection in stool samples, and culturing of the organism followed by phenotypic tests. Gram staining has high sensitivity and specificity during the acute phase of the disease, and the organism may be detected in blood and stool cultures, or in food samples.

Colonies which have a typical Gram stain appearance and are oxidase positive may be considered provisionally to be *Campylobacter* species, and the hippurate hydrolyis test can be used to identify *C. jejuni*.

However, culturing the organism has a number of limitations, most notably in the time taken to obtain results. It usually takes at least 48 h to identify a positive result, but the time lag may be as much as five days if only a few organisms are present and an enrichment culture is required. This delay may seriously hamper the investigation and control of outbreaks. Culture methods may also introduce a bias against detecting rarer *Campylobacter* species, leading to an underestimation of their relative importance.

Serological approaches are also effective for identifying *Campylobacter* with latex-agglutination and enzyme-linked immunosorbent (ELISA) methods having high specificity and sensitivity.

Molecular Methods

The complete genome sequence has been determined for a number of *Campylobacter* strains, and this has enabled the use of a large array of molecular-based methods for investigating and characterizing the organism.

Molecular techniques offer more precision than phenotypic methods in identifying specific strains, and are thus extremely useful in linking cases and sources of infection in outbreak investigations, and in understanding the pathogenesis and determinants of virulence of campylobacteriosis. Although molecular diagnostic techniques are not yet generally used in routine *Campylobacter* identification, this may change in the near future.

One molecular method that has proved useful for investigating the *Campylobacter* organism is pulsed-field gel electrophoresis (PFGE). In this method an enzyme is used to digest the genome into fragments of different sizes, which can then be separated and visualized using gel electrophoresis.

Multilocus sequence typing (MLST) is another useful technique in *Campylobacter* research. MLST is a genotyping method in which bacterial isolates are characterized by indexing the variation present in several genes, thus allowing gene lineages to be identified. Comparisons can then be made between human isolates and isolates obtained from other sources such as food or water.

A number of polymerase chain reaction (PCR) assays have been described for species-specific identification of *Campylobacter*. In this method, specific genetic locations are targeted and amplified. PCR has shown particular promise in studies testing food products for *Campylobacter* contamination.

In an extensive review of molecular typing methods and their use in the investigation of Gram-negative foodborne pathogens, Foley *et al*. noted that no particular method is superior: instead, the choice of method will depend on the requirements of the investigation. For example, PCR-based methods can give rapid results, but PFGE results may be more consistent across multiple laboratories in a widespread outbreak. Limited resources may also be a consideration, as methods differ in their requirements for expensive equipment and highly trained personnel.

Although molecular techniques are exciting to contemplate, offering the possibility of resolving many of the unanswered questions in *Campylobacter* research, it is worth noting that no method is infallibly precise.

The methods described above may produce varying results when used to differentiate between strains; sometimes the best approach is to use a combination of methods. Moreover, because *Campylobacter* exhibits high strain variability, it may not be clear whether two similar, yet nonidentical, strains are epidemiologically related or should be considered to be separate entities. Different statistical modeling approaches may lead to different conclusions in this regard.

It is thus important to be aware that molecular methods are not intended for use in isolation, but rather in association with, and complementary to, epidemiological data. Only in this way can a full and accurate picture be obtained.

Investigating Campylobacteriosis

Common-Source Outbreaks

Outbreak investigation uses two main types of epidemiological investigations, with the choice largely determined by the type of outbreak. Outbreaks affecting a well-defined group, such as a wedding party, are usually investigated using a retrospective cohort study. Dispersed outbreaks, such as might occur from a widely distributed food or drink, are usually investigated using a case–control study. Such studies have some important limitations when investigating campylobacteriosis outbreaks. Given the relatively long incubation period, and the wider range of potential sources that such studies often need to investigate, they are prone to recall bias. They are also limited to investigating immediate sources of infection, and cannot usually identify reservoirs of infection.

Although it is generally accepted that *Campylobacter* outbreaks are far less common than sporadic cases, the increasing use of molecular techniques may change this perception by demonstrating links between cases which previously would have been regarded as discrete entities.

Conversely, molecular methods can also show that a case which appears to be linked to an outbreak is in fact a separate occurrence. This ability to exclude unrelated cases is very useful in epidemiological studies, as inclusion of unrelated cases in an outbreak investigation may obscure a true association.

Source Attribution

A key challenge in *Campylobacter* investigation is source attribution, that is, the ability to identify and quantify the contribution of different sources to the observed burden of disease. These studies are usually concerned with the total burden of disease, which for campylobacteriosis is largely sporadic infections and small clusters. A variety of approaches are available, including microbiological and epidemiological approaches, intervention studies, and expert elicitation.

This is where molecular techniques are particularly useful because they allow investigators to differentiate between organisms at strain level, and hence to link cases to likely sources of infection.

A number of studies have been published worldwide, demonstrating the use of molecular techniques in source attribution. For example, Frost *et al*. reviewed reported outbreaks of campylobacteriosis in the UK from 1995 to 1999, and found that foodborne transmission accounted for 70% of the outbreaks, with implicated food types including poultry, red meat, fish and shellfish, salads, fruits and vegetables, milk and milk products. Animal contact and person-to-person transmission were thought to account for 18% of the cases, and waterborne transmission in rural areas accounted for 8%.

Although some variation in results can be seen between regions and between studies, there is a consistent finding that foodborne infections form the majority of reported campylobacteriosis infections in industrialized nations, and that within these, poultry is the type of food most commonly implicated in the disease.

These findings are particularly important in determining appropriate control measures for the prevention of *Campylobacter* infection.

Control/Preventive Measures

The major components to *Campylobacter* control are:

- Treatment and management of infected individuals;
- Control of outbreaks;
- Prevention of *Campylobacter* infection;
- Surveillance to support prevention and control measures.

Treatment of *Campylobacter* Infection

The World Health Organization (WHO) advises that apart from supportive measures such as electrolyte replacement and rehydration, treatment is not generally indicated for campylobacteriosis. Antimicrobial treatment (erythromycin, tetracycline, or quinolones) may be indicated in severe cases or to eliminate the carrier state. Severe cases or cases with complications (e.g., GBS) may require admission to an intensive care unit for appropriate support.

Antibiotic resistance among *Campylobacters* is of great concern. The routine use of fluoroquinolones in commercial poultry flocks led to an increase in the prevalence of human *Campylobacter* isolates testing positive for ciprofloxacin resistance. In 2005, the Food and Drug Administration (FDA) in the US withdrew approval for these agents for use in poultry.

Control of Outbreaks

An important public health function is the rapid identification and control of common-source outbreaks, particularly if they are continuing or likely to recur. In the case of campylobacteriosis, this activity is relatively less important than for some enteric infections because the bulk of disease does not occur as part of recognizable outbreaks. As noted, there is a range of analytical methods available to support such investigations.

Prevention of *Campylobacter* Infection

Preventing *Campylobacter* infection is probably the most important and challenging component of global efforts to reduce the public health impact of this infection. Because the organism is widespread in the environment and in food sources, exposure is common. The infective dose is low. Consequently, a successful control program many need multiple components to reduce the risk of infection to acceptably low levels.

It is useful to consider approaches to *Campylobacter* prevention in terms of the important sources and settings of the infection. They are:

1. Contaminated food
2. Contaminated water
3. Contaminated environments, particularly in rural settings
4. Direct contact with infected animals
5. Direct contact with infected people
6. Foreign travel

Each source of infection and its relevant control measures will be considered separately, and all have a place in the prevention of *Campylobacter* infection. However, because foodborne routes of transmission account for the majority of reported *Campylobacter* infections, public health strategies for reducing infection risk have prioritized foodborne transmission in the control of *Campylobacter* infection.

There is a strong focus internationally on preventing the transmission of infection by contaminated poultry products, because analytical studies have consistently indicated that the majority of human *Campylobacter* infections are from poultry products. Furthermore, poultry contamination levels are known to be high. In their 2008 meta-analysis of *Campylobacter* contamination of retail poultry, Suzuki *et al*. found the prevalence of contamination to be 58% when averaged across the results of 72 studies worldwide. Consequently, the

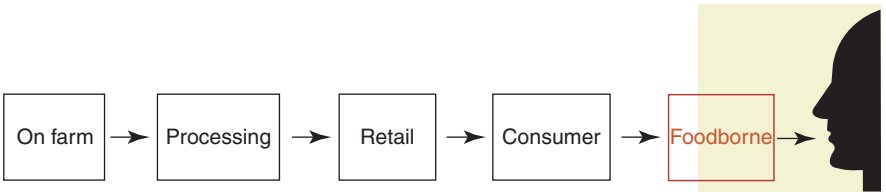

Figure 4 Control of foodborne *Campylobacter* infections: Points in the food production chain where interventions can operate.

following discussion provides most specific details on control of *Campylobacter* in chicken (Figure 4).

1. Control of foodborne *Campylobacter* infection

It is useful to consider each stage of food production in turn. They are:

a. On-farm/primary production
b. Processing
c. Retail and distribution
d. Consumer

a. On-farm/primary production: Primary prevention strategies include experimental concepts such as the selection of genetically resistant animals, as well as practical measures such as preventing contamination of the environment on farms and during transport of animals (frequently referred to as biosecurity measures). Other proposed measures include prevention of vertical transmission, eliminating *Campylobacter* from drinking water given to animals, additives to feed and water that may prevent colonization, and biological methods including vaccines. Of particular importance is the cleaning and disinfection of chicken houses before re-stocking, cleaning of transportation crates, and routine surveillance of flocks. Poultry meat arising from contaminated flocks may be designated for freezing only, a strategy that has proved effective in Iceland. This approach may also provide a financial incentive for farmers to keep their flocks free of *Campylobacter*, as frozen meat is less desirable to the consumer and therefore attracts a lower retail price.

   In future, primary prevention is likely to be an extremely effective strategy in the control of human disease; however, elimination of *Campylobacter* is expensive and difficult to achieve with currently available technology. As *Campylobacter* colonization does not appear to have an impact on the health and welfare of animals, there may be little perceived benefit of primary prevention for food producers.

b. Processing: This stage includes slaughter of broiler chickens, which involves a high risk of cross-contamination during scalding, plucking, and evisceration procedures. The risk may be reduced by the use of disinfectants such as acidified sodium chlorite.

   In general, it is more cost-effective to control contamination of the finished food product. Milk production is a good example of this: it is difficult to prevent raw milk from becoming contaminated with *Campylobacter*, but pasteurizing milk before distribution is an effective method of inactivating the organism.

   Various methods can be employed in the treatment of contaminated food. *Campylobacter* is sensitive to heat and can be eliminated by pasteurization or normal cooking temperatures. Freezing will reduce organism numbers, albeit to a limited extent, and other physical measures such as acidification (as occurs in pickling), salt, and irradiation can be effective. The organism's limited ability to survive in air at room temperatures reduces the risk from cooked food.

c. Retail and distribution: Control measures at retail level include the use of leak-free packaging and monitoring of *Campylobacter* contamination levels in retail poultry, as well as regulation of restaurants and commercial food premises.

d. Consumer: Measures available to the consumer include care with food preparation so as to avoid contamination of fresh food with raw meat, and cooking all meat thoroughly. This information can be conveyed to consumers as a targeted education campaign. However, the evidence base supporting the effectiveness of consumer education is very limited. Changing consumer behavior is difficult. There are also technical limitations. Kitchen contamination studies show that preparation of meals with raw chicken results in widespread cross contamination of hands, plates, chopping boards, utensils, and ready-to-eat food.

2. Contaminated water

Measures to decrease the risks from contaminated water include:

- Provision of a clean treated municipal water supply in urban areas
- Support for local water treatment methods for rural areas
- Public education about drinking water from safe sources
- Effective sewage treatment and disposal

3. Animals: The CDC advice regarding *Campylobacter* and contact with domesticated animals stresses the importance of handwashing. Persons who are immunocompromized are advised to be particularly cautious of contact with animals, especially if the animals have diarrhea. This advice is available to the public on the CDC website.

4. Contaminated environments: The epidemiological evidence indicates that children living in rural areas are particularly at risk from contaminated environments. This exposure source is difficult to control, although caregiver awareness of this risk (with associated hygiene measures) may help minimize *Campylobacter* infection in this setting.

5. Direct contact with infected people: In any healthcare setting where campylobacteriosis patients are treated, it is essential to ensure adequate handwashing and enteric precautions to avoid further transmission of the infection. Similar control measures are also necessary in settings such

as childcare centers where there is a higher risk of contact with contaminated feces.
6. Travelers: The WHO has published food safety advice for travelers which is available on their website. Contamination of drinking water is likely to be of particular concern to travelers in developing countries.

Surveillance

Surveillance is critically important to support both prevention and control measures for campylobacteriosis. It has two main purposes. In common with other infectious diseases

1. Control-focused surveillance – provides information to support control measures, notably the identification of outbreaks. This is the reason why campylobacteriosis is a notifiable disease in many countries and also frequently under surveillance by laboratories.
2. Strategy-focused surveillance – provides information to support prevention strategies. This includes a wider set of aims, notably:

- Monitoring the occurrence and distribution of disease, including epidemiological, clinical, and microbiological features – for example, to describe disease burden and the impact of interventions.
- Monitoring the occurrence and distribution of hazards, risk factors and determinants – for example, contamination levels in fresh poultry.
- Monitoring coverage and effectiveness of interventions – for example, the extent to which food retailers are complying with food safety standards.

Surveillance systems established for control-focused surveillance generally also support strategy-focused aims. This is particularly the case for notifiable disease surveillance where a well-functioning surveillance system should be able to alert health authorities in good time when a common-source *Campylobacter* outbreak has occurred locally. Data gathered by the system can be very helpful in identifying and eliminating the source as quickly as possible. These data are also useful for describing incidence trends at the local, regional, and national levels.

The USA, for example, has several highly developed systems in place for *Campylobacter* surveillance, and data compiled by these systems have contributed to scientific knowledge about campylobacteriosis as well as facilitating disease control.

The CDC has been operating a national *Campylobacter* surveillance program since 1982. National surveillance is conducted through the Public Health Laboratory Information System (PHLIS). In response to an increasing need for detailed information on foodborne diseases, an active surveillance system was instituted in five sites in 1996 and subsequently expanded to ten sites. This is known as the Foodborne Diseases Active Surveillance Network, or FoodNet.

FoodNet monitors the incidence and trends of human *Campylobacter* infection and conducts studies to identify risk factors for infection. A key feature of FoodNet is its close links with other agencies. FoodNet is a collaborative project of the CDC, 10 Emerging Infections Program (EIP) sites, the US Department of Agriculture (USDA), and the FDA. The USDA conducts research on prevention in poultry, and the FDA has developed a model for safety in the food industry (the Food Code). This is regularly updated and is used as the basis for food safety controls in the USA. In addition to these systems for monitoring campylobacteriosis, the National Antimicrobial Resistance Monitoring System (NARMS) conducts surveillance on antimicrobial resistance of *Campylobacter*. Data acquired from these surveillance systems are regularly analyzed and the results have added considerable knowledge about *Campylobacter* epidemiology and control.

Many of the interventions outlined above have been in use for some years in various countries, and the key question is: Are they succeeding in their aim of reducing *Campylobacter* infections? A number of countries, including the USA, the UK, Iceland, Denmark, Norway, and Sweden have reported a decline in campylobacteriosis rates following the introduction of control measures in poultry production. However, one of the most dramatic declines of recent years occurred in New Zealand during the years 2007–2008.

Campylobacteriosis first became notifiable in New Zealand in 1980. Over time, notifications and hospitalizations for campylobacteriosis were seen to increase, and this was found at least in part to reflect a true increase rather than a notification artifact. By 2006, campylobacteriosis notifications in New Zealand exceeded 380 per 100 000 population. This exceptionally high incidence was investigated using standard epidemiological methods and source attribution modeling, and the results strongly implicated poultry as the major source of infection.

Accordingly, a number of interventions were introduced, with the aim of reducing the risk of poultry-associated foodborne *Campylobacter* infections in New Zealand. These interventions included implementation of an updated industry Code of Practice for primary processing of poultry with mandatory targets; monitoring and reporting of contamination levels during production; leak-proof retail packaging; consumer education; and enhanced human campylobacteriosis surveillance and source attribution research.

Using the period 2002–2006 as the baseline for comparison, campylobacteriosis notifications and hospitalizations showed a decrease of greater than 50% in 2007–2008, coinciding with the introduction of the above interventions. Analysis of the surveillance data indicated that the decline was unlikely to have occurred by chance, with the interventions being the most likely explanation for the decline. This conclusion was also supported by source attribution modeling work undertaken over the same period, with a reduction seen in the proportion of human cases attributable to poultry, as compared to other sources. Although no single intervention could be identified as being responsible for the reduction in notifications, key informants identified two particularly important individual measures: the monitoring and reporting of *Campylobacter* enumeration on carcasses at the end of primary processing; and mandatory *Campylobacter* performance targets for contamination levels at the end of primary processing.

Research Needs

Pathogenesis Research

One very important research need is for a better understanding of *Campylobacter* pathogenesis, including the relationship of immunological and virulence factors to disease in humans and animals. For example, it would be helpful to be able to predict which campylobacteriosis patients are most at risk of serious complications. A detailed understanding of disease and resistance mechanisms would greatly facilitate the search for new, effective methods of prevention and control.

Research in this field has been considerably hampered by the lack of readily available animal models. Mouse models are used for studying immunity and vaccine responses in a number of diseases. However, mice are not naturally colonized by *Campylobacter* and do not usually develop diarrhea, necessitating cautious extrapolation from mouse studies to studies of human disease.

Chicken models are helpful in studying colonization and *in vivo* survival of the organism, but provide very limited information on the mechanisms of gastroenteritis, as chickens are frequently colonized by *Campylobacter* yet rarely develop symptomatic disease.

However, studying *Campylobacter* infection in chickens is a fruitful line of research in its own right, as successful strategies for reducing infection in the chicken population are likely to reduce the risk of foodborne infection in humans as well.

In the absence of good animal models, useful information has been derived from studies using human volunteers; but recent research has highlighted the importance of campylobacteriosis as a cause of GBS, and this raises considerable ethical concerns about exposing volunteers to the risk of such a serious complication. Work continues on developing new animal and tissue models.

Vaccines

There is much research interest in the possibility of vaccination both for humans and poultry.

Methods under investigation for human vaccines include whole-cell vaccines (using live attenuated organisms or killed organisms); subunit vaccines; and live attenuated *Salmonella* strains expressing *Campylobacter* proteins.

There is concern about the potential of whole-cell vaccines to cause GBS by inducing cross-reactivity with ganglioside cells. This in turn indicates an urgent research need for clear information about the mechanisms of GBS induced by *Campylobacter* infection, in order to avoid the complication of vaccine-induced paralysis.

There is also considerable research interest in developing a *Campylobacter* vaccine for chickens, as a way of decreasing the prevalence of contamination of poultry flocks.

Laboratory Methods

There is an ongoing need for sensitive, rapid, and cost-effective *Campylobacter* detection methods for food testing and surveillance purposes. The ability to test quantitatively is important as this allows food industry standards to be set and maintained, and quantitative testing can demonstrate specific steps in food production where the risk of contamination is unacceptably high.

There is also a need for robust methods of strain differentiation in order to continue source attribution work. As current control methods become effective, the relative contribution of the various sources of infection may change. There is also likely to be a geographical variation in relative contribution, for example, between rural and urban populations, and a clear understanding of this variation will inform the development of control strategies appropriate to specific circumstances and environments.

Other *Campylobacter* Species

As detection methods become more sensitive, it is possible that further *Campylobacter* species will be implicated as pathogens in the human disease. It will be important for clinical diagnosis and effective surveillance to take this evolving knowledge into account.

Novel Control Strategies for Poultry

Several novel control strategies are being investigated, with the goal of eliminating or reducing *Campylobacter* contamination of poultry flocks. They include:

- Competitive exclusion: The principle of competitive exclusion is that if the chicken gut is colonized with harmless bacteria at an early age, there will be less opportunity for colonization with harmful organisms. This has already been shown to be effective in limiting colonization with *Salmonella* spp., and work is now in progress to develop competitive exclusion products suitable for *Campylobacter*.
- Bacteriocin treatment: Bacteriocins are proteins produced by bacteria. They are of interest because they have an antimicrobial action against other bacteria, yet offer several advantages over standard antimicrobial therapy. Bacteriocin treatment for *Campylobacter* is still at an experimental stage, but appears promising.
- Bacteriophages: Bacteriophages (also known as phages) are a promising area of *Campylobacter* research. These are described as natural predators of bacteria, and as such may have useful antimicrobial properties. A number of *Campylobacter*-associated phages have been identified and work is in progress to establish their potential to control *Campylobacter* contamination of poultry flocks.
- Vaccination as mentioned above.

Climate Change

Given the high current global burden of campylobacteriosis, it will be important to monitor the impact of climate change on the epidemiology of *Campylobacter* infection.

Clostridium botulinum

MW Peck, Institute of Food Research, Norwich Research Park, Colney, UK

Glossary

Botulinum neurotoxin Most potent toxins known (30 ng is sufficient to cause illness and possibly death), formed by *Clostridium botulinum* and some strains of *C. baratii* and *C. butyricum*, seven neurotoxin types (types A–G).

Botulism A severe and often fatal neuroparalytic intoxication caused by a botulinum neurotoxin.

Clostridium A diverse genus of Gram-positive rod-shaped endospore-forming anaerobic bacteria.

Clostridium botulinum A heterogeneous species containing four phylogenetically and physiologically distinct bacteria that share the common feature of forming the botulinum neurotoxin.

Background

A disease frequently reported in Central Europe in the eighteenth and nineteenth centuries involved muscle paralysis, breathing difficulties, and a high fatality rate. This disease was often associated with consumption of blood sausage, and came to be known as 'botulism,' after the Latin word *'botulus'* meaning sausage. A major study by the Chief Medical Officer of Wurttemburg (Germany) in 1793 of 19 cases (six fatal) of muscle paralysis and breathing difficulties reported that the illness may have been due to consumption of nightshade leaves or berries, although consumption of locally produced blood sausage *blunzen* (pig stomach filled with blood and other ingredients, briefly boiled, preserved by smoking) was also considered. In July 1802, however, a warning notice was issued about consumption of harmful smoked blood sausages. Following this outbreak, there was an increase in the number of reported cases of sausage poisoning, prompting a study by Justinius Kerner. He described more than 200 cases, made suggestions for its prevention and treatment, and proposed that anaerobic conditions are required for toxin formation, and that the toxin was a highly potent biological neurotoxin.

In December 1895, more than 100 years after the outbreak in Wurttemburg, Emile van Ermengem investigated an outbreak of botulism in Ellezelles (Belgium). This outbreak affected 23 musicians (three fatally) who consumed homemade raw salted ham at a funeral wake. Importantly, van Ermengem isolated an obligately anaerobic spore-forming bacterium from cultures of ham. He called the isolated bacterium '*Bacillus botulinus*,' and although now lost, the physiological properties are consistent with those of nonproteolytic *Clostridium botulinum*. He also demonstrated that portions of macerated ham, filtered extracts, and bacterial culture filtrates caused flaccid paralysis and were toxic to various animal species. Thus, it was conclusively demonstrated that botulism was not an infection but an intoxication caused by a toxin formed by '*B. botulinus*.' At this time there was an increased use of canning and bottling processes both commercially and in the home to extend the shelf-life of foods. In 1904, Landmann investigated a large botulism outbreak in Darmstadt (Germany) that affected 21 people (11 fatally) that was associated with canned white beans. An obligately anaerobic spore-forming bacterium was again isolated, but the neurotoxin type was different from that formed by the strain isolated by van Ermengem, and could be distinguished by differential neutralization with specific antisera. The bacterium, also now lost, was probably proteolytic *C. botulinum*. The use of canning and bottling processes increased over the next few decades, and resulted in many hundreds of botulism cases as ineffective heat treatments were used. For example, the first reported outbreak of foodborne botulism in the UK (in 1922) affected eight people (all fatally), and was associated with consumption of a picnic lunch of sandwiches containing (underprocessed) wild duck paste at Loch Maree (Scotland). Between 1920 and 1930 the number of botulism cases fell following the identification and successful application of a standard minimum heat treatment (known as the botulinum cook) for canned and bottled foods. Since this time, occasional, but often severe, outbreaks of foodborne botulism have been reported in many countries either when known control measures have not been implemented, or when unsafe processes have been followed.

Characteristics of the Bacterium and Neurotoxins

Characteristics of the Six Bacteria that Form Botulinum Neurotoxins

Clostridium is a phylogenetically diverse genus of Gram-positive rod-shaped endospore-forming anaerobic bacteria.

This genus includes more than 100 species, many of which are pathogenic, including *C. botulinum*, *Clostridium tetani*, *Clostridium difficile*, and *Clostridium perfringens*. All bacteria that form the botulinum neurotoxin are members of the genus *Clostridium*. The species known as *C. botulinum* is defined on the basis of just one physiological property, which is the ability to form botulinum neurotoxin, rather than any close phylogenetic relationship. This approach is taken in order to recognize and emphasize the importance of neurotoxin formation. *C. botulinum* is in fact a heterogeneous species that can be separated into four distinct phylogenetic groups (*C. botulinum* Groups I–IV), with the distinction among the groups strong enough to merit separation into four different species. For each of the four groups, a phylogenetically equivalent, but non-neurotoxigenic, organism has been described. For example, strains of *C. botulinum* Group I are very closely related to *Clostridium sporogenes*, but only distantly related to strains of other *C. botulinum* groups. A relatively recent discovery has been that some strains of *Cbutyricum baratii* and *Cbutyricum butyricum* also possess the ability to form botulinum neurotoxin, and except for this ability they are indistinguishable from other more typical strains. The different physiological properties of the six botulinum neurotoxin-forming clostridia reflect their different genetic backgrounds.

Proteolytic C. botulinum *(*C. botulinum *Group I)*

Proteolytic *C. botulinum* is frequently associated with foodborne botulism, and also with wound and infant/intestinal botulism. Strains possess one or two neurotoxin genes of type A, B, or F (Table 1). Some of these strains form two active neurotoxins, with the major and minor neurotoxin types designated by an uppercase and lowercase letter. For example, type Ab strains form a larger quantity of type A neurotoxin than type B neurotoxin. Other strains form only one active neurotoxin; some have a single neurotoxin gene, whereas some have two neurotoxin genes, one of which does not encode an active neurotoxin. For example, type A(B) strains possess a type A and a type B neurotoxin genes, but only form active type A neurotoxin. The neurotoxin gene(s) is (are) located on the chromosome or on a large plasmid, and have evolved independently of the remainder of the genetic complement. Proteolytic *C. botulinum* is a mesophilic bacterium with a minimum growth temperature of 10–12 °C, although some

[e]+ all strains positive, +/− some strains are positive with others negative, − all strains negative.

strains grow poorly below 15 °C. The optimum growth temperature is in the range of 37–42 °C, and the maximum is approximately 48 °C. Growth and neurotoxin do not occur at pH < 4.6, or at ≥ 10% NaCl (Table 1). Spores of proteolytic *C. botulinum* are of high heat resistance and the principal concern for the safe production of low acid canned foods. The botulinum cook (121 °C for 3 min) is used by the canning industry as the standard minimum heat treatment for low acid canned foods. Quantifying the effect of various combinations of preservative factors on growth and neurotoxin formation and on thermal death is important to ensure the safety of foods with respect to proteolytic *C. botulinum*. Software packages, such as ComBase, are freely available that contain this information (www.combase.cc), and predictive models have been developed (www.combase.cc/predictor).

The genomes of several strains of proteolytic *C. botulinum* have been sequenced. All have a low %G + C content (28%) and are of a similar size (3.8–4.3 Mb). The genome of the type A strain ATCC 3502 (Hall 174) was the first to be sequenced, and comprised a circular chromosome (3.9 Mb, 3650 coding sequences (CDSs)), and a small plasmid (16.3 kb, 19 CDSs). The genomes of more recently sequenced strains of proteolytic *C. botulinum* show synteny with the ATCC 3502 genome. Based on whole genome analysis, it is estimated that for 61 strains of proteolytic *C. botulinum* and *C. sporogenes*, the core gene set comprises 2155 of the CDSs (approximately 63%) of ATCC 3502. These observations provide one line of evidence for the close genetic relationship between strains of proteolytic *C. botulinum* and *C. sporogenes*, and for a relatively stable genome. From analysis of the ATCC 3502 genome and various physiological tests, it seems that proteolytic *C. botulinum* is a bacterium well adapted to a saprophytic lifestyle, which relies on the highly potent neurotoxin to kill a wide range of species, and then a variety of extracellular enzymes to obtain nutrients. This bacterium is highly proteolytic, and also secretes enzymes dedicated to the catabolism of carbohydrates (including starch and chitin) and lipids. Five putative chitinases are widespread amongst strains of proteolytic *C. botulinum* and *C. sporogenes*, suggesting that chitin is an important source of carbon and nitrogen.

Nonproteolytic C. botulinum *(C. botulinum Group II)*

Nonproteolytic *C. botulinum* is primarily associated with foodborne botulism, with only a single case reported involving infant and wound botulism. Strains form a single neurotoxin of type B, E, or F (Table 1), and possess a single neurotoxin gene that is located on the chromosome or on a plasmid. Nonproteolytic *C. botulinum* is a psychrotrophic saccharolytic bacterium that ferments a wide range of sugars (Table 1). Nonproteolytic *C. botulinum*, unlike proteolytic *C. botulinum*, is not highly proteolytic. The minimum temperature for growth and neurotoxin formation is 2.5 °C–3.0 °C, although some strains grow poorly below 5 °C. The optimum growth temperature is approximately 25 °C–30 °C, and the maximum approximately 40 °C. Nonproteolytic *C. botulinum* does not multiply or form neurotoxin formation at pH < 5.0, or at ≥ 5% NaCl (Table 1). Spores of nonproteolytic *C. botulinum* are less heat resistant than those of proteolytic *C. botulinum*, and heat resistance is not related to the type of neurotoxin formed. Measured spore heat resistance can be substantially increased by the presence of lysozyme in the recovery medium. The highest reported *D*-value for spores heated in phosphate buffer at 82.2 °C (185 °F) is 2.4 min with recovery in the absence of lysozyme, and 231 min with recovery in the presence of lysozyme (Table 1). These heat treatments give sublethally injured spores that are unable to germinate. Lysozyme can circumvent the sublethal damage, and induce germination by hydrolyzing peptidoglycan in the cortex, enabling growth. This effect of lysozyme may be significant for food safety, as it is naturally present in many foods and is relatively heat-stable. Care also needs to be taken when using lysozyme as a food preservative. Quantifying the effect of various combinations of preservative factors on growth and neurotoxin formation, and on thermal death is important to ensure food safety, and software packages and predictive models are freely available (e.g., ComBase (www.combase.cc; www.combase.cc/predictor)).

At present, the genomes of only two strains of nonproteolytic *C. botulinum* have been sequenced. The genomes of these two strains are marginally smaller (3.7–3.8 Mb) than those of strains of proteolytic *C. botulinum*, and the %G + C is slightly lower (27%). However, although the genomes of the two nonproteolytic *C. botulinum* strains are similar to each other and show synteny, they are very different from the genomes of proteolytic *C. botulinum* strains and there is no synteny. This finding supports earlier tests that demonstrated the wide phylogenetic and evolutionary distance between proteolytic *C. botulinum* and nonproteolytic *C. botulinum*.

C. botulinum *Group III*

Strains of *C. botulinum* Group III are not associated with botulism in humans, but are responsible for botulism in birds (avian botulism) and animals (e.g., horses, cows, sheep, farmed foxes, and mink). *C. botulinum* Group III is a mesophilic saccharolytic bacterium, with strains forming either type C or type D neurotoxin. Strains have a minimum growth temperature of approximately 15 °C, and an optimal growth temperature of 40 °C (Table 1). Spores are of an intermediate heat resistance. The genome sequence of one *C. botulinum* Group III strain has been completed and other draft genomes are available. The small chromosome (2.8 Mb, %G + C = 28%) is highly conserved amongst isolates and closely related to that of *Clostridium novyi*, but not that of other *C. botulinum Groups*. The neurotoxin genes are located on a bacteriophage. Strains that lose this bacteriophage no longer form neurotoxin, and reinfection with the bacteriophage re-establishes neurotoxin formation. The bacteriophage can be easily lost in laboratory cultivation; thus maintenance of strains forming type C or type D neurotoxin is demanding. A bacteriophage containing a type C neurotoxin gene was found to contain linear double-stranded DNA of 186 kb with low %G + C content (26%), and its sequence has been published.

Clostridium argentinense *(C. botulinum Group IV)*

Strains of *C. argentinense* form type G neurotoxin. This bacterium has not been associated with botulism in humans, animals, or birds, although laboratory tests have shown that type G neurotoxin causes a typical flaccid paralysis in a range of animals. *C. argentinense* is a mesophilic proteolytic bacterium, with an optimum growth temperature of 37 °C. The

spores are of an intermediate heat resistance. *C. argentinense* was originally isolated from soils in Argentina, and is the least studied of the six botulinum neurotoxin-forming organisms. The *C. argentinense* genome has a low %G + C (28–30%), and is presently being sequenced. The type G neurotoxin gene is located on a single large plasmid of 123 kb. This plasmid and its ability to form neurotoxin are very easily lost in culture, and the resulting non-neurotoxigenic isolates are indistinguishable from *Clostridium subterminale*.

C. baratii *type F*

Strains of neurotoxigenic *C. baratii* type F have been associated with at least one case of foodborne botulism, and several cases of infant botulism and adult intestinal botulism. *C. baratii* type F is a mesophilic saccharolytic bacterium with a minimum growth temperature of 10–15 °C, and an optimum growth temperature of 30–45 °C (Table 1).

Typical strains of *C. baratii* that do not form neurotoxin and strains of neurotoxigenic *C. baratii* type F are closely related, but are phylogenetically separated from other botulinum neurotoxin-forming clostridia.

C. butyricum *Type E*

Outbreaks of foodborne botulism involving neurotoxigenic *C. butyricum* type E have been reported in Italy, China, and India, although human cases are more commonly associated with infant botulism and adult intestinal botulism. *C. butyricum* type E is a mesophilic saccharolytic bacterium, with a minimum growth temperature of 12 °C, and an optimum growth temperature of 30–37 °C (Table 1). Spores of neurotoxigenic strains of *C. butyricum* type E are of intermediate heat resistance. Neurotoxigenic strains of *C. butyricum* type E are closely related to the more commonly isolated nonpathogenic strains of *C. butyricum* that do not form neurotoxin, rather than other botulinum neurotoxin-forming clostridia.

Characteristics of the Seven Botulinum Neurotoxins and Their Encoding Genes

Properties of the Neurotoxins and Neurotoxin Complex

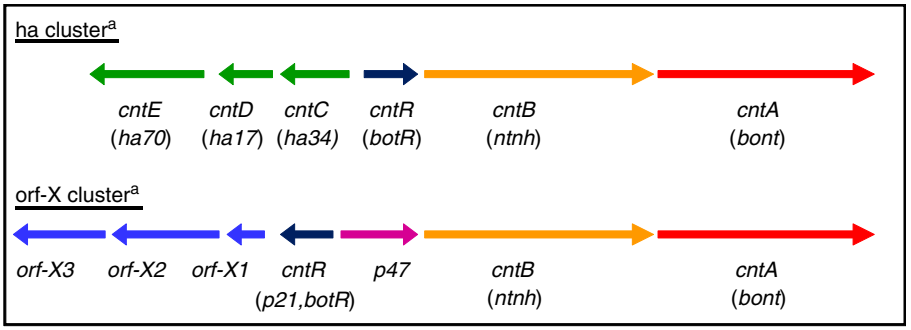
The botulinum neurotoxins are the most toxic substance known, being several orders of magnitude more potent than ricin or cyanide. The specific toxicity of botulinum neurotoxin complexes ranges from 3×10^7–10^8 MLD_{50} (mouse minimum lethal doses)/mg protein, and from cases of foodborne botulism and various animal experiments it has been estimated that symptoms of foodborne botulism or even death might be caused by consuming as little as 3000 MLD_{50} or 30–100 ng of neurotoxin (depending on the size of the neurotoxin complex). In a 2006 outbreak of foodborne botulism in Canada/USA involving temperature abused carrot juice (that contained 7×10^5 MLD_{50}/ml of neurotoxin), it appeared that consumption of only 5 µl of carrot juice, or a few micrograms, would have been sufficient to cause botulism. In reality, much larger quantities were consumed, resulting in severe cases of botulism. The botulinum neurotoxins are relatively sensitive to heating at 80 °C or higher. For example, heating in buffer at 85 °C for 5 min reduced the concentration of active neurotoxin by a factor of 10 000, although some foods were protective.

There are seven major types of botulinum neurotoxin (types A–G) and more than twenty subtypes (including five subtypes of type A neurotoxin (termed A1–A5) and five subtypes of type B neurotoxin). The seven major types of botulinum neurotoxins were originally distinguished using polyclonal antibodies raised against purified neurotoxins (as was the case for the neurotoxins formed by the strains isolated by van Ermengem and Landmann). The classification is supported by comparison of neurotoxin gene sequences and studies of the site of action of the neurotoxins. Subtypes of each botulinum neurotoxin serotype can be distinguished using monoclonal antibodies and by comparison of gene sequences.

The botulinum neurotoxins are synthesized as single-chain proteins, and converted to the more toxic dichain molecule by an extracellular bacterial protease (or an added protease such as trypsin). The dichain molecule consists of a heavy chain of approximately 100 kDa and a light chain of approximately 50 kDa, linked by a disulfide bond. The neurotoxins form complexes of various sizes from 300 to 900 kDa (depending on the neurotoxin type) with other proteins (e.g., haemagglutinin and nontoxic nonhaemagglutinin) that protect the neurotoxin and facilitate its absorption into the body. The neurotoxins act in a four-step process. Firstly, the C-terminal domain of the heavy chain binds to receptors on the surface of the presynaptic membrane of the motor neurone, and secondly the bound neurotoxin is internalized into the newly formed vesicle by receptor-mediated endocytosis. Thirdly, a conformational change in the neurotoxin, caused by acidification of the vesicle lumen, exposes surface hydrophobic domains, enabling the N-terminal translocation domain of the heavy chain to form an oligomeric structure with permeable channels in the vesicle membrane through which the now unfolded light chain can pass into the motor neurone cytosol. Once in the neutral pH of the cytosol, the light chain refolds. Fourthly, reduction of the interchain disulfide bond leads to the release of the light chain in the motor neurone cytosol. The neurotoxin light chains possess endopeptidase activity, and cleave proteins in the neurotransmitter (acetylcholine)-containing synaptic vesicle docking/fusion complex (SNARE proteins). Each light chain demonstrates stringent substrate specificity and mostly acts at a single site. The light chain of type A, C, and E neurotoxins targets the synaptosome-associated protein of 25 kDa (SNAP-25), the light chain of type B, D, F, and G neurotoxins targets the vesicle-associated membrane protein (VAMP), and the type C light chain also cuts syntaxin. Cleavage of just one of the SNARE proteins reduces the stability of the SNARE complex, preventing binding of acetylcholine-containing synaptic vesicles and therefore neurotransmitter release, leading to flaccid muscle paralysis.

Properties of the Gene Cluster Encoding the Neurotoxin and Neurotoxin Complex

The genes encoding the neurotoxins and associated proteins (such as haemagglutinins and nontoxic nonhaemagglutinin) are located together in two major neurotoxin cluster types, the



[a] ha cluster includes neurotoxin genes; A1[b], A5, B, C[c], D[c], G[d]; orf-X cluster includes neurotoxin genes; A1[b], A2, A3, A4, E[e], F[e,f]. *cntA* encodes neurotoxin; *cntB* encodes nontoxic nonhaemagglutinin; *cntC*, *cntD* and *cntE* encode haemagglutinins; *cntR* encodes neurotoxin cluster regulator; *p47*, *orf-X1*, *orf-X2* and *orf-X3* encode proteins of unknown function
[b] Most type A1 genes in ha cluster in single toxin gene strains; all type A1 genes in orf-X cluster in dual toxin gene strains
[c] *cntR* is downstream of *cntE*
[d] *cntC* is absent from type G neurotoxin cluster
[e] *cntR* absent from type E neurotoxin cluster, and some type F neurotoxin clusters
[f] Presence of *orf-X1*, *orf-X2* and *orf-X3* not confirmed in *C. baratii* type F neurotoxin cluster

Figure 1 Generalized view of two major neurotoxin gene cluster arrangements. Reproduced from Peck MW, Stringer SC, and Carter AT (2011) *Clostridium botulinum* in the post–genomic era. *Food Microbiology* 28(2): 183–191.

'ha cluster' and the 'orf-X cluster' (Figure 1). These clusters are present either on the chromosome or plasmid (proteolytic *C. botulinum* and nonproteolytic *C. botulinum*), a bacteriophage (*C. botulinum* Group III), or a plasmid (*C. argentinense*). Most strains contain a single neurotoxin gene and one neurotoxin gene cluster, although some strains of proteolytic *C. botulinum* possess two neurotoxin genes and two neurotoxin gene clusters. Recently strains of proteolytic *C. botulinum* have been described that unusually contained two neurotoxin genes (full type A5 and truncated type B neurotoxin gene) in a single neurotoxin gene cluster. The designation of genes within the neurotoxin cluster has been inconsistent, and several schemes have been used. Here the suffix *cnt* for clostridial neurotoxin is used for all genes of known function located within the botulinum neurotoxin clusters. All botulinum neurotoxin genes are designated *cntA*, with the type A neurotoxin gene designated *cntA/A* and the type B neurotoxin gene *cntA/B*, etc. (also sometimes known as *bont/a* and *bont/b*, respectively). The ha cluster contains two transcriptional units, with the neurotoxin (*cntA*) and nontoxic nonhaemagglutinin (*cntB*, also known as *ntnh*) encoding genes, which are cotranscribed. The haemagglutinin encoding genes (*cntC*, *cntD*, *cntE*, also known as *ha*34, *ha*17, and *ha*70, respectively) are in a second transcriptional unit and are transcribed in the opposite direction (Figure 1). A gene encoding a sigma 70 factor (*cntR*, also known as *botR*) that is responsible for the positive regulation of genes in the neurotoxin gene cluster is present between these two transcriptional units. Neurotoxin genes of types A1 (most single neurotoxin gene strains), A5, B, C, D, and G are present in the ha cluster (Figure 1). In the case of type C and D neurotoxins gene clusters, *cntR* is located downstream of *cntE*, whereas the type G neurotoxin gene appears to be associated with only two haemagglutinin encoding genes.

The orf-X cluster comprises genes encoding the neurotoxin (*cntA*), nontoxic nonhaemagglutinin (*cntB*), sigma 70 factor (*cntR*, also known as *p21* or *botR*), a group of three open reading frames (*orf-X1*, *orf-X2*, and *orf-X3*), and a single CDS (*p47*) of unknown function (Figure 1). The three haemagglutinin genes are absent from the orf-X cluster. It seems that *cntA*, *cntB*, and *p47* are cotranscribed, as are *orf-X1*, *orf-X2*, and *orf-X3*, both from conserved neurotoxin gene cluster promoters. The functions of the proteins encoded by *p47*, *orf-X1*, *orf-X2*, and *orf-X3*, and their role (if any) in the neurotoxin complex remain to be established. The type A1, A2, A3, A4, E, and F neurotoxin genes are located in an orf-X cluster (Figure 1). The type A1 neurotoxin gene in single neurotoxin gene strains is more commonly found in the ha cluster than the orf-X cluster, whereas in all dual neurotoxin gene strains the type A1 neurotoxin gene is in an orf-X cluster. No *cntR* homolog has been identified in clusters containing a type E neurotoxin gene. The sequencing of further genomes will undoubtedly provide further information on neurotoxin gene clusters.

The neurotoxin genes and neurotoxin gene clusters appear to have evolved independently of each other, and of the bacterium, and are likely to have arisen from a series of recombination events. Transfer of plasmids and bacteriophages containing neurotoxin genes has undoubtedly contributed to horizontal gene movement. Putative mobile genetic elements located close to the neurotoxin gene cluster may also have played a role, and the center of the *cntB* gene (encoding nontoxic nonhaemagglutinin) is reported to be a hot spot for recombination events.

Neurotoxin formation by proteolytic *C. botulinum* and nonproteolytic *C. botulinum* is primarily associated with late exponential and early stationary phase, and the quantity of neurotoxin formed is dependent on the strain and growth conditions. It is not, however, fully understood how neurotoxin formation is regulated. The sigma 70 factor (*cntR*) is involved in the positive regulation of the genes in the

neurotoxin gene cluster transcriptional units. Each cluster type carries its own distinguishable *cntR* gene, and although *cntR* is not present in clusters that carry a type E neurotoxin gene, neurotoxin formation is tightly regulated, indicating the presence of a presently unidentified positive regulator. Evidence is beginning to emerge that neurotoxin formation, and therefore also *cntR*, is regulated by a quorum sensing mechanism. Neurotoxin release from the cell is not dependent on autolysis, and the absence of any potential signal peptide at the N-terminus raises the possibility that neurotoxins may be secreted through a nonsignal peptide mediated secretion system (e.g., holin, flagella export apparatus).

Clinical Manifestation of Botulism

Botulism is a severe neuroparalytic disease, caused by the botulinum neurotoxin, which affects animals, birds, and humans. There are three major types of human botulism: foodborne botulism, infant/intestinal (adult) botulism, and wound botulism. Foodborne botulism is caused by ingestion of food containing preformed botulinum neurotoxin, following growth of proteolytic *C. botulinum* or nonproteolytic *C. botulinum* (or more rarely *C. baratii* type F or *C. butyricum* type E) in the food. The first symptoms can be observed within 2 h, although 12–36 h is more common, but it can be as long as 8 days. Nausea and vomiting may precede other symptoms and are not caused by the neurotoxin but by other substances produced during microbial growth in the food. The first symptom of botulism is often blurred vision, followed by difficulty swallowing and speaking, paralysis of face muscles, a descending bilateral flaccid paralysis, and generalized muscle weakness. In severe cases, this may be followed by flaccid paralysis of the respiratory or cardiac muscles, and can result in death if not treated. It is likely that cases of foodborne botulism are not recognized or misdiagnosed, sometimes being confused with the Guillain–Barré syndrome, Myasthenia gravis, and the effects of other foodborne pathogens. With the use of equine antitoxin and strong supportive therapy (including mechanical ventilation), the fatality rate for adults suffering from botulism has been reduced to less than 10% of cases. In many severe cases, however, complete recovery can be very slow, taking months or even years. The use of human botulism immune globulin for treatment of infant botulism has led to a significant reduction in the time spent on mechanical ventilation, in intensive care, and in hospital.

Some strains of *C. botulinum* form as much as 1000 human lethal doses of neurotoxin per gram. Thus, consuming only a few micrograms of food in which proteolytic *C. botulinum* and nonproteolytic *C. botulinum* (or more rarely *C. baratii* type F or *C. butyricum* type E) has grown could result in foodborne botulism. Consumption of as little as 30 ng of neurotoxin is sufficient to cause illness and even death. Because the quantity of neurotoxin consumed is so small, the body is unlikely to raise its own antibodies to the neurotoxin, and several individuals have contracted foodborne botulism more than once. Further details of the epidemiology of foodborne botulism are given in the next section.

Infant and intestinal (adult) botulism are both infections of the gastrointestinal tract. The first clinical cases of infant botulism were described in 1976. Between 1976 and 2006, 2419 cases were reported in the USA (where it is now the most frequently reported type of botulism), 366 cases in Argentina, and 158 cases in other countries. Only a few dozen cases of intestinal (adult) botulism have been described world-wide. Infant botulism affects those less than 12 months of age (infants between 2 and 26 weeks are most susceptible), and intestinal (adult) botulism affects adults with a suppressed normal intestinal flora (e.g., by antibiotic treatment). The consumption of as few as 10–100 spores of proteolytic *C. botulinum* (or more rarely *C. baratii* type F, nonproteolytic *C. botulinum*, or *C. butyricum* type E) can lead to colonization of the large intestine and the formation of neurotoxin *in vivo*. Colonization and multiplication by these neurotoxigenic clostridia in the gastrointestinal tract is prevented by a normal adult intestinal flora. Two major sources of spores have been identified for infant botulism: the environment (e.g., soil, dust) and honey. This association with honey has led to the recommendation in several countries that jars of honey should carry a warning indicating that the product should not be consumed by infants less than 12 months of age. Typical symptoms include extended constipation and flaccid paralysis. The fatality rate is approximately 1% of cases. Infant botulism has been proposed as one possible cause of sudden infant death syndrome.

Wound botulism is an infection involving growth and neurotoxin formation (almost invariably by proteolytic *C. botulinum*) in a wound in the body. Wound botulism was first described in 1943, and for approximately half a century was an uncommon disease generally associated with gross trauma. Many countries have recently reported their first cases of wound botulism or a significant increase in the number of reports, associated with drug abuse. Spores either originally present in heroin or on contaminated needles enter the body via subcutaneous or intramuscular injection. The spores then germinate, leading to growth and neurotoxin formation in a wound or abscess that provides the necessary anaerobic environment. Wound botulism has also been associated with inhalation of cocaine (and spores), and subsequent growth and neurotoxin formation in the sinus. Other types of human botulism are extremely rare, and include botulism following injection of licensed and unlicensed botulinum neurotoxin intended for therapeutic purposes, and the inadvertent inhalation of aerosolized neurotoxin by veterinary workers. Additionally botulinum neurotoxin has attracted the attention of some governments and terrorist groups as a potential bioterrorism weapon. For example, between 1990 and 1995, aerosols of botulinum neurotoxin were dispersed in Japan by the Aum Shinrikyo cult in a series of unsuccessful attacks.

Epidemiology of Foodborne Botulism

Overview

Despite the severity of foodborne botulism the true incidence of this disease is under-reported, with the extent of under-reporting varying from country to country. In 1999/2000, more than 2500 cases of foodborne botulism were reported in Europe, with a high incidence reported in Russia, Belarus, Azerbaijan, Armenia, Poland, Uzbekistan, Georgia, and Turkey

Table 2 Reported foodborne botulism in European countries in 1999/2000

Country	*Number of reported cases*
Russia	887
Belarus	344
Azerbaijan	181
Armenia	176
Poland	169
Uzbekistan	131
Georgia	122
Turkey	114
Kyrgyzstan	94
France	60
Lithuania	36
Portugal	33
Moldova	32
Germany	30
Italy	21
Bulgaria	18
Croatia	16
Czech Republic	7
Latvia	7
Slovenia	7
Norway	5

Note: Modified from Peck (2006). Only includes countries reporting five or more cases. May also include cases of other types of botulism.

Table 3 Reported foodborne botulism in different countries

Country	*Period*	*Number of cases*	
		Total	*Average per year*
Argentina	1980–2004	84	3
Belgium	1982–2000	32	2
Canada	1971–2005	439	13
China	1958–1983	4377	168
Denmark	1984–2000	18	1
France	1971–2003	1286	39
Georgia	1980–2002	879	40
Germany	1983–2000	376	22
Italy	1979–2000	750	34
Japan	1951–1998	530	11
Poland	1971–2000	9219	307
Romania	2003–2008	210	35
Spain	1971–1998	277	10
Sweden	1969–2000	13	1
UK	1971–2006	38	1
USA	1971–2008	1029	27

Note: Modified from Lund and Peck (2000) from various sources. May also include cases of other types of botulism.

(Table 2). The Republics of Armenia, Belarus, and Georgia have amongst the highest nationally reported rates of foodborne botulism per head of population. In recent years, between 20 and 40 cases of foodborne botulism have been recorded annually in France, Georgia, Germany, Italy, and USA, with a higher incidence in China and Poland (Table 3). In view of the severity of the foodborne botulism hazard, improperly processed foods are often recalled if faulty processing is known or strongly suspected.

To understand the causes of botulism outbreaks and to prevent any recurrence, it is highly desirable to identify the type of neurotoxin formed, and essential to establish which of the neurotoxigenic clostridia is responsible. For example, if type B or type F neurotoxin is detected, but the organism not isolated, it is unclear whether proteolytic *C. botulinum* or nonproteolytic *C. botulinum* is responsible. Outbreaks of foodborne botulism have involved foods prepared in the home and commercially, often when known control measures have not been implemented. Outbreaks of foodborne botulism are most frequently associated with proteolytic *C. botulinum* or nonproteolytic *C. botulinum*, very rarely with neurotoxigenic strains of *C. baratii* type F or *C. butyricum* type E, but not with *C. botulinum* Group III or *C. argentinense*. Because proteolytic *C. botulinum* and nonproteolytic *C. botulinum* are physiologically distinct and present different hazard scenarios, it is appropriate to consider the epidemiology of foodborne botulism for each separately.

Foodborne Botulism Outbreaks Associated with Proteolytic *C. botulinum*

Most outbreaks are concerned with strains that form type A or type B neurotoxin. The original Landmann strain was probably proteolytic *C. botulinum* type A. One very large botulism outbreak in Algeria in 1998 was associated with commercially produced Cashir sausage, in which proteolytic *C. botulinum* type A had grown and formed neurotoxin. There were 340 cases and 37 deaths reported. Three factors have contributed to a majority of foodborne botulism outbreaks associated with proteolytic *C. botulinum*. Further details of recent outbreaks are given in Table 4.

Inadequate Heat Processing of Canned or Bottled Foods

Low acid canned (or bottled) foods rely on the effective delivery of the botulinum cook to ensure safety, and outbreaks of foodborne botulism have occurred when it has not been fully delivered. Proteolytic *C. botulinum* has been responsible for most outbreaks of botulism involving such foods (Table 4), a reflection of high spore heat resistance. The failure to deliver the botulinum cook to home canned bamboo shoots led to a very large botulism outbreak in Thailand in March 2006. Spores of proteolytic *C. botulinum* type A survived the inadequate heat treatment, and led to growth and neurotoxin formation during subsequent ambient storage. Consumption of the bamboo shoots at a local religious rite resulted in 209 cases of botulism, 42 of which required mechanical ventilation. It is likely that there would have been significant mortality if the Thai authorities had not rapidly mobilized such a large number of mechanical ventilators. Proteolytic *C. botulinum* type A had been earlier associated with a 1998 botulism outbreak involving home canned bamboo shoots in Thailand. In June 2007, spores of proteolytic *C. botulinum* type A survived the inadequate thermal process applied to cans of hot dog chili sauce at a commercial canning facility in Augusta (Georgia, USA). Subsequent consumption of the hot dog chili sauce led to four cases of foodborne botulism, all of whom required mechanical ventilation. This outbreak was associated

Table 4 Examples of outbreaks of foodborne botulism

Country (year)	*Product*	*Bacterium*	*Toxin type*	*Cases (deaths)*	*Factors contributing to botulism outbreak*
Madagascar (1982)	Commercial pork sausage	Nonproteolytic *C. botulinum*	E	60 (30)	Inadequate preservation
USA (1985)	Uneviscerated salted, air-dried fish (*kapchunka*)	Nonproteolytic *C. botulinum*	E	2 (2)	Poorly controlled salting, lack of refrigeration
Canada (1985)	Commercial garlic-in-oil	Proteolytic *C. botulinum*	B	36	Temperature abuse
USA/Israel (1987)	Commercial uneviscerated salted, air-dried fish (*kapchunka*)	Nonproteolytic *C. botulinum*	E	8 (1)	Poorly controlled salting, lack of refrigeration
Canada (1987)	Bottled mushrooms	Proteolytic *C. botulinum*	A	11	Underprocessing and inadequate acidification
UK (1989)	Commercial hazelnut yoghurt	Proteolytic *C. botulinum*	B	27 (1)	Underprocessing of hazelnut conserve
Japan (1989)	Herring, Flounder and Dace *Izushi* (3 outbreaks)	Nonproteolytic *C. botulinum*	E	6	Poor fermentation
Japan (1991)	Dace and Ayu *Izushi* (2 outbreaks)	Nonproteolytic *C. botulinum*	E	2	Poor fermentation
Egypt (1991)	Commercial uneviscerated salted fish (*faseikh*)	Nonproteolytic *C. botulinum*	E	>91 (18)	Putrefaction of fish before salting
USA (1992)	Commercial uneviscerated salted fish (*moloha*)	Nonproteolytic *C. botulinum*	E	8	Insufficient salt
USA (1993)	Restaurant, commercial process cheese sauce	Proteolytic *C. botulinum*	A	8 (1)	Contaminated after opening, then temperature abused
Italy (1993)	Commercial canned roasted egg plant in oil	Proteolytic *C. botulinum*	B	7	Insufficient heat treatment; improper acidification
Sweden (1994)	Vacuum-packed hot-smoked rainbow trout	Nonproteolytic *C. botulinum*	E	?	Temperature abuse (?)
USA (1994)	Restaurant; potato dip (*skordalia*) and egg plant dip (*meligianoslata*)	Proteolytic *C. botulinum*	A	30	Baked potatoes held at room temperature
USA (1994)	Commercial clam chowder	Proteolytic *C. botulinum*	A	2	Temperature abuse at home
USA (1994)	Commercial black bean dip	Proteolytic *C. botulinum*	A	1	Temperature abuse at home
Georgia (1994)	Fish consumed at wedding	Nonproteolytic *C. botulinum* (?)	E?	173	?
Japan (1995)	Salmon, Gizzard Shad, and Dace *Izushi* (3 outbreaks)	Nonproteolytic *C. botulinum*	E	10	Poor fermentation
Canada (1995)	'Fermented' seal or walrus (4 outbreaks)	Nonproteolytic *C. botulinum*	E	9	Unsafe process
Italy (1996)	Commercial mascarpone cheese	Proteolytic *C. botulinum*	A	8 (1)	Temperature abuse
Japan (1997)	Char and Dace *Izushi* (2 outbreaks)	Nonproteolytic *C. botulinum*	E	4	Poor fermentation
Germany (1997)	Commercial hot-smoked vacuum-packed fish (*Raucherfisch*)	Nonproteolytic *C. botulinum*	E	2	Suspected temperature abuse
Argentina (1997)	Home cured ham	Nonproteolytic *C. botulinum*	E	6	?
Germany (1997)	Home smoked vacuum-packed fish (*Lachsforellen*)	Nonproteolytic *C. botulinum*	E	4	Temperature abuse
Italy (1997)	Home-made pesto/oil	Proteolytic *C. botulinum*	B	3	Unsafe process
Germany (1997)	Home-prepared beans	Proteolytic *C. botulinum*	A	1	Poor preparation
Iran (1997)	Traditional cheese preserved in oil	Proteolytic *C. botulinum*	A	27 (1)	Unsafe process
Germany (1998)	Commercial smoked vacuum-packed fish	Nonproteolytic *C. botulinum*	E	4	Temperature abuse (?)

(*Continued*)

Table 4 Continued

Country (year)	*Product*	*Bacterium*	*Toxin type*	*Cases (deaths)*	*Factors contributing to botulism outbreak*
France (1998)	Commercial frozen vacuum-packed seafood (2 outbreaks)	Nonproteolytic *C. botulinum*	E	2	Temperature abuse (?)
Thailand (1998)	Home canned bamboo shoots	Proteolytic *C. botulinum*	A	13 (2)	Inadequate processing (?)
Argentina (1998)	Commercial chilled meat roll (*matambre*)	Proteolytic *C. botulinum*	A	9	Temperature abuse
UK (1998)	Home bottled mushrooms in oil (imported from Italy)	Proteolytic *C. botulinum*	B	2 (1)	Unsafe process
Japan (1998)	Bottled olives in brine	Not known[a]	B	18	?

with a massive product recall involving tens of millions of cans.

Temperature/Time Abuse of Products Intended to be Stored Chilled

Proteolytic *C. botulinum* has a minimum growth temperature of 10–12 °C, and the only barrier to controlling neurotoxin formation by this bacterium in many chilled foods appears to be refrigerated storage. Temperature abuse of commercial chilled carrot juice permitted growth and neurotoxin formation by proteolytic *C. botulinum* type A, resulting in a very severe botulism outbreak in Canada (Toronto) and USA (Florida and Georgia) in 2006. It is probable that the six people affected all consumed massive quantities of neurotoxin, because as little as 5 µl of carrot juice may have constituted a lethal dose (see Properties of the Neurotoxins and Neurotoxin Complex). All six required mechanical ventilation, one of whom died, and two were still dependent on mechanical ventilation 1 year after the initial intoxication. Temperature abuse of commercial chicken enchiladas in France in August 2008 allowed growth and neurotoxin formation by proteolytic *C. botulinum* type A, resulting in a small botulism outbreak (Table 4). Both people affected required mechanical ventilation, and probably consumed large quantities of neurotoxin. It has been estimated that 10 mg of food may have constituted a lethal dose.

Addition of Ingredients Containing Preformed Botulinum Neurotoxin to a Correctly Refrigerated Product

In 1989, 27 people were intoxicated with botulinum neurotoxin (one fatally) in the largest botulism outbreak in the UK. The outbreak involved commercially produced hazelnut yoghurt. An inadequate heat treatment was delivered to the hazelnut conserve permitting the survival of spores of proteolytic *C. botulinum* type B, and after subsequent ambient storage neurotoxin was formed. Hazelnut conserve containing type B neurotoxin was then added to natural yoghurt. In 1994, a large botulism outbreak in the USA was associated with consumption of *skordalia* in a restaurant. Thirty people were affected, four of whom required mechanical ventilation. Foil-wrapped potatoes were baked in an oven, and then held at ambient temperature. Spores of proteolytic *C. botulinum* type A survived the heat treatment, and then multiplied and formed neurotoxin during ambient storage. Potatoes contaminated with neurotoxin were then added to natural yoghurt to give *skordalia* (Table 4).

Foodborne Botulism Outbreaks Associated with Nonproteolytic *C. botulinum*

Reported outbreaks of foodborne botulism associated with nonproteolytic *C. botulinum* most frequently involve strains forming type E neurotoxin (Table 4). Strains forming type B neurotoxin are, however, also very important, and many outbreaks in Europe associated with type B neurotoxin undoubtedly involve strains of nonproteolytic *C. botulinum* type B. It is likely that the original van Ermengem strain was nonproteolytic *C. botulinum* type B. Three types of foods are commonly associated with foodborne botulism outbreaks and nonproteolytic *C. botulinum* (Table 4).

Salted Fish

Inadequate salting, particularly of fish, has been associated with a number of outbreaks of foodborne botulism. The

consumption of commercially produced uneviscerated salted fish (*faseikh*) led to a very large outbreak of foodborne botulism in Egypt in 1991 that affected more than 91 people (18 fatally). The fish, from fish ponds, was stored in a cool room for 1 day to allow putrefaction before salting, enabling growth and neurotoxin formation by nonproteolytic *C. botulinum* type E before the salting process was complete. Other outbreaks involving inadequate salting of fish and a lack of appropriate refrigeration have been reported in the USA and Israel (Table 4).

Vacuum and Smoked Fish

Botulism outbreaks in several European countries have been associated with vacuum-packed fish. Temperature and/or time abuse has been suspected in a number of these outbreaks. For example, three botulism cases were associated with suspected temperature abuse of vacuum-packed hot-smoked whitefish in France in September 2009.

Fermented Foods

A number of outbreaks of botulism in Japan have been caused by consumption of home-prepared *izushi* or a similar fermented fish product (Table 4). *Izushi* is prepared by soaking fleshy pieces of fish in water for a few days, with occasional changes of water to remove blood, and then packing the fish tightly in a tub with diced vegetables, cooked rice, vinegar, salt, and spices and allowing to ferment for several weeks. The product is consumed without cooking. Neurotoxin formation by nonproteolytic *C. botulinum* type E may occur during soaking or early fermentation, but not once the fermentation has taken the pH below pH 5.0. Home-made foods prepared by the peoples of Alaska and north Canada (e.g., fermented seal flipper, fermented beaver tail and paw, and fermented salmon roe and *muktuk*) are responsible for outbreaks of foodborne botulism on an annual basis. These foods are generally fermented before consumption, and if this fermentation takes place at a temperature of 3 °C or higher then growth and neurotoxin formation by nonproteolytic *C. botulinum* may occur. Further details of recent outbreaks are given in Table 4.

Analytical Methods for *C. botulinum* and Its Neurotoxins

Methods for the Isolation of Proteolytic *C. botulinum* and Nonproteolytic *C. botulinum*

The extreme potency of the botulinum neurotoxins and the hazardous nature of the six botulinum neurotoxin-forming clostridia require that all practical work is restricted to containment laboratories that afford a high level of worker protection. When enumerating or isolating proteolytic *C. botulinum* or nonproteolytic *C. botulinum* from foods or the environment it is essential to determine the efficiency of the method(s) used, by demonstrating that known strains can be recovered following addition in low numbers to test samples. Because proteolytic *C. botulinum* and nonproteolytic *C. botulinum* are physiologically distinct, a single enrichment procedure cannot be relied upon for both organisms. A heat treatment or ethanol treatment, before enrichment, can be used to eliminate or reduce the number of competing vegetative bacteria. A heat treatment at 75–80 °C for 10–15 min should be used during isolation of proteolytic *C. botulinum*, whereas a lower heat treatment (e.g., 60 °C for 30 min) is more suitable when culturing from spores of nonproteolytic *C. botulinum*. There may also be merit in testing untreated samples to isolate vegetative bacteria. The enrichment media should be fully anaerobic, and the redox dye resazurin is a useful indicator. A temperature of 35 °C is used for enrichment cultures of proteolytic *C. botulinum*, whereas a lower incubation temperature (e.g., 12 °C or 26 °C) has been used for nonproteolytic *C. botulinum*. Lysozyme may be added to the enrichment medium to increase recovery of heated spores, whereas addition of trypsin may inactivate bacteriocins that may be formed by closely related clostridia. An extended period of incubation (7 day or longer) should be allowed for growth and neurotoxin formation. A portion of the enriched culture can be used to test for botulinum neurotoxin or the encoding gene, and a portion plated onto a selective (e.g., *C. botulinum* Isolation (CBI) agar, Botulinum Selective Medium (BSM)) or nonselective plating medium (e.g., egg-yolk agar). Egg-yolk is included in these plating media as colonies of proteolytic *C. botulinum* and nonproteolytic *C. botulinum* have a typical appearance associated with their lipase activity.

Molecular Methods for the Detection and Characterization of Proteolytic *C. botulinum* and Nonproteolytic *C. botulinum*

Polymerase chain reaction (PCR)-based tests have been developed that detect botulinum neurotoxin genes, including multiplex PCR methods for simultaneous detection of type A, B, E, and F neurotoxin genes in a single reaction. Detection in these tests is achieved by gel electrophoretic confirmation of product size. There is merit in confirming the specificity of a positive PCR result, for example by sequencing of the PCR product. Real time PCR methods have also been developed. PCR-based tests have been widely used in the investigation of botulism outbreaks, and in the testing of enrichment media during surveys for the presence of proteolytic *C. botulinum* and nonproteolytic *C. botulinum* in food, clinical, and environmental samples.

Various typing methods have been used for the molecular characterization of strains of proteolytic *C. botulinum* and nonproteolytic *C. botulinum*. These include ribotyping, pulsed-field gel electrophoresis (PFGE), amplified fragment length polymorphism (AFLP), multilocus sequence typing (MLST), DNA sequencing, and comparative genomic indexing. Ribotyping is widely used for molecular typing of unknown bacteria, and can distinguish strains of proteolytic *C. botulinum* and nonproteolytic *C. botulinum*. PFGE has a higher discriminatory power than ribotyping, and involves the digestion of genomic DNA with rare-cutting restriction enzymes, followed by separation by electrophoresis. PFGE has been used to investigate the diversity of strains of proteolytic *C. botulinum* and nonproteolytic *C. botulinum*. AFLP involves digestion of genomic DNA with a pair of restriction enzymes, ligation with restriction site-specific adapters, and PCR amplification of a subset of the fragments. AFLP clearly differentiates between

proteolytic *C. botulinum* and nonproteolytic *C. botulinum*, and is suitable for typing at the strain level. MLST has been shown to discriminate strains of proteolytic *C. botulinum*. Whole genome sequencing is now becoming affordable and rapid, and provides excellent discrimination of strains. Comparative genomic indexing using a DNA microarray based on the genome sequence of proteolytic *C. botulinum* is an effective tool to distinguish strains of proteolytic *C. botulinum*, but not those of nonproteolytic *C. botulinum* as they are too distinct. A separate DNA microarray based on the genome of strain(s) of nonproteolytic *C. botulinum* would be needed for this purpose. Unlike other typing methods, these two methods provide extra information on the genome content of the tested strains.

Methods for the Detection and Quantification of Botulinum Neurotoxins

For a great many years, the gold standard method for detection and identification of botulinum neurotoxins has involved intraperitoneal injection into mice. Specificity is achieved by looking for typical symptoms of botulism and the use of specific antisera. Advantages of the mouse test are that it is extremely sensitive (5–10 pg of neurotoxin), measures the biological activity of the neurotoxin, is repeatable and reproducible, and should detect previously undescribed neurotoxins. The major disadvantage of the mouse test is the ethical issue concerning the use of animals; other limitations are the need to wait several days before a sample can be judged negative, the need for highly skilled personnel, and the cost. Alternative animal methods have been described, some of which are nonlethal.

Immunochemical methods have been widely used for the detection and quantification of botulinum neurotoxins, including enzyme-linked immunosorbent assays (ELISA), affinity immunochromatography columns (AICC), and lateral flow immunoassays (LFIA). These methods are cheaper, quicker, and much easier to use than the mouse test, and in some cases have the same sensitivity and specificity. Limitations of the various immunochemical methods may include a failure to detect undescribed neurotoxins, a different response to neurotoxin subtypes (that differ antigenically), response to biologically inactive neurotoxin, crossreactivity, and some tests require complex and expensive amplification systems.

Advantage has been taken of the highly specific endopeptidase activity of the botulinum neurotoxin light chains to develop a series of *in vitro* assays. The first assays used an immunochemical approach to detect cleavage of SNAP-25 or VAMP by botulinum neurotoxins, and some are as sensitive as the mouse test. Other assays employ a synthetic peptide (to mimic SNAP-25 or VAMP), labeled with quenched fluorophores, as the substrate. These peptides are cleaved by the endopeptidase activity of the botulinum neurotoxins, releasing fluorescence. Although these tests measure the biological activity of the light chain (but not the heavy chain) and are not affected by variations in antigenicity of neurotoxin subtype, interference by other proteases can be a limitation requiring the incorporation of an additional step to capture the neurotoxin before measurement of endopeptidase activity.

Control and Prevention of Foodborne Botulinum

Overview

In order to set processes to control the foodborne botulism hazard, it is necessary to have information on the extent of contamination of the environment and foods with spores of proteolytic *C. botulinum* and nonproteolytic *C. botulinum*. Figure 2 summarizes data from 83 independent surveys of incidence of *C. botulinum* spores in soils and sediments across the globe. Many of the original surveys may have well been subjected to various limitations; for example, small sample size, use of heat treatments that may have destroyed spores of nonproteolytic *C. botulinum*, and a failure to distinguish between proteolytic *C. botulinum* and nonproteolytic *C. botulinum*. The overall picture, however, is that proteolytic *C. botulinum* and nonproteolytic *C. botulinum* are ubiquitous in the environment, although generally present at a low spore concentration. From the summary presented in Figure 2, the most frequently reported spore concentration is in the range of 11–100 spores per kg. Occasionally, however, higher concentrations of spores will be found, and very occasionally much higher concentrations will be present. In view of the severity of foodborne botulism, the approach taken is to assume that a high concentration of spores will be present, and to deliver an appropriate control process to the food.

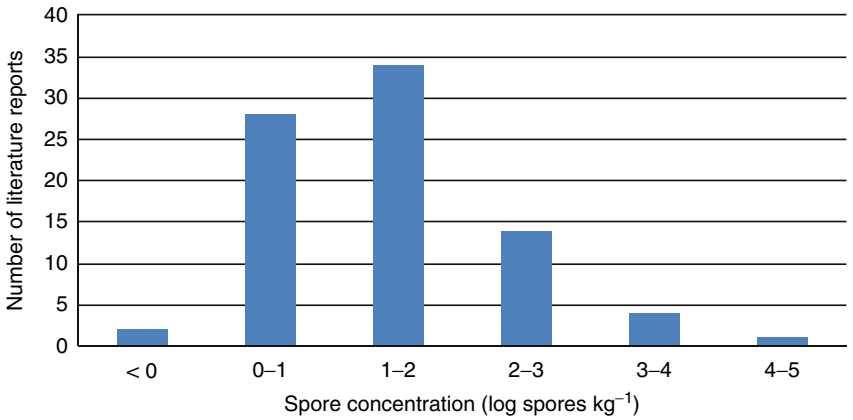

Figure 2 Summary of literature reports on the incidence of *C. botulinum* spores in the environment.

Quantitative microbiological risk assessments have been developed for a number of products. Because proteolytic *C. botulinum* and nonproteolytic *C. botulinum* are physiologically distinct it is necessary to apply different control processes (either single factors or combinations of factors) to prevent growth and neurotoxin formation by these two pathogens. It is estimated that in the USA, each case of foodborne botulism associated with a commercial product costs $30 million, at least three orders of magnitude greater than that for a case of listeriosis or salmonellosis.

Control of Proteolytic *C. botulinum* in Food Processing Operations

Proteolytic *C. botulinum* produces spores of high heat resistance and is the principal concern for the safe production of low acid canned foods. A heat treatment at 121.1 °C for 3 min has been adopted as the minimum standard for a botulinum cook for canned foods. This heat treatment (the botulinum cook) is intended to deliver a safety factor of at least 10^{12} (12-D (12-decimal) process) with respect to spores of proteolytic *C. botulinum*, and its use has ensured the safe production of low acid canned foods over many decades. Botulism outbreaks have occurred only when the full heat treatment has not been appropriately delivered or there has been postprocess contamination. Other controlling factors include storage at less than 10–12 °C, pH < 4.6, or by ≥ 10% NaCl. The use of other factors and combinations of factors to control or prevent growth of proteolytic *C. botulinum* has been described, and predictive models have been developed.

Control of Nonproteolytic *C. botulinum* in Food Processing Operations

Spores of nonproteolytic *C. botulinum* are much less heat resistant than those of proteolytic *C. botulinum*, and are therefore readily killed by the botulinum cook given to low acid canned foods. Various single and combinations of control factors have been identified to prevent growth and neurotoxin formation by nonproteolytic *C. botulinum*, and predictive models have been developed. Sales of minimally heated refrigerated foods (variously known as refrigerated processed foods of extended durability (REPFEDs), cook–chill foods and ready meals) are increasing by approximately 10% per annum in many countries. These foods receive a minimal heat treatment (typical maximum of 70–95 °C) and are not therefore sterile, and are stored under refrigeration (typically ≤ 8 °C). They can be packed under a modified low oxygen atmosphere or vacuum, but even when packed in air the foods themselves are likely to be highly reduced (enabling growth and neurotoxin formation). For some foods, intrinsic/extrinsic factors may also contribute to product safety. The UK Advisory Committee on the Microbiological Safety of Food (ACMSF) has made recommendations on the safe production of vacuum and modified atmosphere packed chilled foods with respect to *C. botulinum* and the associated foodborne botulism hazard. It is recommended that the heat treatments or combination processes deliver a safety factor of 10^6 (a 6-D process) with regard to spores of nonproteolytic *C. botulinum*. The recommended safety factors are as follows:

1. storage at < 3.0 °C;
2. storage at ≤ 8 °C and a shelf-life of ≤ 10 day;
3. storage at chill temperature (specified as ≤ 8 °C in England and Wales) combined with heat treatment of 90 °C for 10 min or equivalent lethality (e.g., 80 °C for 129 min, 85 °C for 36 min);
4. storage at chill temperature combined with ≤ pH 5.0 throughout the food;
5. storage at chill temperature combined with a salt concentration ≥ 3.5% throughout the food;
6. storage at chill temperature combined with ≤ a_w 0.97 throughout the food;
7. storage at chill temperature combined with a combinations of heat treatment and other preservative factors, which can be shown consistently to prevent growth and neurotoxin production by *C. botulinum*.

Emerging Issues: The Continued Control of Proteolytic *C. botulinum* and Nonproteolytic *C. botulinum* in Food Processing Operations

In view of the severity of foodborne botulism, vigilance is needed to ensure that proteolytic *C. botulinum* and nonproteolytic *C. botulinum* do not become emerging pathogens. The correct application of known control measures in the home and in the commercial setting is essential for the prevention of botulism, and there have been many botulism outbreaks across the globe where such control measures have not been effectively applied. One example is the home and commercial canning of foods, where a failure to apply the botulinum cook has led to botulism outbreaks in many countries. There is, therefore, a need for improved training and education of food handlers to ensure that known control measures are effectively implemented. It is also important that proteolytic *C. botulinum* and nonproteolytic *C. botulinum* are controlled as new foods (e.g., minimally heated refrigerated foods) are developed and new food processes are applied (e.g., high hydrostatic pressure). Climate change may provide new niches and opportunities for the multiplication of proteolytic *C. botulinum* and nonproteolytic *C. botulinum* in the environment, and present new challenges with respect to controlling growth and neurotoxin formation in food. The increased movement of people, and raw materials and foods (through trade globalization) may also bring an increased risk. There is also the need to be alert to the potential transfer, either naturally or deliberately, of botulinum neurotoxin genes to other bacteria, and to the deliberate introduction of botulinum neurotoxin or neurotoxigenic clostridia into the food chain through a bioterrorism act.

BACTERIA

Clostridium perfringens

S Robertson, J Li, and BA McClane, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Glossary

Claudins Major constituents of tight junctions. There are 24 different claudins currently recognized. These ~22 kDa proteins have four transmembrane domains and two extracellular loops. They polymerize into strands and are critical for tight junction structure and function.

***D* value** Time a bacterial culture or spores must be held at a given temperature to reduce viability by one log.

Multilocus sequence typing (MLST) analysis A molecular biology technique for characterizing the relatedness of different strains of a bacterial species. It involves comparing the DNA sequences of internal sequences of multiple housekeeping genes and then using that information to differentiate strains based upon their allelic variations.

Sigma factor Protein that binds to RNA polymerase that provides promotor specificity.

Small acid soluble protein Produced by sporulating cells of both *Clostridium* and *Bacillus* spp. These small proteins bind to, and protect, DNA in spores. They are important contributors to the resistance properties of bacterial endospores. They are also degraded during germination, where they can provide amino acids and energy for germinating cells. *Clostridium perfringens* produces at least four different small acid soluble proteins.

Tight junction Also known as the zonula occludens, this is a region where membranes of two adjacent mammalian epithelial or endothelial cells interact to form a seal. Tight junctions are comprised of protein strands and possess both fence and gate properties. They are 'fences' that prevent nonregulated passage of fluids between cells and maintain polarity differences between the apical and basolateral cell surface. However, they also have 'gate' functions that regulate the paracellular permeability between two adjacent cells.

Historical Background

Clostridium perfringens was first associated with food poisoning in 1945. However, its well-deserved prominence as a major foodborne pathogen was firmly acquired following the classic report by Hobbs in 1953 describing *C. perfringens* (then *Clostridium welchii*) type A food poisoning. Another key development in understanding *C. perfringens* type A food poisoning occurred in the early 1970s, when the *C. perfringens* enterotoxin (CPE) responsible for causing the gastrointestinal (GI) symptoms of this food poisoning was identified, purified, and characterized. Since that time, extensive studies have provided insights into the action and genetics of CPE, as well as factors contributing to the resistance properties of *C. perfringens* type A food poisoning isolates.

Characteristics

Clostridium perfringens is a rod-shaped, encapsulated, endospore-forming, gram-positive bacterium. This bacterium is classified as an anaerobe because it does not produce colonies on agar plates exposed to air; however, compared to many other anaerobes, *C. perfringens* is relatively aerotolerant. It grows when provided a low oxidation–reduction potential (E_h) environment, which can be influenced by environmental factors such as pH. *Clostridium perfringens* also produces reducing molecules such as ferredoxin that modify the environmental E_h to create favorable growth conditions. The E_h of common foods such as raw meats, poultry, seafoods, or their derivative products like gravy or stews is sufficient to support *C. perfringens* growth.

Clostridium perfringens has an extremely short generation time, with some food poisoning strains (as described later) capable of doubling in ~10 min at the optimum growth temperature of 43 °C. This rapid growth can contribute to foodborne illness by facilitating the presence of large numbers of vegetative cells in precooked food products following spore germination. In addition, some food poisoning strains can grow slowly at temperatures >50 °C, which confirms the importance of rigid adherence to temperature control guidelines (discussed later) for food preparation and holding.

The virulence of *C. perfringens* is largely dependent upon toxin production, with 17 different *C. perfringens* toxins reported in literature. However, individual isolates of this bacterium never produce all these toxins, forming the basis for a classification scheme used to assign *C. perfringens* isolates into one of five types (A–E) based upon their production of five typing toxins (Table 1). As implied by its name, *C. perfringens* type A food poisoning almost always involves type A isolates.

However, it is important to appreciate that only a small proportion of type A isolates, i.e., the <1–5% of isolates producing CPE, can cause *C. perfringens* type A food poisoning. Although rare in developed countries (and thus only briefly discussed in this article), beta toxin-producing *C. perfringens* type C isolates can cause a foodborne disease named enteritis necroticans, also known as Pigbel.

Amongst *cpe*-positive type A isolates, the *cpe* gene encoding the enterotoxin can be either chromosomal or carried on large plasmids. Importantly, ~75–80% of *C. perfringens* type A food poisoning isolates in the USA and Europe carry a chromosomal *cpe* gene. Type A plasmid *cpe* isolates may be somewhat more important for food poisoning in Japan compared to the USA or Europe, perhaps due to differences in food preparation and consumption.

The association between type A chromosomal *cpe* isolates and food poisoning, particularly in the USA and Europe, does not involve these isolates producing a CPE variant or a greater amount of CPE compared to plasmid *cpe* isolates. Instead, this association likely involves, in part, the spores and vegetative cells of most *C. perfringens* type A chromosomal *cpe* food poisoning isolates possessing considerably greater resistance against food environment stresses such as heat, cold, osmotic pressure, pH, and chemical preservations, for example, nitrites (Table 2). For example, the spores of type A chromosomal *cpe* food poisoning isolates possess, on average, approximately 60-fold-higher *D* values at 100 °C compared to spores made by either type A plasmid *cpe* isolates or *cpe*-negative *C. perfringens* strains (Table 2). These vegetative cell and spore resistance properties of chromosomal *cpe* isolates should favor their survival in foods, so they can later cause food poisoning.

Small acid soluble proteins (Ssps) contribute to spore resistance properties by binding to, and thus protecting, DNA inside bacterial spores. The strong spore resistance properties exhibited by most type A chromosomal *cpe* food poisoning isolates are attributable, in part, to the ability of these strains to express a variant of a small acid soluble protein named Ssp4 (Table 3). *Clostridium perfringens* type A food poisoning strains produce a variant Ssp4 with an Asp at residue 36, whereas this Ssp4 residue is a Gly in *C. perfringens* strains producing sensitive spores. At least in part, the Asp variant Ssp4 is more protective for the environmentally resistant spores made by most food poisoning strains because it binds more tightly to spore DNA compared to the Gly Ssp4 variant made by those *C. perfringens* isolates producing environmentally sensitive spores. Additional factors are also likely to contribute to the exceptional spore resistance properties of chromosomal *cpe* isolates. For example, the spore core is smaller in type A chromosomal *cpe* isolates compared to other *C. perfringens* isolates. Differences in concentrations of DPA and metal ions, density of the spore core, and protoplast-to-sporoplast ratios may also contribute to the unusual spore heat resistance properties of chromosomal *cpe* isolates.

Other factors besides stress resistance probably also contribute to the strong association between type A chromosomal *cpe* isolates and food poisoning. For example, between 25 and 43 °C, chromosomal *cpe* isolates grow faster than either type A plasmid *cpe* isolates or type A *cpe*-negative isolates. Their faster growth, which (as mentioned) includes a generation time of only ~10 min at 43 °C, likely allows type A chromosomal *cpe* strains to more quickly reach pathogenic levels in foods compared to type A plasmid *cpe* isolates. In addition, relative to other *C. perfringens* isolates, type A chromosomal *cpe* isolates can grow at higher maximum (53.3 °C ± 0.7 °C) and lower minimum temperatures (12 °C ± 1.9 °C), which may facilitate the ability of the chromosomal *cpe* isolates to multiply in temperature-abused foods. However, no *C. perfringens* isolates grow at 6 °C or less, supporting the importance of storing food at proper refrigeration temperatures in order to prevent *C. perfringens* food poisoning outbreaks (further discussion later).

These growth differences suggest there are considerable variations between the genetic backgrounds of type A chromosomal *cpe* isolates versus other *C. perfringens* isolates, including type A isolates carrying a plasmid-borne *cpe* gene. This conclusion is supported by multilocus sequence typing (MLST)

Table 1 Toxin type classification of *C. perfringens* isolates

Type/Toxin	*Alpha*	*Beta*	*Epsilon*	*Iota*
Type A	+	−	−	−
Type B	+	+	+	−
Type C	+	+	−	−
Type D	+	−	+	−
Type E	+	−	−	+

SM101::*ssp4*(pJIR751)	9.3	3.8	1.03	1.86

[a]The designation '::*ssp4*' indicates a null mutant unable to produce Ssp4. SM101 is a chromosomal *cpe* food poisoning isolate and F4969 is a plasmid *cpe* isolate.
[b]pCS is a complementing plasmid encoding the Asp36 Ssp4 variant of SM101.
[c]pCF is a complementing plasmid encoding the Gly36 variant of F4969.
[d]pJIR751 is the empty shuttle vector (no *ssp4* insert).

approaches, indicating that, regardless of their geographic origin, date of isolation, or isolation source, type A chromosomal *cpe* isolates show considerable genetic relatedness to one another. However, compared to other *C. perfringens* isolates, chromosomal *cpe* isolates possess a distinct genetic background. The chromosomal *cpe* gene of type A isolates is associated with a putative transposon. Therefore, it is possible that type A chromosomal *cpe* food poisoning isolates have resulted from integration of a transposon (carrying the *cpe* gene) onto the chromosome of a unique *C. perfringens* progenitor cell whose vegetative cells and spores already possessed numerous favorable traits for growth and survival in the food environment.

Epidemiology

Clostridium perfringens has a widespread distribution in soil, feces, and the GI tract of humans and other animals, which provides this bacterium with ample opportunities to contaminate food. However, the specific reservoir remains uncertain for the type A chromosomal *cpe* isolates, which most commonly cause food poisoning. These bacteria are not usually found in soil or on home kitchen surfaces and are only infrequently present in healthy human carriers and sewage. However, they can be present in raw meats and seafood by the time of retail purchase (discussion later).

Recent statistics from the US Centers for Disease Control indicate that *C. perfringens* currently ranks as the second most common cause of bacterial foodborne disease in the USA. Estimates indicate that one million Americans become ill with *C. perfringens* type A food poisoning each year, resulting in approximately 10 deaths (typically in the elderly) and economic losses exceeding $200 million dollars. This food poisoning is also the second most commonly identified bacterial foodborne illness in the UK and Australia. Further supporting its worldwide importance, *C. perfringens* has been responsible for ~20% of all foodborne disease outbreaks in Finland and for at least 4000 cases of Japanese foodborne illness each year.

Typically, *C. perfringens* type A food poisoning outbreaks are large (average 50–100 people) and occur in institutionalized settings. *Clostridium perfringens* type A food poisoning occurs throughout the year, but is somewhat more common during the summer. It typically results from temperature abuse during food holding, storage, or cooking. Although rare outbreaks involving only vegetables have been reported, the most common food vehicles include meats, particularly beef and poultry, or meat-containing foods such as stews and gravies.

Surveys have detected *C. perfringens* in 70% of Japanese raw retail meats and in 30–80% of American raw retail meats or seafood. Of more direct relevance for understanding the epidemiology of *C. perfringens* type A food poisoning, ~0.5% or ~3% of Japanese raw meats or American raw meats/seafood, respectively, are reportedly contaminated with *cpe*-positive type A *C. perfringens* strains at the time of retail purchase. Those potentially enterotoxigenic strains are most commonly present in turkey, chicken, pork/pork products, beef, and fish, all of which are known vehicles for *C. perfringens* type A food poisoning. CPE-producing type A strains have also been found in spices, which thus represent another potential source of food contamination.

The strong association between *C. perfringens* type A food poisoning and meats or meat products could be attributable, in part, to *C. perfringens* requiring several presynthesized amino acids for growth that may be supplied by meats. Another possible explanation for the association between meats and *C. perfringens* type A food poisoning is the common presence of this bacterium in the intestinal tract of food animals, which might foster meat contamination at the time of slaughter.

Clinical Manifestation (Disease)

As shown in Figure 1, *C. perfringens* type A food poisoning typically begins with the ingestion of foods contaminated with

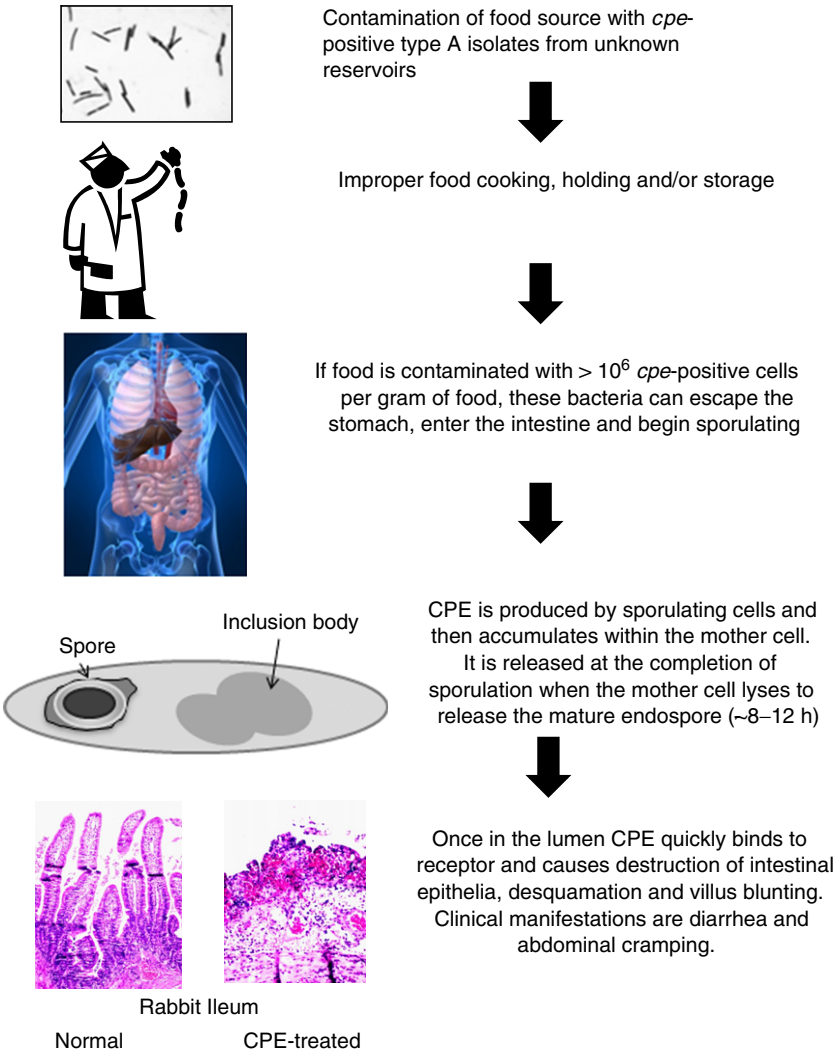

Figure 1 An overview of *Clostridium perfringens* type A food poisoning.

large numbers of vegetative cells of a type A chromosomal *cpe* strain. The infectious dose requires ingestion of $>10^6$–10^7 vegetative cells of a *cpe*-positive isolate/gram of contaminated food.

Following ingestion of a contaminated food, many vegetative cells are destroyed by exposure to gastric acid. However, when the contamination burden is sufficiently high (see preceding paragraph), some vegetative cells survive to escape the stomach. Once present in the small intestine, these vegetative cells initially multiply. During this *in vivo* multiplication, the short doubling times of the chromosomal *cpe* isolates likely contribute to the intestinal presence of large numbers of these bacteria.

After stimulation by various factors, probably including stomach acids and intestinal bile salts, the vegetative cells begin sporulating in the small intestine. It is during this *in vivo* sporulation that *cpe*-positive *C. perfringens* strains produce CPE. Production of CPE is regulated by the master sporulation regulator Spo0A, along with several alternative sigma factors. One of these alternative sigma factors, SigF, apparently directs the production of two other sigma factors named SigK and SigE. Interaction of SigE and SigK with RNA polymerase then drives CPE expression from three SigE- or SigK-dependent promoters located upstream of the *cpe* gene. The presence of multiple *cpe* promoters likely helps to explain why some *cpe*-positive strains produce very high levels of the enterotoxin, i.e., CPE can represent up to 20% of total protein inside some sporulating *C. perfringens* cells. After expression, CPE is not secreted but instead accumulates inside the mother cell. It is eventually released into the intestinal lumen when the mother cell lyses to release the mature endospore.

Once present in the intestinal lumen, CPE rapidly binds to receptors (discussed later) and damages the intestinal epithelium. Figure 1 shows an example of CPE-induced desquamation of the intestinal epithelium in animal models. This damage is apparently required to obtain the fluid and electrolyte losses that present clinically as diarrhea during *C. perfringens* food poisoning. Typically, symptoms of

C. perfringens type A food poisoning are relatively mild and self-resolving and include, besides diarrhea, abdominal cramps. These symptoms usually develop within 8–22 h of ingestion of contaminated foods. This incubation period roughly corresponds to the time needed for completion of *in vivo* sporulation and subsequent lysis of the mother cell to release CPE into the lumen. Illness is then usually resolved within 24 h. There are unusual reports of some patients having less severe symptoms lasting for up to 2 weeks. Fatalities are not common in the young and healthy but can occur in the elderly and physically debilitated due to secondary complications from dehydration. *Clostridium perfringens* type A food poisoning cannot be readily spread person-to-person because the doses required to initiate disease are so large.

It is sometimes incorrectly claimed that *C. perfringens* type A food poisoning is an intoxication. However, there is only one documented case involving disease following ingestion of preformed CPE toxin, in contrast to the many intoxication cases involving foodborne botulism. Furthermore, although ingestion of purified CPE by human volunteers can reproduce all the effects caused by the natural disease, those people had to consume very large amounts of toxin plus sodium bicarbonate to neutralize stomach acidity.

As mentioned, *C. perfringens* type A food poisoning cases usually resolve with little to no long-term complications. In fact, due to the relatively mild symptoms typical of the disease, it is believed that most cases of this disease go undiagnosed. Many Americans and Brazilians were shown to have detectable levels of serum IgG against CPE, supporting a high prevalence for this food poisoning. However, there is no evidence to suggest that previous exposure provides any substantial protection against future disease.

Although cases of *C. perfringens* type A food poisoning are rarely fatal in younger or middle-aged healthy individuals, in November 2001 an unusually severe outbreak of this food poisoning occurred in an Oklahoma residential care facility for the mentally ill. Seven residents of this institution, with an average age of 50 years old, became ill within 18 h after consuming a Thanksgiving meal. All of these people displayed classical *C. perfringens* type A food poisoning symptoms, including diarrhea and abdominal cramping, with some also experiencing vomiting and fever. Three of the ill people developed necrotizing entertitis, which proved fatal in two patients. Until this *C. perfringens* type A food poisoning outbreak in Oklahoma, necrotizing enteritis (or enteritis necroticans) caused by *C. perfringens* had only been associated with beta toxin-producing *C. perfringens* type C isolates. For comparison, foodborne enteritis necroticans caused by type C strain is much more severe than typical cases of type A food poisoning, with symptoms including abdominal pain, bloody diarrhea, vomiting, and obstruction of intestinal mucosa. Patients with severe cases of enteritis necroticans require prompt surgery or the illness can be fatal.

In the Oklahoma mental institution outbreak, several laboratory findings support the involvement of *C. perfringens* type A food poisoning. First, multiplex PCR identified *cpe*-positive type A isolates obtained from the cultured stools of the infected patients. Second, Western blotting confirmed the expression of CPE. Finally, immunohistochemistry demonstrated CPE binding to colonic epithelium in one of the 2 patients who died (the second patient's epithelium was completely destroyed).

In addition to involving necrotizing enteritis caused by *cpe*-positive type A isolates, the other unusual feature of the Oklahoma food poisoning outbreak was that the deceased patients were relatively young and physically healthy. However, the psychiatric drugs administered to these patients appeared to be a contributing factor to disease severity. Side effects of those drugs include constipation and fecal impaction, which interfere with the traditional course of *C. perfringens* type A food poisoning, where diarrhea flushes CPE from the intestine. Thus CPE, and possibly other toxins made by *cpe*-positive strains of *C. perfringens*, remained in contact with the intestinal mucosa for much longer than usual, causing greater damage that produced necrosis of the colonic tissue.

Recently, i.e., May 2010, another *C. prefringen*s food poisoning outbreak occurred at a Louisiana mental hospital. This outbreak involved 40 patients, leading to three fatalities. Chicken salad contaminated with *C. perfringens* was suggested as the potential food vehicle. Interestingly, the severity of this Louisiana mental hospital outbreak is reminiscent of the 2001 Oklahoma mental hospital outbreak, suggesting an emerging linkage between severe *C. perfringens* type A food poisoning outbreaks and mental institutions.

CPE Causes the Symptoms of *C. Perfringens* Type A Food Poisoning

Compelling evidence indicates that CPE is responsible for the symptoms of *C. perfringens* type A food poisoning. For example, when promptly tested, CPE can be detected in the feces of nearly all *C. perfringens* type A food poisoning victims, although this toxin is not found in the feces of healthy people. Also, the levels of CPE present in feces of food poisoning victims are often similar to CPE concentrations known to cause GI disease in animal models. Third, *cpe*-positive type A strains of *C. perfringens* are substantially more pathogenic than CPE-negative type A strains in animal models. Finally, molecular Koch's postulates approaches showed that CPE expression is essential for a type A chromosomal *cpe* food poisoning isolate to cause GI effects in rabbit ileal loops.

CPE Protein

CPE, a single polypeptide of ~35 kDa, has a relatively unique 319 amino acid sequence, sharing only a limited region of homology with a nontoxic protein produced by *Clostridium botulinum*. The C-terminal half of CPE possesses receptor-binding ability and shares some structural resemblance to the receptor-binding regions of the Cry family of insecticidal toxins produced by *Bacillus thuringiensis*. The N-terminal half of CPE is important for cytotoxicity because it possesses regions involved in complex formation (see CPE Mechanism of Action) and toxin insertion into membranes. The extreme N-terminal sequences of CPE may be removed by intestinal proteases during disease, which may activate CPE toxicity by 2- to 3-fold. Recent structural biology studies identified CPE as a member of the aerolysin pore-forming toxin family.

CPE Mechanism of Action

The preferred animal model to study CPE action is the rabbit, although CPE affects all mammalian species thus far examined. The rabbit small intestine, and in particular the ileum, is very sensitive to the enterotoxin, resulting in fluid and electrolyte losses. In the ileum, CPE rapidly induces histopathological damage with epithelial desquamation and villus shortening. This intestinal damage appears to be necessary to obtain intestinal fluid and electrolyte loss. It may also alter paracellular permeability to further increase the fluid secretion that presents clinically as diarrhea. Electron microscopy studies of rabbit intestinal epithelial cells have shown that CPE specifically causes rapid and extensive damage to intestinal brush border membranes. *In vitro*, high CPE doses cause cell death via oncosis, opening the possibility that inflammatory cytokines may also contribute to intestinal disease in some cases of *C. perfringens* type A food poisoning.

CPE action at the cellular level is overviewed in Figure 2. This process begins when the enterotoxin binds to certain claudins, which are a 24 member family of ~22 kDa proteins found in mammalian tight junctions. At physiologically relevant concentrations, CPE has been reported to bind only to claudins 3, 4, 6, 8, and 14. This binding involves interactions between a loop in the C-terminal half of CPE and residues present in the second extracellular loop of claudin receptors. Recent studies implicate an asparagine residue in the second extracellular loop of claudin receptors as being particularly important for CPE binding.

Binding of CPE to claudin receptors initially results in the formation of an SDS-sensitive small (~90 kDa) CPE-containing complex that localizes on the membrane surface. However, formation of this ~90 kDa complex is not sufficient for cytotoxicity. For example, at 4 °C CPE forms this small complex in cultured cells although no cytotoxicity develops.

At physiological temperatures formation of the small CPE complex is only transitory. This complex is thought to rapidly oligomerize with other small complexes to form a larger (~450 kDa) CPE-containing complex. This ~450 kDa large complex is referred to as CPE hexamer-1 or CH-1 because it contains six CPE molecules. The size of CH-1 also reflects the presence of both claudin receptors and claudins incapable of functioning as CPE receptors. The association of nonreceptor claudins with CH-1 is likely attributable to natural claudin:-claudin interactions that occur in plasma membranes. This natural clustering of claudins, including claudin receptors, in plasma membranes may explain why CPE does not need to use lipid rafts for oligomerization.

CH-1 is believed to initially assemble as a prepore on the plasma membrane surface of enterocytes before it inserts into the membrane to form an active pore. The presence of the active CH-1 pore then results in membrane permeability alterations that allow an influx of small molecules, such as ions, into the cytoplasm of host cells. The influx of calcium then triggers cell death via apoptosis (at low CPE doses) or oncosis (at high CPE doses). These alterations also cause morphologic alterations to the cell that disrupt tight junctions and allow CPE access to the basolateral side of the cell, where even more claudin receptors are present than on the apical cell surface. Besides resulting in formation of additional amounts of CH-1 complex, exposure of the basolateral

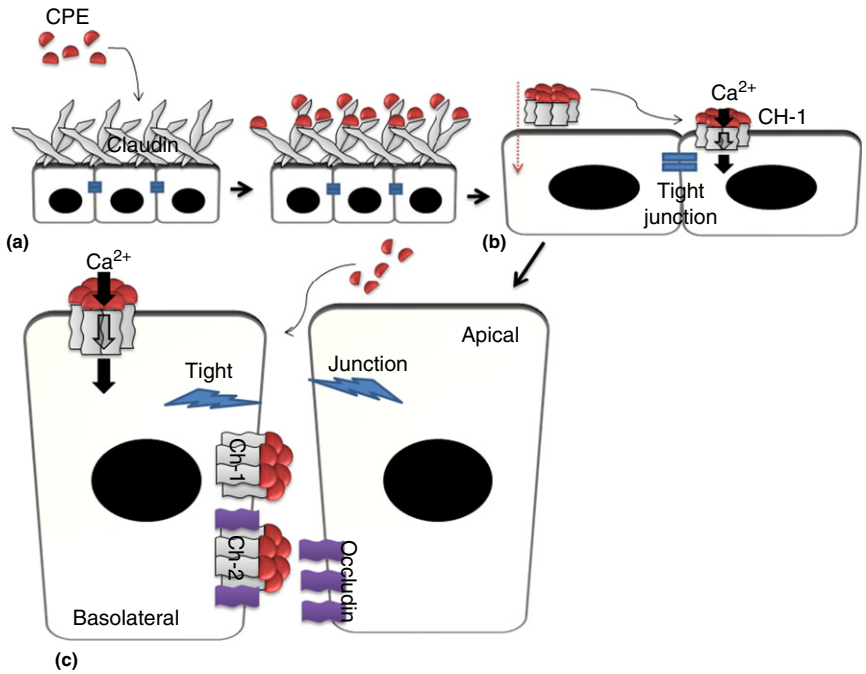

Figure 2 CPE mode of action. (a) CPE binds to claudin receptors on the apical surface of epithelial cells, forming a small ~90 kDa complex. (b) The small complex rapidly oligermerizes to form the ~450 kDA CPE hexamer-1 or CH-1. This hexamer inserts into the cell membrane, forming a pore through which small ions gain access to the cell. (c) This pore causes cell permeability changes leading to cell death. Additionally the tight junctions are disrupted, so free CPE can gain access to the basolateral side, where it can bind more claudin, forming small complex to form more CH-1. A second large CPE complex of ~600 kDa, referred to as the CH-2, now also forms and contains occludin.

cell surface also allows CH-1 access to another tight junction protein named occludin. This results in formation of a second large complex of ~600 kDa, which is termed CH-2 or CPE hexamer 2. Besides containing CPE and claudins, CH-2 also contains occludin. A consequence of CH-1 and CH-2 formation is the internalization of claudins and occludin, which might cause paracellular permeability alterations that contribute to diarrhea.

In summary, CPE is a unique bacterial toxin in many respects. Besides possessing a relatively unique primary sequence, this pore-forming toxin does not require lipid rafts for oligomerization. CPE is also an unusual toxin by remaining closely associated with claudin receptors throughout the pore formation process. Beyond pore formation, CPE may possess a second action, i.e., disruption of tight junctions, which could also contribute to disease.

Analytical Methods for *C. Perfringens* and CPE

Clostridium perfringens type A food poisoning outbreaks have traditionally been diagnosed by demonstrating the presence of large numbers of *C. perfringens* in feces of food poisoning victims or in food vehicles. However, this approach has significant limitations because, for example, feces from some healthy elderly people already contain very high numbers of (*cpe*-negative) *C. perfringens*. A more meaningful diagnostic approach is to demonstrate the specific presence of large numbers of *cpe*-positive *C. perfringens* cells or spores in food vehicles or the feces of food poisoning victims. Because *cpe*-positive strains can also cause other GI diseases, such as antibiotic-associated diarrhea, it is important to consider positive detection of *cpe*-positive isolates in feces within the full epidemiologic context, i.e., is the fecal specimen from a point source foodborne disease outbreak? If so, do the symptoms, incubation time, and duration of the outbreak correspond to those of a typical *C. perfringens* type A food poisoning outbreak? Are there also *cpe*-positive isolates present in the suspected food vehicle? An alternative approach for identifying a *C. perfringens* type A food poisoning outbreak is to demonstrate the presence of CPE in feces of food poisoning victims using commercially available serologic testing kits. This method is most reliable when feces are collected soon after the onset of diarrhea, the time when fecal CPE levels are maximal. However, as stated above for the detection of *cpe*-positive cells in feces of food poisoning victims, positive detection of CPE should also be considered within an epidemiologic context.

Beyond these basic diagnostic approaches, many tools are now available for more detailed epidemiologic studies of *C. perfringens* type A food poisoning. Selective plating methods are available to isolate *C. perfringens* from food, slaughterhouses, soil, sewage, aquatic environments, domestic or commercial kitchens, or human feces. However samples usually should first be enriched for the presence of vegetative cells and spores before plate counts being made for enumeration. An example of isolation and identification of *C. perfringens* type A from food sources has been described by Wen and McClane. A suspected food source is homogenized and aliquots are added to 10 ml tubes of sterile FTG medium. To enrich for samples containing *C. perfringens* spores, one of these tubes is heat shocked at 72 °C for 20 min before a subsequent incubation at 37 °C for 18–24 h. A second tube is grown for the same time period at 37 °C to enrich for *C. perfringens* vegetative cells. Enrichment cultures are then streaked onto TSC plates with egg yolk. Those plates are then anaerobically incubated for ~18 h at 37 °C. Colonies are presumptively *C. perfringens* if they show lecithinase activity on the egg yolk agar. The identity of these colonies can be confirmed using standard methods outlined by the FDA. This approach also provides isolated colonies to perform multiplex PCR to identify toxin type and *cpe* carriage. When *cpe*-positive isolates are identified, a duplex PCR can also be performed to determine whether the *cpe* gene is chromosomal or plasmid. The isolates can be inoculated into sporulation media and, if sporulation is achieved, CPE production can be demonstrated by Western immunoblotting. These assays are described more in detail in the following paragraphs.

The levels of *C. perfringens* per gram of food can be approximated by determining the most probable number (MPN). A 10 g aliquot of a food suspension is diluted in 10 fold increments and those dilutions are each inoculated into 3 tubes containing differential reinforced clostridial broth medium (DRCM), followed by overnight incubations at 37 °C. Cultures that form a black precipitate in the DRCM are considered presumptively positive for *C. perfringens* and results are used to calculate the MPN, as described by Wen and McClane.

A multiplex PCR assay can assign *C. perfringens* isolates to one of five types, A–E, and determine whether an isolate is *cpe*-positive. DNA template is prepared from an isolated colony by suspending it in PBS. After microcentrifugation, the bacteria are resuspended in PCR-quality water and then lysed by microwave. The resulting supernatant is used as the template. PCR analysis is carried out using primers that amplify sequences found in genes encoding alpha toxin (*cpa*), beta toxin (*cpb*), beta-2 toxin (*cpb2*), epsilon toxin (*etx*), CPE (*cpe*), or the A component of iota toxin (*iap*). PCR products are electrophoresed on 2% agarose and visualized by ethidium bromide staining.

To determine whether a *cpe*-positive *C. perfringens* type A isolate carries a chromosomal *cpe* locus or a plasmid *cpe*, a duplex PCR assay can be used, as described by Wen and McClane. For this assay, *cpe*-positive isolates are inoculated into TGY medium and then grown overnight at 37 °C. Genomic DNA is extracted from that culture, as described above, and subjected to PCR using primers that amplify a 2.1 kb product when the *cpe* gene is chromosomal, but a 3.3 kb product from type A isolates carrying most *cpe* plasmids.

CPE Western immunoblotting can be used to determine if a *cpe*-positive isolate can express the enterotoxin. FTG cultures of the *cpe*-positive isolate are inoculated into Duncan-Strong sporulation medium and then incubated at 37 °C for ~8 h or until spores are present. Cultures are then sonicated until >95% of the cells are lysed. The lysate is then subjected to electrophoresis and detection of CPE expression by Western Blot. A limitation of this approach is that not all *cpe*-positive isolates form spores when grown *in vitro*, as required for CPE expression.

Table 4 Examples of some recent *C. perfringens* type A food poisoning outbreaks

Outbreak location	*Food vehicle*	*Persons ill*	*Food handling error*
#1, UK	Chicken curry	73	Inadequate temperature and time control during food preparation and storage
#2, Japan	Braised chop suey (contains pork, seafood, and vegetables)	81	Inadequate temperature control during holding
#3, UK	Chicken and lamb	93	Inadequate temperature control during food handling
#4, USA	Turkey	~60	Inadequate temperature and time control during cooking food storage
#5, USA	Casserole (contained noodles, ground beef, ground turkey, and vegetables)	>100	Inadequate temperature and time control during cooking food storage

Control and Preventative Measures

Clostridium perfringens has ample opportunity to contaminate food because it is widely distributed throughout the natural environment, being found in 75% of soil samples (at levels ranging from 10^3 to 10^4 CFU g^{-1}), in sewage, and (at numbers up to 10^6 CFU g^{-1}) in the GI tract of some healthy livestock and humans. However, as mentioned earlier, the reservoir is not clear for the <5% of all *C. perfringens* type A isolates that possess a chromosomal *cpe* gene, which are the strains causing most cases of food poisoning. Nevertheless, as mentioned, by the time of retail purchase, approximately 0.5–3% of raw retail meats are already contaminated with type A chromosomal *cpe* isolates. Because it is not yet known when food poisoning strains enter the food supply from their (still unidentified) reservoir, it is currently difficult to rationally interfere with the presence of these bacteria in foods.

At present the best practical approach for controlling this food poisoning is provided by epidemiologic observations indicating that temperature abuse during the cooking, cooling, or handling of foods is the major contributor to *C. perfringens* type A food poisoning (Table 4). Temperature abuse is a particularly important factor considering the already-described impressive resistance properties possessed by the cells and spores of most type A food poisoning isolates. Thus, the best way to prevent *C. perfringens* type A food poisoning is rigid adherence to cooking regimens, holding of foods at >60 °C for serving, and rapid cooling of cooked meats for storage. To facilitate rapid cooling, foods should be distributed in small portions in shallow containers. It is also essential that refrigerators be functioning below 6 °C, because food poisoning isolates can grow at lower temperatures than other *C. perfringens* strains.

No vaccine has yet been developed to prevent this food poisoning due to its typical self-resolving nature. However, the noncytotoxic C-terminal fragment of the enterotoxin (C-CPE) has been shown to elicit antibodies capable of neutralizing native CPE. Therefore, C-CPE represents a potential vaccine candidate if ever needed.

Toxigenic Corynebacteria

AA Zasada, National Institute of Public Health – National Institute of Hygiene, Warsaw, Poland

Glossary

Internalization Transfer of molecules from the outside to the inside of a cell usually by phagocytosis.
Invasive infection/disease An infection/disease with the presence of bacteria in normally sterile anatomical sites.
Nontoxigenic (in this article) A strain of *Corynebacterium pseudotuberculosis*, *Corynebacterium ulcerans*, or *Corynebacterium diphtheriae* that does not produce diphtheria toxin.
Toxigenic (in this article) A strain of *C. pseudotuberculosis*, *C. ulcerans*, or *C. diphtheriae* producing diphtheria toxin.
Translocation Transfer of molecules through a membrane, for example a membrane of endosome.

Characteristics of the Genus

The genus *Corynebacterium* has been described as Gram positive (some strains appear Gram variable); straight-to-slightly curved rods with tapered ends; pleomorphic; asporogenous, nonmotile; nonacid fast; forms metachromatic granules; facultatively anaerobic, although some organisms are aerobic; catalase positive; and chemoorganotrophic.

Currently, the genus *Corynebacterium* comprises more than 80 recognized species. Only three of them are known to possess the potential to produce a lethal exotoxin, called diphtheria toxin. These are *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, and *Corynebacterium pseudotuberculosis*. The three species are closely related. The relationship is based on a similar morphology, cell wall composition, as well as 16S ribosomal ribonucleic acid (rRNA) gene sequences. All the three species differ from other corynebacteria by the presence of large amounts of fatty acids. Colonies of all the three species form gray–brown halos on Tinsdale medium, which identifies the production of cystinase, and are pyrazinamidase negative.

Biochemically, *C. ulcerans* and *C. pseudotuberculosis* can be distinguished from *C. diphtheriae* by urease production and the positive reverse CAMP test (the reverse CAMP test is a reaction whereby hemolysis by the *β*-hemolysin of staphylococci is inhibited through the production of phospholipase C or D by some organisms) (Table 1). Moreover, *C. ulcerans* ferments glycogen, starch, and trehalose.

On the basis of colonial morphology and biochemical properties, four biotypes of *C. diphtheriae* were identified: *gravis*, *mitis*, *intermedius*, and *belfanti*. On the Hoyle's tellurite agar, biotypes *mitis* and *belfanti* produce gray/black opaque colonies, 1.5–2.0 mm in diameter with an entire edge and glossy smooth surface. Variation in size is common. Biotype *gravis* produces dull, gray/black opaque colonies, 1.5–2.0 mm in diameter with a matt surface, friable, tending to break into small segments when touched with a straight wire. Colonies of biotype *intermedius* are small, gray/black, discrete, translucent, 0.5–1.0 mm in diameter with shiny surface. On blood agar, colonies of biotypes *mitis*, *intermedius*, and *belfanti* exhibit a small zone of *β*-hemolysis, whereas biotype *gravis* is usually nonhemolytic. Specific biochemical characteristics are presented in Table 1.

The Diphtheria Toxin

The diphtheria toxin is regarded as the main virulence factor of *C. diphtheriae*, *C. ulcerans*, and *C. pseudotuberculosis*. It is encoded by the *tox* gene. The gene is carried on a family of closely related corynebacteriophages of which the *β*-phage is the most extensively studied. The *β*-like phages are capable of integrating into the *Corynebacterium* chromosome during the lysogenic phase of the infective cycle. The integration can occur at two specific sites: *attB1* and *attB2*. The expression of *tox* in lysogens is regulated by the DtxR protein in response to the Fe^{2+} level. DtxR is a global regulator, chromosomally encoded by the *dtxR* gene. This protein regulates the expression of multiple genes involved in iron metabolism, protection against oxidative stress, and pathogenesis. In the absence of Fe^{2+}, apo-DtxR exists as an inactive monomer that is in weak equilibrium with a dimeric form. Once activated by Fe^{2+}, DtxR forms stable dimers, and two pairs of dimers have been shown to bind to almost opposite faces of the *tox* operator sequence. DtxR is composed of two major structural domains linked by a flexible tether containing a proline-rich region. The *N*-terminal domain contains the ancillary and primary metal ion-binding sites, a canonical helix-turn-helix deoxyribonucleic acid (DNA)-recognition motif, and an extensive hydrophobic surface necessary for the formation of stable dimers. After the DtxR dimers bind to the *tox* promoter, the transcription of *tox* promoter is repressed. When iron is in

limiting concentration, the uncomplexed form of DtxR is unable to bind DNA, leading to the induction of diphtheria toxin (Figure 1). Diphtheria toxin is composed of three domains: the catalytic domain, the transmembrane domain, and the receptor-binding domain. The catalytic domain is called fragment A, whereas the transmembrane- and the receptor-binding domains together are called fragment B. Fragment A with fragment B is connected by a disulfide bond. The catalytic domain is an *N*-terminal adenosine diphosphate (ADP)-ribosyltransferase. The transmembrane domain facilitates the delivery of the catalytic domain across the eukaryotic cell membrane. The receptor-binding domain binds to the receptor at the surface of the eukaryotic cell. The intoxication of a single eukaryotic cell is schematically presented in Figure 2. In the first step, the toxin binds to its cell surface receptor through its receptor-binding domain (fragment B). The complex is then internalized by receptor-mediated endocytosis. Both fragments A and B of the toxin unfold in response to low pH in the endosome, leading to the exposure of hydrophobic domains and an increased tendency to interact with the membrane lipids. In the next steps, the transmembrane domain is inserted into the membrane and the fragment A of the toxin is translocated across the membrane to the cytosol. The disulfide bond connecting fragment A and B is reduced. The final step is the translocation of the remainder of the fragment A to the cytosol, where it refolds. The catalytic domain (fragment A) of the toxin stops protein synthesis by inactivating elongation factor 2 via ADP ribosylation from NAD. The result is death of the cell.

Other Virulence Factors

Other Virulence Factors of *C. diphtheriae*

Toxigenic corynebacteria are well investigated with respect to toxin production, whereas little is known about the other virulence factors crucial for colonization of the host, invasion, and avoidance of the host immune system. Microbial factors that distinguish epidemic from endemic strains have not been

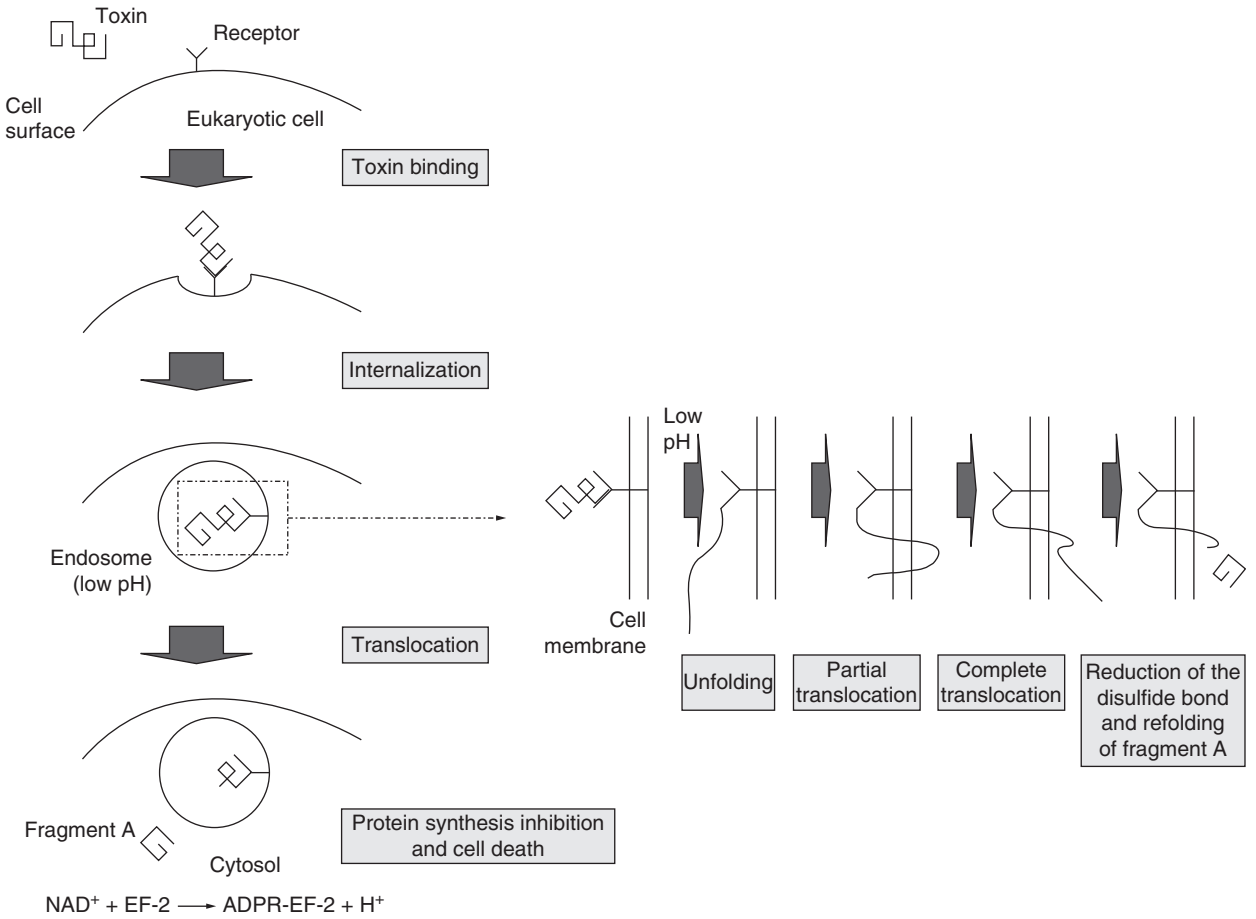

Figure 2 Model of diphtheria toxin action. Description in the text.

identified. The fact that specific epidemic clones are responsible for severe outbreaks of diphtheria with thousands of deaths in industrialized countries supports the argument that bacterial virulence factors, other than toxin, are important for their potential to cause human disease. The increasing frequency of cases of invasive disease, such as endocarditis, bacteremia, pneumonia, osteomyelitis, spleen abscesses, and septic arthritis, caused by nontoxigenic clones of *C. diphtheriae* also points the importance of other microbial factors.

In a few studies, mechanisms of adhesion, invasion, and intracellular survival of *C. diphtheriae* have been investigated. It has been shown that *C. diphtheriae* strains are not only able to adhere to laryngeal HEp-2 or pharyngeal Detroit 562 cells but also enter these cells and survive after the internalization. Although host cell receptors and invasion-associated proteins of the pathogen are still unknown, bacterial adhesion factors have been at least partially characterized recently on the molecular level. *Corynebacterium diphtheriae* is able to assemble at least three distinct types of pili on its surface. Mutant analysis have shown that the SpaA-type pilus is sufficient for adhesion to pharynx cells, shaft proteins are not crucial for pathogen–host interaction, and adherence to pharyngeal cells is greatly diminished when minor pili proteins SpaB and SpaC are lacking. However, the existence of additional proteins besides pili subunits involved in adhesion to larynx, pharynx, and lung epithelial cells have been demonstrated because a total loss of attachment to pharyngeal cells due to mutagenesis of pili- and sortase-encoding genes could not be observed and attachment to lung and larynx cells was less affected by the mutation. Moreover, the potential importance of hemagglutinins, exposed sugar residues, hydrophobins, and *trans*-sialidase enzymes in adhesion have also been revealed. It can be stated that adhesion is a multifactorial mechanism. Furthermore, three distinct patterns of adherence to HEp-2 cells have been described: an aggregative, a localized, and a diffuse form. These observations prove the existence of several adhesion factors and different receptors on the host cell surface. The involvement of different *C. diphtheriae* proteins to adherence to distinct cell types is further reported by the work on adhesion to human erythrocytes, showing that nonfimbrial surface proteins 67p and 72p are involved in this process. Besides different mechanisms of adhesion, growth-dependent effects have also been observed, for example, an effect of iron supply on hemagglutination and lectin-binding properties of *C. diphtheriae*.

Corynebacterium diphtheriae strains are able to produce siderophores and other iron-uptake mechanisms that allow them to express virulence factors, such as toxins and enzymes. Published results also imply regulation of adherence and

slime production as part of a global response to iron-limited environment conditions that includes derepression of genes for the synthesis of cytotoxin and siderophores and transport of the Fe(III)–siderophore complexes.

Interestingly, all genes encoding pili and adhesins as well as iron-uptake systems of *C. diphtheriae* are located in pathogenicity islands. Great heterogeneity in genome organization and in pathogenicity of *C. diphtheriae* have been shown. For example, comparison of genomes of two *C. diphtheriae* strains: NCTC 13129 and C7(−) revealed that 11 of 13 pathogenicity islands identified in the NCTC 13129 strain were absent in the C7(−) strain.

Other Virulence Factors of *C. ulcerans* and *C. pseudotuberculosis*

Corynebacterium ulcerans and *C. pseudotuberculosis* produce phospholipase D (PLD), which is unique among corynebacteria. PLD is a prominent virulence factor of these two species. It promotes the hydrolysis of ester bonds in sphingomyelin in mammalian cell membranes, possibly contributing to the spread of the bacteria from the initial site of infection to the secondary sites within the host. Moreover, it provokes dermonecrotic lesions; and at higher doses, it is lethal to a number of different species of laboratory and domestic animals.

The surface lipids of *C. pseudotuberculosis* are also regarded as a virulence factor. The toxicity of the extracted lipid material has been demonstrated by the induction of hemorrhagic necrosis following intradermal injection in guinea pigs. Moreover, it has been observed that *C. pseudotuberculosis* was resistant to killing and digestion by caprine macrophages due to its lipid coat. Recently, the complete genome sequence of human isolate of *C. pseudotuberculosis* has been published, thus enabling to deduce its more potential virulence factors. The *fagCBA–fagD* genes encoding an iron-uptake system and gene clusters associated with pathways for siderophore biosynthesis have been identified. SpaABC and SpaDEF pili from *C. pseudotuberculosis* showing similarity to subunits of adhesive pili from *C. diphtheriae* can also be regarded as potential virulence factors. Moreover, the genome sequence has revealed four genes encoding secreted proteases. Extracellular proteases may exhibit a wide range of pathogenic potentials when interacting with the defense mechanisms and tissue components of the host. Another candidate virulence factor of *C. pseudotuberculosis* is the extracellular neuraminidase NanH. Neuraminidases, or sialidases, belong to a class of glycosyl hydrolases that catalyze the removal of terminal sialic acid residues from a variety of glycoconjugates and can contribute to the recognition of sialic acids exposed on host cell surfaces. Sialidases located on the bacterial cell surface can be used for the decoration of sugar moiety acceptors with sialic acid to enable the invasion of hosts under certain conditions. Another potential virulence factor of *C. pseudotuberculosis* is represented by the *nor* gene encoding nitric oxide reductase. This enzyme is generally involved in the detoxification of nitric oxide and consequently necessary for the long-term persistence of pathogens in macrophages. Further work should be done to compare the existence of deduced virulence factors genes in other *C. pseudotuberculosis* human and animal isolates in order to evaluate the heterogeneity of the species.

Clinical Manifestation

The clinical features of illnesses caused by toxigenic *C. ulcerans* and *C. pseudotuberculosis* are similar to diphtheria caused by toxigenic *C. diphtheriae*. Depending on the anatomic site that is affected by the disease, there could be respiratory or cutaneous diphtheria. In rare instances, other sites, such as the eye, ear, and vulva, can also be affected. Symptoms of respiratory diphtheria occur usually after an incubation period of 1–10 days. The onset is relatively slow and characterized by moderate fever and a mild exudative pharyngitis. In severe cases, pseudomembranes gradually form in the throat, recognizable by their typical asymmetric, grayish-white appearance, strong attachment to the underlying tissue, and bleeding following attempts to remove or dislodge them. Such pseudomembranes may extend into the nasal cavity and the larynx causing obstruction of the airways. Laryngeal diphtheria, which sometimes occurs even without pharyngeal involvement, is a medical emergency that often requires tracheostomy. Enlarged anterior cervical lymph nodes and edema of soft tissues giving a "bull neck" appearance are also observed.

Cutaneous diphtheria usually appears on exposed parts. The lesions start as vesicles and quickly form small, clearly demarcated, and sometimes multiple ulcers. The lesions are usually difficult to treat and may take months or even years to heal.

Diphtheria toxin absorbed from the mucosal or cutaneous lesions may account for toxic damage to organs, such as the myocardium, kidneys, and nervous system. The following clinical conditions are associated with an increasing risk of toxin-induced systemic disease: (1) the catarrhal form (erythema of pharynx and no membranes), (2) the follicular form (patches of exudates over pharynx and the tonsils), (3) the spreading form (membranes covering the tonsils and posterior pharynx), and (4) the combined form (more than one anatomical site involved, e.g., throat and skin).

Epidemiology of Infections

After the introduction of vaccination against the diphtheria toxin in 1940s, the infections caused by toxigenic corynebacteria have seemed to be well controlled in developed countries. However, infections recorded during the past several years point at *C. ulcerans* and *C. diphtheriae* as reemerging human pathogens.

C. ulcerans Infections

The epidemiology of human infections caused by *C. ulcerans* is not well known. The infections are usually acquired through contact with animals (see Section Occurrence in the Environment and Food) or by eating or drinking unpasteurized dairy products. However, such risk factors have not been identified for some cases of classical diphtheria caused by *C. ulcerans*, which suggest that there may be other routes of infections. Person-to-person transmission of *C. ulcerans* is thought to occur only rarely.

Infections caused by toxigenic strains of *C. ulcerans* are increasingly reported from developed countries. The infections

seem to replace infections caused due to toxigenic *C. diphtheriae*. In UK between 2000 and 2009, 43 isolates of toxigenic corynebacteria were identified, 27 of which (63%) were *C. ulcerans*. In France between 2002–08, 12 (63%) *C. ulcerans* were isolated from 19 cases of toxigenic corynebacteria infections in humans. In USA, 2 (29%) isolates of toxigenic *C. ulcerans* strains were isolated from 7 toxigenic *Corynebacterium* infections during the period 1999–2005; but before 1999, the last reported case of diphtheria-like illness caused by *C. ulcerans* in USA occurred in 1996. Other examples are 3 (33%) isolates of toxigenic *C. ulcerans* of 9 cases of toxigenic corynebacteria infections in Canada from 1999 to 2003 and 1 (33%) isolate of toxigenic *C. ulcerans* of 3 cases of toxigenic *Corynebacterium* infections in Italy from 1999 to 2001. Also in Japan, 2 cases of human infection with toxigenic *C. ulcerans* were identified in 2001 and 2002.

It seems that women are the risk groups acquiring *C. ulcerans* infections, especially those older than 50 years. They are probably more exposed to domestic animals and, as shown in studies conducted in Europe, women have been less protected against diphtheria than men older than 40 years.

C. pseudotuberculosis Infections

Very little information about *C. pseudotuberculosis* have been published. Fewer than 30 human cases have been described in the literature so far. Cases are most often linked to contact with goats and sheep. Toxigenic strains usually cause illness similar to diphtheria. Among 25 European countries participating in Diphtheria Surveillance Network, only three cases of *C. pseudotuberculosis* human infections were recorded during the period 2000–10, two cases in France in 2004 and 2005 and one case in UK in 2008. Infections due to toxigenic strains have been similar to diphtheria. Most human cases of nontoxigenic *C pseudotuberculosis* infections have had lymphadenitis, apart from one case of eosinophilic pneumonia and one case of eye infection.

C. diphtheriae Infections

Infections caused by *C. diphtheriae* are usually acquired through contact with infected persons and objects that have been touched by them. In 1990, a diphtheria epidemic due to *C. diphtheriae* occurred in the Newly Independent States (NIS) of the former Union of Soviet Socialist Republics (USSR). The epidemic began in the Russian Federation in 1990 and affected all the NIS countries by the end of 1994. At the peak of the epidemic in 1995, 50 425 cases were reported in the NIS, compared with 24 cases in other countries. After mass immunization campaigns, the incidence of diphtheria in the Russian Federation and in the NIS began to decrease. Between 1990 and 2001, more than 160 000 cases were reported in the region. In 2002, 1189 cases were reported from the World Health Organization (WHO) European region, 95% of the cases were from the Russian Federation and the NIS. In 2003, a total of 896 cases were reported from the WHO European region and 99% (892) were from the Russian Federation and the NIS; the 4 remaining cases were reported from Turkey (1 case) and UK (3 cases). According to the WHO data, in 2007, 4190 diphtherial cases (due to *C. diphtheriae*) were reported worldwide. Across the European Union, 47 diphtheria cases (due to *C. diphtheriae* and *C. ulcerans*) were reported in 2008. There were 29 cases in Latvia, 6 cases in UK, 5 cases in France, 2 cases in Lithuania, and 1 case in Sweden. The most affected age groups were 5–14 years and 45–64 years. The number of cases was higher among females than among males.

Countries with endemic diphtheria are Algeria, Angola, Egypt, Niger, Nigeria, Sudan, and other sub-Saharan countries; Bolivia; Brazil; Colombia; Dominican Republic; Ecuador; Haiti; Paraguay; Afghanistan; Bangladesh; Bhutan; Burma (Myanmar); Cambodia; China; India; Indonesia; Laos; Malaysia; Mongolia; Nepal; Pakistan; Papua New Guinea; Philippines; Thailand; Vietnam; Iran; Iraq; Saudi Arabia; Syria; Turkey; Yemen; Albania; Russia; and countries of the former USSR.

It is worth underlying that invasive diseases caused by *C. diphtheriae* have been described increasingly worldwide stressing the importance of this species as a serious bloodborne pathogen. Between 1893 and 1995, only 58 cases of bacteremic infections due to *C. diphtheriae* were described. During 1990s, the situation had been changed. During the period 1999–2003, 13 cases of *C. diphtheriae* invasive infections were noticed in Canada. In Switzerland, 14 isolates of *C. diphtheriae* were obtained from invasive infections in 1990–96. In Poland, the first *C. diphtheriae* invasive infection was recorded in 2004; and in the period 2005–07, seven additional cases were recorded. Isolation of *C. diphtheriae* from invasive infections also increased in Brazil during the past years. The invasive diseases are caused by both toxigenic and nontoxigenic *C. diphtheriae* strains. Predisposing factors for the development of the invasive disease are homelessness, injection drug use, alcohol abuse, diabetes mellitus, and homosexuality. More often males are affected than females.

Occurrence in the Environment and Food

Corynebacterium species are a widely distributed group of bacteria, typically found in the environment in soil and on the skin and mucous membranes of human beings and animals. Corynebacteria have also been documented to survive for long periods of time on objects that have been touched by infected individuals.

Corynebacterium ulcerans is a commensal in animals and has been isolated from a wide host of domestic and wild animals (e.g., dogs, cats, horses, goats, cows, pigs, camels, monkeys, squirrels, and otters). The animals may serve as reservoirs for human infection. Moreover, the bacterium causes mastitis in cattle and goats. In mastitis infection, the bacteria are present in milk. A significant portion of human *C. ulcerans* infections has been associated with the consumption of raw dairy products. Also handling of infected animals and their products could be a source of infections. Recently, contact with companion animals, such as dogs and cats, has been recognized as a way of infection.

Corynebacterium pseudotuberculosis is a rare zoonosis. Similar to *C. ulcerans*, raw dairy products are the source of infection as well as handling of infected animals and their products (e.g., butchery). Sheep, followed by goats, are the most

commonly affected animal hosts; but horses, cattle, and deer may also be infected. *Corynebacterium pseudotuberculosis* has also been isolated from milk in mastitis cases.

Corynebacterium diphtheriae is traditionally considered as a nonzoonotic pathogen. However, recent reports of horses as carriers of *C. diphtheriae* highlight the possible emergence of a new route of human infection. *Corynebacterium diphtheriae* has also been isolated from a cat. In older publications, isolation of *C. diphtheriae* from other animals has been reported as well. The species is infrequent cause of bovine mastitis and has been associated with dermatitis with pyrexia in cattle. It is thought to be transferred to cows from infected dairy workers. Moreover, *C. diphtheriae* has been documented in other domestic animals, including equids and canids. The dairy products obtained from infected animals and handling of infected animals could be a source of infection for humans.

Identification and Toxigenicity Testing

A selective tellurite medium, such as Hoyle's agar, and Tinsdale agar are very useful in the first step of identification of potentially toxigenic *Corynebacterium* species (see Section Characteristics of the Genus). Identification of suspected isolates usually relies on Gram staining and biochemical reactions. ApiCoryne system (BioMerieux) is broadly used for biochemical identification of corynebacteria. However, the system does not identify *C. diphtheriae* var. *intermedius* and groups together *C. diphtheriae* var. *mitis* and *C. diphtheriae* var. *belfanti*. Biotypes *mitis* and *belfanti* can be easily distinguished manually on the basis of results of nitrate reduction (included in the ApiCoryne system). But additional tests need to be done for biotype *intermedius* identification.

Molecular methods such as 16S rRNA gene sequence analysis or *rpoB* gene sequence analysis are also used. Nevertheless, *rpoB* sequencing does not differentiate *C. ulcerans* and *C. pseudotuberculosis*. Polymerase chain reaction (PCR) targeting the *pld* gene is very useful for the identification *C. pseudotuberculosis*. Recently, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry has been proposed as a tool for rapid diagnosis of potentially toxigenic *Corynebacterium* species.

Classical and modified Elek tests are commonly used to demonstrate the toxigenicity of *C. diphtheriae*, *C. ulcerans*, and *C. pseudotuberculosis* strains. Moreover, a rapid immunochromatographic method for detection of diphtheria toxin has been developed. But the test is not available commercially. Owing to the problems with diphtheria antitoxin accessibility, some laboratories are using cell culture for detection of diphtheria toxin production. But the test gives a delayed answer to the diagnosis. As faster methods, conventional PCR were described for detection of fragment A and B of the *tox* gene. But positive results in the tests do not confirm whether the strain is producing toxin. Real-time PCR test was also developed, which provide more rapid results than conventional PCR for *C. diphtheriae*. However, it was observed that real-time PCR analysis of *C. ulcerans* isolates could produce atypical amplification of fragment A and no amplification of fragment B, although conventional PCR is useful to detect the presence of subunits A and B of the *tox* gene in *C. ulcerans*. There is no available information concerning the usefulness of real-time PCR for *tox* gene detection in *C. pseudotuberculosis*.

Antimicrobial Susceptibility

Owing to the high fatality rate of potentially toxigenic corynebacteria infections, appropriate antimicrobial treatment is crucial (apart from diphtheria antitoxin treatment). Most of the isolates are susceptible to a broad range of antimicrobial agents. Penicillin and erythromycin are the drugs of choice for treatment of *C. ulcerans*, *C. diphtheriae*, and *C. pseudotuberculosis* infections. Nevertheless, *C. diphtheriae* isolates resistant to β-lactams and erythromycin, intermediate to cefotaxime, as well as multidrug-resistant strains have been described. *Corynebacterium ulcerans* strains resistant to erythromycin and clindamycin have also been isolated. *Corynebacterium pseudotuberculosis* isolates resistant to penicillin, streptomycin, and neomycin have been reported. Moreover, in the experiments where *C. pseudotuberculosis* was growing as a biofilm, the bacterium was highly resistant to all the drugs tested. In case of *C. pseudotuberculosis* infections, the antibiotic therapy alone is usually not successful and should be combined with a surgical intervention. This may be because *C. pseudotuberculosis* is a facultative intracellular pathogen multiplying in macrophages. Cell death and release of bacteria lead to necrotic lesions and to the formation of a thick collagen capsule that protects the bacterium from antibiotics.

Typing Methods

There have been several typing schemes described based on the traditional methods, such as serotyping, phage typing, and bacteriocin typing. The methods are regarded as historical and performed only in a few laboratories in the world. Currently, molecular typing methods are broadly used. Ribotyping has been described as a gold standard for potentially toxigenic corynebacteria. The international nomenclature for *C. diphtheriae* ribotypes has been established and a database of all recognized ribotypes has been built. Eighty-six ribotypes have been described. However, the method is time consuming and labor intensive. To the best knowledge of the author, only three national centers of diphtheria in Europe are currently able to perform ribotyping. Recently, the multilocus sequence typing (MLST) method for *C. diphtheria* typing has been developed together with a database of all recognized sequence types. Until now, 208 sequence types have been described. The method is increasingly used in more and more laboratories and is replacing ribotyping. Also many other molecular typing methods have been described as useful for typing of potentially toxigenic corynebacteria, for example, pulsed-field gel electrophoresis (PFGE), random amplification of polymorphic DNA (RAPD), multilocus enzyme electrophoresis (MLEE), amplified fragment length polymorphisms (AFLP), and enterobacterial repetitive intergenic consensus PCR (ERIC-PCR). In 2005, a microarray-based method called spoligotyping (spacer oligonucleotide typing) was developed as a new genotyping tool with high discriminatory power. The method allows fast and efficient discrimination within the

C. diphtheriae epidemic clonal group. Currently, studies on development of multiple-locus variable-number tandem repeat analysis (MLVA) for *C. diphtheriae* typing are conducted.

Control and Preventive Measures

Infections due to toxigenic and nontoxigenic *C. diphtheriae*, *C. ulcerans*, and *C. pseudotuberculosis* can be prevented by washing hands, especially after contact with animals; avoiding the consumption of raw dairy products; pasteurization of milk; and education of domestic animals owners, persons handling the animals, and dairy workers.

Moreover, infections due to toxigenic strains of *C. diphtheriae*, *C. ulcerans*, and *C. pseudotuberculosis* can be prevented by the use of antidiphtheria vaccine. Antibiotic treatment should be administered to diphtheria patients, contacts, as well as asymptomatic carriers to eliminate the bacteria and prevent the spread of infection. Patients with diphtheria should be nursed in strict isolation until bacteriological clearance has been demonstrated by negative cultures of nasopharyngeal and throat swabs. All objects in direct contact with the patient and objects soiled by discharges from the patient should be disinfected while the patient is in isolation.

Coxiella burnetii

SJ Cutler, University of East London, London, UK

Glossary

16S rRNA 16S ribosomal ribonucleic acid.
Axenic medium Pure culture using artificial cultivation medium.
Containment level 3 Biosafety level three.
HEL Human embryonic lung.
IS*1111* Insertion sequence *1111*.
LCV Large cell variant.
SCV Small cell variant.
Shell vial Cell line supported on glass coverslip.

Background

History

Edward Derrick described a febrile illness among abattoir workers in Brisbane, Australia during 1937, that became known as Query (Q) fever. Shortly after the causative organism now known as *Coxiella burnetii*, was recovered independently by both Burnet and Freeman in Australia and Davis and Cox in USA. Despite significant ensuing research effort, our understanding of this pathogen; its interactions with host species; and pathophysiological mechanisms remain to be fully disclosed.

Characteristics of Pathogen

This obligate intracellular pathogen is grown in various cell culture lines, but was originally cultivated in embryonated eggs. It is a microaerophile with Gram-negative cocco-bacillary cell wall structure (although it cannot be stained using the Gram-staining method, but can be visualized using methods such as Gimenez). The cells are typically pleomorphic ranging from 0.3 to 1.5 μm in length and 0.2–0.4 μm in width. Two antigenic forms of this microbe exist, phase I that is the highly virulent variant associated with acute infection, and the avirulent phase II associated with prolonged *in vitro* cultivation. Its highly infectious nature has led to its requirement for handling under containment level 3. Its significant association with livestock has called into question the role of *C. burnetii* as a potential food safety pathogen.

Systematics of *Coxiella*

Its physiological, lifestyle, and morphological resemblance to the rickettsiales led to its initial mistaken inclusion among this family within the alphaproteobacteria. Application of molecular sequenced-based studies such as 16S rRNA gene analysis, revealed its similarity to *Legionella*, and resulted in its subsequent reclassification. The Coxiellaceae family forms a monophyletic group among the gammaproteobacteria. The phylogenetic proximity to the Legionellales within the gammaproteobacteria has been further confirmed through whole genomic comparisons of available complete sequences. Some have postulated that *C. burnetii* has evolved from a free-living environmental bacterium, possibly related to members of the halophilic gammaproteobacterium. Indeed, this could account for its possession of features such as introns and inteins, likely to have arisen from horizontal gene transfer, now restricted through its current obligate intracellular lifestyle.

Molecular investigations have furthermore disclosed variability among *C. burnetii* with eight different genomic groups within the species. Whether these relate to host correlations or clinical presentations remains speculative. Further subtyping can be achieved through application of high-resolution typing methods such as multispacer typing or variable number tandem repeat typing (see Section Molecular Detection and Typing of *C. burnetii*). These methods are particularly useful for the identification of related strains in the case of suspected outbreaks of infection.

Natural Resistance of *Coxiella*

The SCV of *Coxiella* exhibits remarkable resistance where it has been reported to withstand heat, desiccation, UV light and a variety of different disinfectants. Indeed, it has been reported to have acid resistance up to pH of 4.5. Furthermore, its temperature resistance with survival at 70 °C for 15 min poses particular problems with regard to food hygiene. Similarly, the survival over prolonged periods at 4 °C raises food hygiene concerns. This is compounded by the preference of *Coxiella* to survive and indeed multiply in eggs, again raising concerns regarding food safety issues.

Laboratory Diagnostic Methods

Isolation of C. burnetii

Cultivation of *C. burnetii* requires use of conventional cell culture methods, inoculation of the yolk sac of embryonated

 doi:10.1016/B978-0-12-378612-8.00094-9

eggs, or intraperitoneal inoculation of laboratory animals such as mice, hamsters, or guinea pigs and subsequent recovery from infected spleens. Probably the most frequently used method is the "shell vial" tissue culture with cell lines such as human embryonic lung (HEL) fibroblasts or buffalo green monkey cells. The sample is inoculated into these cells by centrifugation and cells examined for periods of up to 3 weeks for growth of *Coxiella*. Where samples are potentially contaminated, inclusion of selective antimicrobials such as gentamicin (50–100 $\mu g\,ml^{-1}$), penicillin (50–100 $\mu g\,ml^{-1}$), or streptomycin (100–200 $\mu g\,ml^{-1}$) can assist isolation. Some have used tick or insect cell lines particularly when attempting to isolate *C. burnetii* from arthropods. Tissue cultures are assessed using staining with Gimenez, Macchiavello, Stamp, or Giemsa methods to reveal the typical morphological appearance of *C. burnetii*.

Recently, growth of *C. burnetii* has been reported in axenic medium, however, it remains uncertain whether this would be suitable for primary isolation.

Serodiagnosis of Q Fever

Conventional serological methods have been used for serological diagnosis of Q fever in both humans and animals. Complement fixation tests have been superseded by the use of either indirect immunofluorescence tests or enzyme-linked immunosorbent assays. These can be used to detect specific IgM, IgG, or IgA antibodies as appropriate. For IgM, titers more than 1:50 are usually considered positive, whereas for IgG, the cutoff is often set at 1:200 for acute infection (see Table 1). The two phase variants of *C. burnetii* should both be assessed, with acute infection associated with elevated titers against the phase II variant, whereas those with chronic infection will produce raised titers against both phase I and phase II variants. The phase variants of *C. burnetii* are associated with a change in the lipopolysaccharide O-chain, with phase I representing virulent cells, whereas phase II is associated with the nonreversible loss of branched-chain sugars virenose and dihydrohydroxystreptose, resulting in a nonpathogenic variant. This has been likened to the smooth (phase I) and rough (phase II) variants seen among other Gram-negative bacteria. The structure of the phase I *C. burnetii* variant is pivotal for its toll-like receptor 4-mediated uptake by phagocytic cells.

On a cautionary note, some infected animals have been reported not to seroconvert. Similarly, seroconversion has been reported following consumption of infected milk after effective pasteurization. Slight differences in serological reactivity have been noted depending on the infecting strain used as antigen and variability noted among commercially available assays. Serology is, however, good for population studies to give evidence of disease activity. Similarly, on an individual level, it can provide useful information regarding acute or chronic infection.

Table 1 Diagnostic serological titers

Stage	*Immunoglobulin class*	*Phase I antigen*	*Phase II antigen*
Acute	IgM	<1:50	>1:50
	IgG	<1:200	>1:200
	IgA	<1:50	>1:25[a]
Chronic	IgM[c]	>1:50[b]	<1:50
	IgG	>1:800	>1:200
	IgA	>1:25[a]	>1:25[a]

[a]Elevated IgA is not observed in all cases.
[b]Not elevated in all cases.
[c]Low levels of IgM can persist in chronic Q fever.

Molecular Detection and Typing of C. burnetii

Polymerase chain reaction (PCR) provides probably the best methods for detection of *C. burnetii*. Not only does this eliminate the need to cultivate, but can also be used to type these organisms, sometimes directly in clinical material if sufficient numbers of organisms are present (see Table 2). Various primers sets have been used, with the most frequently used being the IS*1111* insertion sequence. This is a multicopy target (ranging from 7 to 110 copies depending on isolates characterized to date) is present in all isolates of *C. burnetii*, thus enhancing sensitivity over single-copy targets. The main disadvantage of this method is its lack of detecting viability,

Table 2 Advantages and disadvantages of different laboratory diagnostic methods

Detection method	*Advantages*	*Disadvantages*
Microscopy	Quick and cheap	Poor sensitivity and nonspecific (*Chlamydophila* and brucellae may resemble *Coxiella*)
Isolation	Demonstrates viability and provides isolate for further typing	Time consuming (may take 3 weeks), expensive, requires tissue culture facilities at containment level 3, and low yield
Serology	Cheap and good for high-throughput testing	Imprecise, may require repeat testing during acute infection, need to test phase I and phase II antigens, and seroconversion can follow exposure to nonviable organisms
PCR	Quick, can also be used to type organisms detected, good during acute infection, and can be used to detect organisms in foods	Will not demonstrate viability, appropriate samples need to be tested (blood is not often positive), PCR inhibitors, and expensive
Animal Inoculation	Provides viable isolates and good when contaminated samples are used	Time consuming, expensive, infection risks, and requires legislative justification

thus when used for testing milk or foods, it may still detect nonviable organisms killed by effective processing.

Molecular typing of *C. burnetii* has been achieved through use of various high-resolution typing methods. Use of multiple noncoding intragenic spacers has been of particular value for differentiating different clonal groups of Coxiellae, with several new groups being recently added to our expanding knowledge of strain diversity. Alternatively, variable tandem repeat typing has been shown to also be highly discriminatory. These methods being PCR-based, can be applied to clinical samples or produce where suitably large numbers of *C. burnetii* are present. Post-genomic sequencing has also permitted design of single nucleotide polymorphism (SNP)-based typing, alleviating the need to undertake sequence analysis.

Of the above methods, only PCR-based approaches have potential for detection in food as the others are unlikely to offer suitable sensitivity. The food matrix might be refractory to amplification, thus DNA should be extracted before testing. Another dilemma results from the lack of information on viability, thus complicating interpretation and assessment of infection risk.

Epidemiology

Natural Maintenance Reservoirs

Transmission routes for *C. burnetii*. The organism, being an obligate intracellular pathogen, requires a suitable host cell environment in which it can multiply. It was thought that the natural reservoir for *C. burnetii* was livestock, however, over recent years, the organism has been detected in numerous diverse sources ranging from fresh-water amoeba, various arthropods including ticks (both hard and soft ticks), domestic pets, exotic zoo animals, reptiles, amphibians, birds, and rodents. Infection in the majority of these species appears to be silent. It may be that natural ecological niches for this organism remain silent, with only accidental "spill over" hosts, such as humans, manifesting clinical consequences. Indeed, even humans infected do not uniformly succumb to clinical disease, with an estimated 60% of infection believed to remain asymptomatic. Despite these diverse natural reservoirs, human infection is significantly correlated with livestock infection, thus behaving as a zoonotic disease.

Once infected, mammals (including man) can chronically excrete *Coxiella* in bodily secretions such as milk, feces, urine, and vaginal secretions. In livestock this shedding of *C. burnetii* can be protracted lasting several months. Attempts to reduce shedding through treatment of livestock appear not to succeed in reducing either the shedding or the duration of shedding. Conversely, vaccination of livestock with phase I cells, has been reported to reduce shedding and to offer a protective effect when used before exposure, however, vaccine availability is currently limited to certain countries (see Section Vaccination).

The organism may produce both large cell and small cell variants (LCV and SCV, respectively). It is the SCV that has been likened to an endospore, which demonstrates particular resistance to adverse conditions (see Section Natural Resistance of *Coxiella*), enabling prolonged extracellular environmental persistence or survival within food. It is this SCV that is typically taken up by the new host. In contrast, the more fragile, but metabolically active LCV appears within the phagolysosomes of infected host cells. It is within this intracellular niche of an acidic parasitophorous vacuole, that *C. burnetii* multiplies.

Clinical Manifestation

Human Q Fever

Infection results in a flu-like illness with fever in approximately 40% of individuals, often resolving without complications (Figure 1). Disease manifestations show a spectrum of severity, with some developing atypical pneumonia or hepatitis, or less frequently myocarditis, pericarditis, meningitis or encephalitis, potentially requiring hospitalization (approximately 5%, Figure 1, Table 3). More seriously, infection may result in potentially life-threatening endocarditis in approximately 1% of individuals, particularly among those with preexisting cardiac defects (Figure 1). Furthermore, the increased incidence in adverse outcomes following acquisition of infection during pregnancy is a worrying concern. Infection has been associated with placentitis, premature birth, fetal death and spontaneous abortion. Numbers studied to date have been small, thus further studies are needed to fully assess the risks of infection during pregnancy.

Less well established is the potential for infection to result in a protracted "chronic fatigue" syndrome. Long-term clinical follow-up of several notable outbreaks have been associated with increased incidence of fatigue-like complications. These studies have been restricted in size and consequently their ability to conclusively establish the cause and effect, thus this potential consequence is still hotly debated. Many obligate intracellular bacterial pathogens have a propensity for persistence, some showing reactivation at stages later in life. Thus, it would not be surprising if latent infection might follow primary infection.

Livestock Infections

In livestock, when symptomatic, infection is primarily associated with late stage abortion particularly among small ruminants. High bacterial numbers are found in placental and fetal membranes. Abortion, stillbirth, reduced fertility, and endometritis have all been linked with *C. burnetii* infection. Infected cattle often remain asymptomatic, but may show abortion, reduced fertility, or metritis. Transmission is likely to be particularly high among animals confined in close proximity under poor conditions such as those in Figure 2.

A recent major outbreak in the Netherlands (2007–10) was correlated with intensive goat farming practices in close proximity with highly populated human areas. Although some abortion has been noted among goats, the infection has been largely silent, with airborne transmission to humans the probable route of spread. Intervention attempts including vaccination and culling of pregnant goats finally abated this outbreak.

Epidemiology of Disease

Coxiella burnetii is considered ubiquitous affecting all countries with the exception of New Zealand. Incidence data are patchy

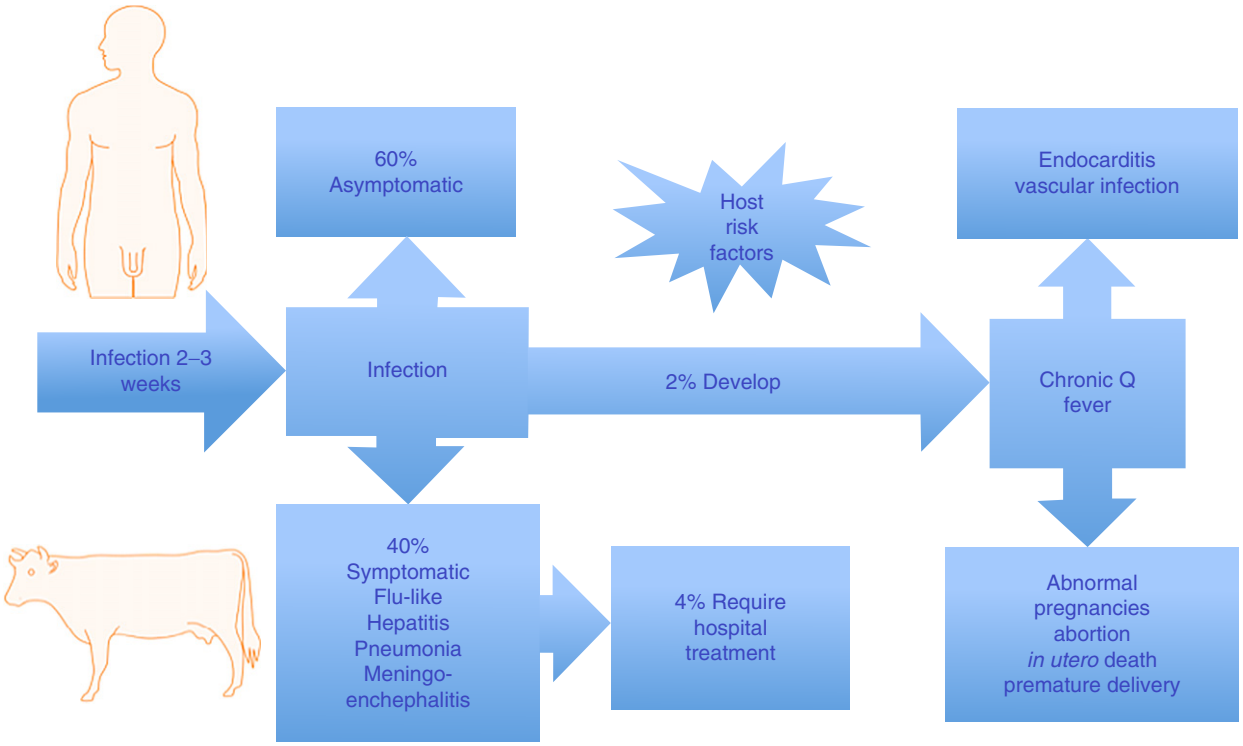

Figure 1 Postinfection natural history of *C. burnetii* infection in humans. Adapted from Tissot-Dupont H and Raoult D (2007) Clinical aspects, diagnosis, and treatment of Q fever. In: Raoult D and Parola P (eds.) *Rickettsial Diseases*, pp. 291–301. London: Informa Healthcare.

Table 3 Clinical signs of Q fever seen in humans

Acute Q fever
Fever and systemic signs
- Abrupt onset of high fever with or without flu-like illness
- Incubation 14–39 day (average 20 day)

Respiratory symptoms
- Cough, shortness of breath, chest pain, pneumonia, or no respiratory signs

Cardiovascular symptoms
- Chest pain
- Myocarditis – can be fatal

Neurological signs
- Stiff neck and headache
- Meningoencephalitis or encephalitis, meningitis and myelitis, and peripheral neuropathy

Chronic Q fever
Endocarditis
- "Culture negative" endocarditis. Can occur months to years after acute infection
- Accompanied by fatigue, fever, dyspnea, and rash

Various physical findings dependent on clinical syndrome (aneurisms, osteomyelitis, chronic hepatitis, and vasculitis)

Figure 2 Animal husbandry practices can facilitate *C. burnetii* transmission. Reproduced from Cutler SJ, Paiba GA, Howells J, and Morgan KL (2002) Q fever – a forgotten disease? *Lancet Infectious Diseases* 2: 717–718.

reflecting local research interests rather than results of systematic surveillance. Incidence reports from Australia have ranged from 3 to 4.99/100 000, whereas results from Marseille, France have suggested that this might reach as high as 50/100 000.

Intriguingly, clinical Q fever is found more often in men than women, even if an equal seroprevalence exists in both groups (in some studies approaching 2.5:1). It has been hypothesized that female sex hormones (such as estrogen), might have a protective effect with ovarectomized mice showing male levels of symptomatic disease. Epidemiological studies from around the globe have confirmed the

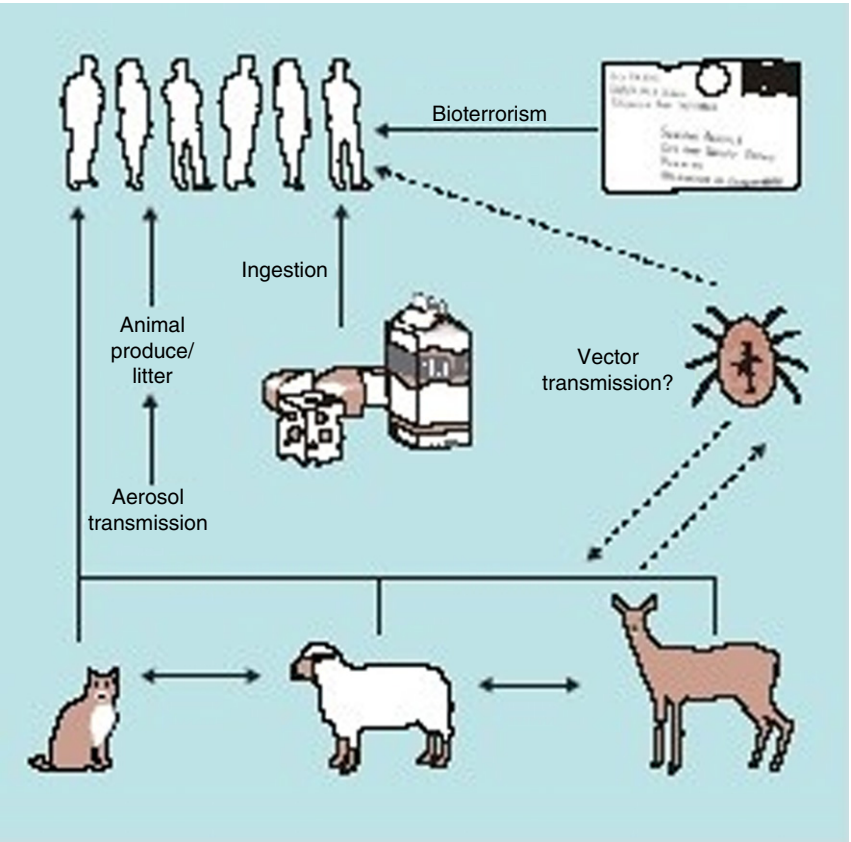

Figure 3 Transmission routes for *C. burnetii*. Reproduced from Tissot-Dupont H and Raoult D (2007) Clinical aspects, diagnosis, and treatment of Q fever. In: Raoult D and Parola P (eds.) *Rickettsial Diseases*, pp. 291–301. London: Informa Healthcare, with permission from Taylor and Francis.

predominance of clinical infection in males, and a remarkable lack of symptomatic disease among children.

The seasonality observed for acquisition of Q fever correlates with the lambing or calving seasons, thus underscoring the role of parturient livestock in human Q fever.

Transmission Routes

Probably the most important transmission route through which infection is acquired, is the respiratory route (Figure 3). Indeed, it is estimated that as few as 10 organisms are sufficient to result in human infection. Contact with infected material is again an important route for infection (Figure 3), with sporadic and clusters of infection attributed to contact with straw (probably contaminated with animal excreta). Whether this is direct physical contact, or a result of aerosolization of infected materials is difficult to conclusively prove. Human infection has been recorded as a consequence of occupational contact with livestock (abattoir workers; veterinary staff; farmers). Further cases have been linked with parturient companion animals, with liberation of infectious particles associated with delivery.

The role of tick bites appears not to be a major risk for acquisition of Q fever. Even though the Nine Mile reference isolate was isolated from a *Dermacentor andersoni* tick, no human cases have been directly attributed to tick bites. Even sexual contact has been described for transmission between an occupationally exposed worker and his wife. By far the most important exposure appears to be respiratory transmission following exposure to liberated infectious particles, often approaching 10^9 organisms per gram of placental tissue during delivery of livestock, and subsequent environmental contamination, and prolonged shedding in the milk, urine, feces and vaginal secretions of infected animals.

Potential for Foodborne Infection

The significance of foodborne infection remains a realistic possibility, however, study designs have usually been restricted to demonstration of *C. burnetii* in foodstuffs rather than causation of disease following consumption of infected foods. Consumption of contaminated milk has been demonstrated to result in seroconversion, however, clinical cases did not ensue, nor was recovery of *C. burnetii* attempted from those individuals who seroconverted. Given the expanding environmental niches being demonstrated for persistence, the plethora of potential host species and innate resistance of the SCV to many procedures used to process our foods such as desiccation, heat, biocides, and acidic conditions (pH 4–5), it is likely that exposure by this route does occur, but significance remains to be established.

Food Hygiene Implications

With regard to food hygiene, risk assessment models whereby hazard identification; exposure assessment; dose–response; and risk characterization are important steps used to assess food safety. Often added to this are steps to manage risks identified, and communication. By following these steps, it is clear that *C. burnetii* might readily be present in meats and milk destined for human consumption. Furthermore, experimental studies have highlighted the highly infectious nature of *C. burnetii*, although these studies have used respiratory exposure rather than via the gastrointestinal tract. Exposure assessment aspects are challenging to interpret regarding *C. burnetii*, in part through the clinical diversity seen following infection, and protracted clinical course that subsequently follows infection.

General foodborne infection reduction measures applied to improve food safety are likely to reduce the burden of infection. Regarding livestock, the association of *C. burnetii* with abortion episodes and its subsequent excretion over the ensuing months following delivery, highlight the potential role of dairy products as a vehicle of infection rather than meat. Indeed, this has led to initial evaluation of *C. burnetii* as an indicator organism for successful pasteurization. Studies from USA have reported 94% of bulk tank milk samples to be positive by PCR for *C. burnetii*. Such data illustrate the potential for exposure and underscore why *C. burnetii* was used as an indicator for evaluation of temperatures and times for pasteurization. Studies from the 1950s determined that 30 min at 62.8 °C or 15 s at 71.7 °C were sufficient to maximize destruction of viable *Coxiella*. These investigations formed the basis for pasteurization recommendations aimed at reducing vegetative bacterial burden to a level considered safe for human consumption. It was also recognized that even following successful pasteurization, that seroconversion might follow, thus multiple passage in guinea pigs was used to assess successful killing of test organisms. This raises an important issue regarding the use of serology as a diagnostic tool for Q fever and could account for some of the high levels of positive serology reported in the absence of clinical signs. Indeed, a study based on a farming population utilized ambulance drivers as a control group without agricultural exposure, and found a higher seroprevalence among controls than the test group of farmers.

We cannot directly disregard meat as a source for infection. Indeed, when we broaden our perspectives to include those involved in the processing of food, significant outbreaks of infection have been linked with abattoirs and meat-packing workers. A recent abattoir-associated outbreak occurred in Stirling, Scotland following spontaneous abortion of a sheep in the holding area, resulting in infection of more than 200 workers associated with the abattoir. Whether retail meat could serve as a vehicle for transmission remains to be assessed (see Figure 4).

Surveillance of bulk milk samples has disclosed an excess of 94% positive for *C. burnetii* DNA using PCR from countries such as USA. European studies have reported much lower values of 4.7% (Switzerland) and 3.5% (Turkey) of bovine and ovine milks, respectively. Prolonged shedding of *C. burnetii* has been reported in bovine milk; however, this does not appear to be the case for milks from ovine or caprine sources. The significance of oral infection remains unresolved. Studies of human volunteers drinking contaminated milk resulted in seroconversion, but not overt clinical disease. It must, however, be remembered that 60% of respiratory-exposed individuals will similarly seroconvert, but remain asymptomatic, thus the afore mentioned volunteer studies might just reflect experimental groups of insufficient size. Where milk and milk products are likely to have a more prominent role in transmission is more likely where consumption of unpasteurized milk and goat cheese is a commonplace in many parts of the world. Figure 5 illustrates a typical example of goat's cheese in Peru often made with unpasteurized milk.

Figure 4 Could retail meat markets further the dissemination of *C. burnetii*?

Figure 5 Unpasteurized goat's cheese on sale at a market in Peru.

The role of eggs and their products has also been questioned, with 4.2% of shell eggs and 17.6% of mayonnaise samples from Japan testing positive by PCR. Few studies elsewhere have addressed the role of shell eggs as a potential source for infection, but a study from Switzerland was unable to corroborate these findings.

Our knowledge of *C. burnetii* is still formative and continuing to evolve making it important to use recent data sources to avoid misinformation. Indeed, peer-reviewed data from 1997 in reputable food microbiology journals would have make you believe that *C. burnetii* was exotic to the

Netherlands and that human infection was of little significance! This was then followed by a major and protracted outbreak from 2007 to 2010 involving more than 4000 human cases, serving as a reminder of the need to remain vigilant. Such misled opinions underscore the need for multidisciplinary approaches to assess the infection risks of such pathogens within the food chain.

Control and Prevention of Disease

As with many zoonoses, control is best delivered through reduction of infection in the reservoir, in this case, among livestock. This will reduce both direct and indirect human infection (such as through the food chain). Several measures have been suggested which are detailed below.

Animal Husbandry and Hygienic Measures

Various husbandry and hygienic measures can reduce the level of infection. These include stringent vermin control measures coupled with rendering of any aborted fetuses or placental material together with incineration of bedding. Movement restrictions help to contain infection where detected. Farmyard manure poses additional risks as this is often spread on the land as fertilizer from where it can be aerosolized posing risk of infection. This should be composted for 3 months before use on the land.

Vaccination

Inactivated vaccines have been prepared from phase I cells (Coxevac, CEVA, Hungary) and used to show some protective effect in animals, however, annual vaccination is generally recommended to prevent infection among vulnerable livestock species. Vaccination of infected livestock has been suggested to show some beneficial reduction of shedding into the environment. Human vaccination (Q-VAX, CSL Ltd., Australia) has been used to protect high-risk individuals in certain countries (such as abattoir workers in Australia), but has been associated with adverse side effects, particularly among those with preexisting exposure. Consequently, serological testing should be a prerequisite before vaccination.

Conclusion

Interest in both *C. burnetii* and Q fever has been elevated in part through its inclusion as a potential biothreat agent, and following several notable large outbreaks of infection. These have served to highlight our knowledge gaps regarding the various natural reservoirs, transmission, and pathophysiological mechanisms employed by *C. burnetii*. Many unanswered questions remain, such as why disease is rarely seen during childhood; the reasons as to why infection predominates in males; the risks of infection during pregnancy; and the role of nonrespiratory transmission of *C. burnetii*? We hope that renewed research efforts into genomic analysis, improved diagnostics, and continuing efforts to produce vaccines to both prevent disease and shedding of the organism into the environment will enable us to reduce the risks of infection in years to come.

Glossary

Animal reservoir Animals that directly or indirectly transmit a pathogen, although being immune to its effects.
Genomic plasticity Characteristic of the bacterial chromosomes allowing the exchange of DNA between microorganisms and causing their genomes to adapt rapidly to changes in the environmental conditions.
Pathogenicity island Bacterial DNA trait vehiculating genes involved in virulence, and containing other genes, governing the insertion and excision from an integration site in the bacterial chromosome.
Polymerase chain reaction Technology allowing the specific amplification of a DNA fragment from complex DNA preparation, increasingly used to detect DNA sequences associated with specific pathogens in foodstuffs.
Super-shedder cattle Individuals who excrete many more *E. coli* O157 than others.

Introduction

Escherichia coli is part of the microflora of the gastrointestinal tract of mammals and birds, but certain strains have been associated with diarrheal diseases in both humans and animals. Pathogenic *E. coli* have evolved the capability to colonize almost every district of the human organism and cause a wide range of diseases and symptoms. The extraintestinal pathogenic *E. coli* (ExPEC) infect the mucosal districts outside the gastrointestinal tract and are a leading cause of urinary tract infections. Some ExPEC can be isolated from the blood of children with neonatal meningitis. The *E. coli* strains involved in the induction of enteric forms are clustered in a large pathogroup termed diarrheagenic *E. coli*, which is in turn subdivided into a number of different pathotypes based on the pathogenetic mechanism of the induced disease. Diarrheagenic *E. coli* are able to cause diarrhea as a result of the acquisition by horizontal gene transfer of genetic elements coding for toxin production, adhesion to and invasion of host cells, and interference with cell metabolism. The different diarrheagenic pathotypes include: (1) enterotoxigenic *E. coli* (ETEC), which produce enterotoxins that are able to stimulate the small intestine to secrete electrolytes and water, resulting in diarrhea. ETEC are considered a leading cause of diarrhea in the low-income world and an agent most commonly involved in traveler diarrhea; (2) enteroinvasive *E. coli* , closely resembling *Shigella*, are able to invade and damage colonic mucosa cells and cause a dysenteric form of diarrhea in humans; (3) enteropathogenic *E. coli* (EPEC), which are able to adhere to the intestinal cells causing attaching and effacing (A/E) lesions and represent a major cause of profuse watery infantile diarrhea in low-income countries; (4) enteroaggregative *E. coli* (EAEC), which cause watery diarrhea by adhering to the epithelium of terminal ileum and colon in a characteristic aggregative pattern followed by a damage/secretion stage; (5) Shiga toxin (Stx)-producing *E. coli* (STEC), characterized by the production of potent cytotoxins that inhibit the protein synthesis within eukaryotic cells and can cause severe illnesses such as hemorrhagic colitis (HC) and hemolytic uremic syndrome (HUS), especially among children and the elderly.

Most of the pathogenic groups of *E. coli* have only the human reservoir and infections are diffused via the oral–fecal route. An animal origin and the foodborne transmission have been postulated for some ExPEC causing urinary tract infections (UTIs), but this matter is still under debate. On the contrary, STEC represent the only pathogenic group of *E. coli* that has a definite zoonotic origin, with ruminants, and in particular cattle, being recognized as the major reservoir for human infections. A large variety of *E. coli* serogroups has been identified in ruminants capable of producing Stx. However, only a few serogroups have been consistently associated with human disease and just a dozen of them are routinely isolated from the most severe forms of infection. As a matter of fact, approximately half of the HUS cases reported in the last 20 years in Europe were caused by STEC O157, and the vast majority of the remaining cases were due to infection caused by STEC belonging to serogroups O26, O111, O103, and O145. As a consequence, in 2007, a scientific opinion of the European Food Safety Authority (EFSA) formulated the definition of highly pathogenic STEC as *E. coli* strains able to produce Stx, to colonize the host gut by the A/E mechanism, and belonging to one of the five serogroups most associated with HUS.

STEC are by far the *E. coli* pathotype most relevant in food safety and, therefore, this article will be focused on their virulence properties, modes of transmission, and strategies and methods for their detection in food.

STEC Virulence Factors

The main STEC virulence feature is the production of Stx, potent cytotoxins, which cause inhibition of protein synthesis upon internalization by the sensitive cells. The Stx-coding genes (*stx*) are carried by bacteriophages belonging to the lambda family, which are maintained in a lysogenic state in the bacterial chromosome but retain the capability to enter the lytic cycle and disseminate from one host to the other. Stx include two main antigenically distinct types, Stx1 and Stx2, and numerous subtypes identified by differences in the deoxyribonucleic acid (DNA) sequence of the coding genes. Three subtypes of Stx1 and seven subtypes of Stx2 have been described so far, which can be found in any combination in a single STEC cell.

STEC associated with severe human illness, such as HC or HUS, possess additional virulence factors boosting their pathogenicity. Those encoded by the genes located on the pathogenicity island termed as locus of enterocyte effacement (LEE) are associated with enterocyte lesions termed 'attaching and effacing', characterized by the effacement of the brush border microvilli, followed by the intimate attachment of the bacterium to the plasma membrane. The key structure intervening the induction of the A/E lesion is a type III secretion system (T3SS). This is basically made by a needle, which is used to inject bacterial effectors inducing cytoskeleton rearrangements directly into the enterocyte. Besides the T3SS and effectors, the LEE encodes an outer membrane protein called intimin (*eae* gene), which mediates the direct binding of the bacterium to the host cell surface, and its translocated receptor, Tir (translocated intimin receptor).

Other virulence genes described in highly pathogenic STEC include *efa1/lifA*, which is located on a pathogenicity island known as OI-122 and encodes a factor involved in the colonization by inhibiting the host lymphocyte activation, and the genes carried by the pathogenicity island OI-57, probably involved in the modulation of bacterial adhesion.

A large plasmid, called pO157 in STEC of serogroup O157, is also present in most of the STEC associated with severe human disease. It encodes the enterohemolysin, a catalase peroxidase, and a serine protease. The pO157 also carries another large gene, called *toxB*, whose product has an effect comparable to that of *efa1/lifA*. Such a gene is present in the virulence plasmid of all STEC O157 and in most of the STEC belonging to serogroups O26, but it has also been described, in its entire form or as remnant, in the virulence plasmid of STEC belonging to the serogroups O103, O111, and O145.

Genomic Plasticity and STEC Evolution

E. coli is a ubiquitous species present in the intestinal tract of humans and animals as a commensal and in almost all the environmental niches, including water and soil. Its capability to survive insuch diverse environments is based on the acquisition of different abilities, such as those related with the exploitation of the available resources, such as adhesion to almost every surface, and the capability to form biofilms. As a matter of fact, an extraordinary genomic plasticity not only allows *E. coli* to easily gain DNA traits bringing new useful features but also lose genetic determinants conferring disadvantageous or obsolete characters. Such DNA exchanges are facilitated by the action of mobile genetic elements (MGEs) – DNA molecules encoding all the necessary components for the mobilization machinery and are able to accommodate part of the genomic content of the host bacterial cell – variable in size from a few to several thousand base pairs. MGEs like bacteriophages, transposons, and pathogenicity islands can excide from the bacterial chromosome upon sensing a stress signal and integrate in the genome of a different bacterial cell, ensuring their propagation in return of new features, possibly conferring advantages to the recipient cell.

The process of gaining and loosing genetic material is defined as 'horizontal gene transfer' and represents the engine for the emergence of the *E. coli* pathotypes.

As far as highly pathogenic STEC are concerned, it has been proposed that they emerged due to a stepwise mechanism, including the passage through an intermediate EPEC ancestor. An environmental *E. coli* could have first acquired the LEE locus and other MGEs encoding accessory effectors and adhesins, such as the genomic islands OI-122 and -57. Later, a plasmid carrying the *bfp* operon, encoding the fimbriae used by EPEC to trigger the intestinal adhesion, could have entered into the chimeric *E. coli*, originating the EPEC-like ancestor of STEC. Finally, the displacement of the *bfp*-carrying plasmid (EPEC adherence factor (EAF) plamid) by another one similar to the plasmid now present in STEC O157 (pO157 like), and the acquisition of an Stx-converting bacteriophage would have caused the emergence of a pathogenic STEC prototype. Such a model has been used to describe the evolution of STEC O157:H7 from an EPEC of serotype O55:H7. Evidence of contacts between pO157-like structures and the typical EAF plasmid support this theory. As a matter of fact, one of the typical features of the pO157 is the presence of the large virulence gene *toxB*. This gene is also present in STEC belonging to the pathogenic serogroups and remnants of its coding sequence are present in the EAF plasmid of the prototype EPEC strain E2348/69.

Evolution Outside the Box: The *E. coli* O104:H4 Example

Horizontal gene transfer can either cause the emergence of bacterial pathogens from harmless species, or originate new pathotypes by combining virulence genes from different pathogenic types. The *E. coli* O104:H4 strain that caused the large epidemic outbreak of HUS in Germany and other European countries in 2011 is paradigmatic of the latter scenario. The episode was one of the largest STEC outbreak that ever occurred, with more than 4000 cases, 900 of whom had HUS, and with a heavy toll of 50 deaths. Interestingly, the *E. coli* O104:H4 did not match the typical definition of pathogenic STEC. As a matter of fact, it did not belong to the list of STEC serogroups usually associated with HUS, and did not possess the *eae* or enterohemolysin-coding gene, which are markers of the LEE pathogenicity island (PAI) and pO157-like plasmids, respectively.

The whole-genome sequencing of the outbreak strain revealed a rare combination of virulence determinants, with a bacteriophage carrying the genes responsible for the production

of Stx2 inserted in the genomic backbone of another *E. coli* pathotype, the EAEC. It can be hypothesized that the emergence of such chimeric Stx-producing EAEC could have been the consequence of the biphasic 'lifestyle' of EAEC. The *E. coli* strains belonging to this pathogenic group circulate predominantly in the human host, particularly in low-income countries, and their existence is ensured by their capability to survive either in the host, where they usually cause uncomplicated diarrhea, or in the environment (out-of-the-host phase), where they are released with human feces. In turn, the environment, particularly surface waters, represents the main vehicle for spreading the infection, thus completing the epidemiological cycle.

In the human host, EAEC usually do not come into contact with the Stx phages, which have an animal reservoir and are particularly abundant in the gastrointestinal tract of ruminants and environments contaminated with ruminants' manure. It is conceivable that, in areas of the globe characterized by poor hygienic conditions, a high load of pathogenic *E. coli* of human origin, such as EAEC, can be released with insufficiently treated sewage into an environment also contaminated with animal feces. When such human *E. coli* strains are forced to coexist in the same niche with strains from animal sources, they may undergo remodeling of their genomes by the action of MGE. In the case of the epidemic *E. coli* O104:H4 strains, an EAEC belonging to this serotype may have represented a suitable recipient for an Stx2 bacteriophage.

In agreement with the model proposed, the *E. coli* O104:H4 epidemic strain seems to have originated in a low-income country, because the sprouts that caused the outbreak were produced in Germany from fenugreek seeds produced in a rural area of Egypt.

Pathogenesis of Human Infections

STEC infection is usually acquired by ingestion of contaminated food or water or by close contact with ruminants, contaminated environments, or infected persons. Illness can result from a very low infective dose, for example, <100 cells. The pathogenetic process initially involves colonization of the gut. Highly pathogenic STEC, like *E. coli* O157 and O26, adhere to the intestinal mucosa with the characteristic A/E mechanism. They later release large amounts of Stx in the intestinal lumen, which pass through the intestinal epithelium to target the endothelial cells lining the small blood vessels in the gut, kidney, brain, and other organs. The clinical manifestations include HC and HUS. The latter condition usually occurs in children below 5 years of age and is the major cause of acute renal failure in childhood. Besides the direct damage on endothelial cells, the Stx-induced activation of prothrombotic and proinflammatory cascades has a leading role in the development of HUS and central nervous system complications. Progression to HUS may depend on both the characteristics of the infecting STEC strain and host factors. Usually, STEC strains associated with HUS produce Stx2 and cause A/E lesions.

Laboratory Diagnosis of Human Infections

Laboratory diagnosis of human infections is important to perform appropriate treatment early in the course of infection, to timely detect and respond to outbreaks, and to identify emerging serotypes and monitor trends in STEC epidemiology.

For STEC isolation, colonies grown upon media suitable for *E. coli* may be tested for Stx production by immunoassays or presence of *stx* genes by polymerase chain reaction (PCR). Commercial kits are available for both purposes. STEC isolates should be forwarded to public health laboratories for confirmation and serotyping. Noncultural methods are based on the detection of free Stx in feces by using either the Vero cell cytotoxicity assay or commercial immunological assays. A serological diagnosis can also be made by detecting circulating antibodies to the lipopolysaccharide (LPS) of STEC O157 or other serogroups most involved in human infections.

Epidemiology of STEC

Human Infections

In 1982, STEC O157 was first identified as a human pathogen capable of causing foodborne disease. During the 1980s, the outbreaks caused by this new pathogen became a serious public health problem, mainly in North America and the United Kingdom. The food vehicles involved were hamburgers or other beef products, and thus this infectious disease came to be known as the 'hamburger disease' to the public. In the 1990s, STEC infections were reported throughout the industrialized world and serogroups other than O157, such as O26, O103, O111, and O145, were recognized as a frequent cause of bloody diarrhea and HUS. The last decade has been characterized by outbreaks associated with an enlarged spectrum of food vehicles, mainly of vegetal origin, or due to environmental exposures.

One of the most important features of the epidemiology of STEC infections is the occurrence of outbreaks of food- or waterborne origin in the community, often involving high numbers of cases, over long periods of time, and in large geographic areas. The German outbreak by STEC O104:H4 represents a typical, dramatic example of such outbreaks. Some of the major outbreaks that occurred in the world are reported in Table 1, according to their source. Smaller outbreaks due to secondary person-to-person transmission of STEC infection are also frequently reported in specific settings, such as schools, day care centers, and households, especially when a child is the primary case-patient.

The prompt recognition and management of outbreaks and implementation of specific strategies to control the spread of the infection in the community should be based on reliable surveillance systems, covering not only the epidemic outbreaks but also sporadic cases of infection. As a matter of fact, sporadic cases of severe illness, such as bloody diarrhea and HUS, may reveal a wider circulation of STEC strains in a community and should be considered as possible syndromic sentinel events of possible underlying clusters of infections.

HUS represents the most peculiar clinical manifestation of STEC infection in children and usually requires specialized treatment in pediatric nephrology units. Therefore, due to its high predictive value of STEC infection, it is targeted as a key event in STEC surveillance in many countries. HUS is considered a rare disease and children with HUS represent only a

Table 1 Major outbreaks of STEC infection, according to their source and setting

Year	*Number of cases*	*Country*	*STEC serogroup*	*Source/setting*
1990	174	Japan	O157	Well water
1990	633	Scotland	O157	Drinking water
1992	9[a]	Italy	O111	Unknown
1993	501	USA	O157	Hamburger (restaurant chain)
1994	>100	Scotland	O157	Contaminated pasteurized milk
1995	21[a]	Australia	O111	Fermented sausages
1996	>10 000	Japan	O157	Alfalfa sprouts
1996	120	Scotland	O157	Cross contaminated meat
1996	45	USA	O157	Unpasteurized apple juice
2000	2300	Canada	O157	Drinking water
2003/2004	25	Denmark	O157	Organic pasteurized milk
2005	135	Sweden	O157	Lettuce
2005	69	France	O157	Frozen beef burger
2006	196	USA	O157	Fresh spinach
2006	67	USA	O157	Green onions
2006	17	Norway	O103	Cured mutton sausages

small proportion of the overall number of cases of STEC infection in a population. However, the occurrence of a single case of HUS should alert public health authorities to the potential exposure of other people in the community to an active source of STEC infection. A wider surveillance approach could consist of extending the target population to adults and persons with bloody diarrhea, which is also strongly associated with STEC infection. Effective surveillance of STEC infection in public health should not only rely on syndromic surveillance systems, such as those based on early detection of STEC in HUS or bloody diarrhea, but also integrate molecular typing data. This would be of great benefit in terms of timeliness and sensitivity of surveillance and outbreak detection.

STEC infections are usually considered a problem in industrialized countries with respect to low-income countries, probably because of differences in the production and distribution of food. However, the entity of the problem in the latter areas could be underestimated, due to the lack of surveillance systems. In industrialized countries, STEC infections contribute significantly to the overall burden of enteric diseases, in particular for the occurrence of severe long-term sequel, which are usually associated with a high degree of disability.

In the European Union (EU), STEC were given a high priority among zoonotic pathogens since the beginning of the last decade, and STEC infections are subjected to compulsory monitoring in Member States, under the surveillance system coordinated by the European Center for Disease Prevention and Control. Moreover, as a foodborne zoonosis, prevention of STEC infections is primarily approached through harmonized control policies along the whole food production chain.

Animal Reservoirs

The presence of STEC has been reported in numerous animal species, but ruminants, and in particular cattle, represent the major reservoir of STEC, being asymptomatic shedders of these organisms, which are part of their gut microflora. Although most bovine STEC strains do not exhibit the accessory virulence factors associated with human disease and are not found in human infections, cattle are considered to be the most important source of human infections with STEC O157.

The prevalence of STEC O157 in cattle feces appears to be influenced by the age of the animals, and is higher in post-weaned calves and heifers than in younger and older animals. It also depends on the season, as increased rates of fecal shedding have been repeatedly reported in summer months. Carriage of STEC O157 is usually short, but some animals, designated as super-shedders, have been reported to shed high numbers of the organism for long periods of time, and could play a major role in the transmission of STEC O157 to human beings.

STEC, including those belonging to O157 serogroup, have also been isolated from other farm animals, such as pigs or poultry, or from domestic animals and synanthropic rodents

and birds. However, carriage by nonruminant species is rare and it is likely that these animals do not represent actual hosts but are transiently colonized by STEC after contacts with ruminant manure.

Routes of Transmission and Food Vehicles

STEC are considered typical foodborne pathogens. However, the epidemiology of STEC infections has remarkably evolved during recent years and new routes of transmission have emerged, including the direct contact with animals and a wide variety of environment-related exposures. Outbreaks associated with direct animal contact have frequently occurred during school visits to farms or petting zoos, but also among persons attending fairs, after direct contact with animals on display. Waterborne outbreaks have been less frequently described, but they often involved large number of persons. Ruminant's manure washed out from the nearby environment can cause contamination of drinking water supplies in rural settings, but outbreaks have also been associated with swimming in contaminated lakes.

Although all these routes of transmission have to be carefully considered during outbreak investigations, contaminated foodstuffs still remains the most important source of STEC infections, with a wide variety of foods that can be involved in STEC transmission.

Outbreaks have been historically associated with undercooked ground beef and raw milk, products of bovine origin that can be contaminated during slaughtering and milking operations. However, a growing number of outbreaks have been traced back to fruits and vegetables during the recent years, thus increasing the concern that plants might be more important as a vehicle for STEC infections than previously thought. Vegetables can be contaminated during either the preharvest or postharvest operations, and some of the associated outbreaks have caused large numbers of cases and heavily affected the consumers' demand for the fresh produce categories involved, with serious economic consequences for the related agriculture activities. The recent outbreak of STEC O104:H4 in Europe, associated with the consumption of contaminated sprouts, besides an extremely high burden of human casualties and health-associated costs, caused a dramatic reduction of consumer confidence in vegetable consumption, a drop of the vegetable market as a whole, and trade disputes between the EU and some non-EU countries.

STEC can move from animal reservoirs via their feces into the environment, including soil, surface, and ground water, leading to contamination of crops and entire food chain. As a matter of fact, manure, soil, and irrigation water are important sources of the STEC that contaminate plants. The interactions between vegetables and STEC may be considerably more complex than previously thought. It has been shown that *E. coli* O157 is able to colonize the exterior as well as the interior of lettuce and tomato seedlings grown in soil amended with contaminated manure, and these interactions could make it difficult to remove the bacteria from contaminated produce only by washing. Fresh produce like lettuce, tomatoes, and coleslaw are established vehicles of STEC infection, as well as unpasteurized fruit juices, which are increasingly popular among consumers. An increasing role is played by contaminated sprouts, which have caused several episodes of both STEC infections and salmonellosis. As shown in the recent outbreak of STEC O104:H4 in Germany, contaminated seeds represent the most frequent source of sprout contamination. The risk for human infections is increased by the low infectious dose (<100 organisms) of STEC, which has been demonstrated, at least for STEC O157 and O111, by microbiological testing of food consumed by persons who became ill during outbreaks sustained by strains belonging to these serogroups.

Detection of STEC in Food

STEC are characterized by a low infectious dose, thus their detection in food require the use of very sensitive methods. The detection approaches commonly used in food microbiology, based on the use of selective/differential media, are not applicable for the detection of these pathogens, due to the difficulty to discriminate STEC from the commensal *E. coli* that are frequently present in food samples.

Some of the pathogenic STEC serogroups, such as O157 and O26, display phenotypic features suitable, in principle, for their detection using cultural approaches. In fact, these strains are not able to ferment sorbitol or rhamnose, respectively, and thus can be discriminated from the majority of other *E. coli* on solid media containing these sugars. However, these biochemical features are not completely reliable. As a matter of fact, sorbitol-fermenting strains of STEC O157 have become a public health issue, with growing reports concerning severe cases of infections, and rhamnose-fermenting STEC O26 have been reported as well. Furthermore, even in the presence of these metabolic features there is no certainty that a given *E. coli* strain is indeed a STEC.

Detection of *E. Coli* O157 in Food and Feed

A cultural method, the international standard International Organization for Standardization (ISO) 16654:2001, has been developed a decade ago for the detection of *E. coli* O157 in food. It is based on the use of magnetic particles coupled with antibodies raised against the O157 LPS antigen, used to specifically capture and concentrate the bacterial cells exposing this O-antigen that are present in the preenrichment cultures of food samples. The coated beads are kept in contact with an aliquot of the preenrichment culture and later plated onto MacConkey agar plates containing sorbitol in place of lactose (SMAC), where *E. coli* O157 forms white colonies among the wealth of other *E. coli*, which grow forming red colonies. The selection of *E. coli* O157 is favored by the addition to the SMAC plates of supplements such as cefixime and K-tellurite. These compounds exert an antimicrobial action toward the majority of the bacteria possibly present in an enrichment culture from a food sample, but do not influence the growth of *E. coli* O157.

Although being very effective in identifying and isolating *E. coli* O157, the ISO 16654:2001 method has important

limitations as a tool for the routine control of foods. In particular, it is not able to detect the other STEC serogroups causing severe disease, and it doesnot allow to distinguish between the *E. coli* O157 strains that produce Stx and those that do not have this capability.

Detection of Non-O157 STEC in Food

To face the public health risks related to the exposure of EU consumers to pathogenic STEC, the European Commission entrusted the European Normalization Committee (CEN) with the task of developing an international standard aiming at the detection of all the pathogenic STEC in food and feed. This resulted in the development of a laboratory procedure destined to the detection, in these matrices, of highly pathogenic STEC matching the definition issued by EFSA. The draft document has been approved by CEN in 2008 in its first form and modified after the STEC O104:H4 outbreak occurred in Germany and France in 2011, with the aim of widening its scope by including a larger spectrum of pathogenic verocytotoxin-producing *E. coli* (VTEC). The final document has been approved and published by the ISO in November 2012 as the ISO Technical Specification 13136.

This method is based on the PCR screening of enrichment cultures of food samples for the presence of the genes *stx*1 and *stx*2, as well as of genes specifically associated with the highly pathogenic serogroups, such as the *eae* gene and those associated with the LPS antigens O157, O26, O103, O111, and O145.

PCR technology is no longer just a privilege of research laboratories but also its variant Real Time PCR, which allows following the reaction in real time and can benefit from an increasing number of companies dealing with the production of reagents for the molecular screening of foodstuffs for the presence of microbial pathogens, including STEC. ISO/Technical Specification (TS) 13136 allows a quick identification of the negative food samples by excluding those negative to the *stx* PCR and allowing their release in less than 24 h.

Samples positive for the *stx* genes can be tested for the *eae* and five serogroup-associated genes before the isolation step. For samples positive for one of the five serogroups, isolation can be facilitated by using immunomagnetic separation (IMS) techniques similar to that recommended by the ISO 16654:2001 method for the detection of *E. coli* O157. Magnetic beads coated with antibodies directed against the five pathogenic VTEC serogroups are commercially available and the information on the serogroup obtained in the PCR screening step will indicate the appropriate IMS reagent. Otherwise, colonies selected on general *E. coli* media (e.g., Tryptone Bile X-Glucuronide (TBX) or eosin–methylene blue (EMB)) will be tested for the presence of *stx* genes identified in the first screening of the enrichment culture.

Regulatory Context for STEC in Food

An epidemiology-based approach has been used in the United States (US) to develop regulations for the detection of VTEC in particular food matrices and the associated methodologies. The Centers for Disease Control and Prevention estimated that approximately 36% of the foodborne STEC illnesses occurring in the US each year are caused by *E. coli* O157:H7. This implies that the remaining 64% of the total 175 905 domestically acquired foodborne illnesses associated with STEC annually are caused by non-O157 STEC. Because of its lethality, in 1994, the Food Safety and Inspection Service (FSIS) at the United States Department of Agriculture (USDA) has considered STEC O157:H7 to be an adulterant of raw nonintact beef products and the raw intact components used to manufacture these products. Since then, these food commodities are tested for the presence of the bacterium and a recall is sought if food is found contaminated with *E. coli* O157:H7.

The characterization of the STEC strains isolated from human cases of severe disease showed that most of the confirmed non-O157 STEC illnesses are caused by STEC belonging to the following six serogroups: O26, O45, O103, O111, O121, and O145. This epidemiological picture seems to overlap to the distribution of the STEC serogroups causing severe disease in the EU with the exception of the O45 and O121 serogroups, which appear to be underrepresented in Europe.

In the US, ground beef products have been identified as the source of at least one outbreak and several sporadic cases of non-O157 STEC infection. Moreover, the six non-O157 STEC serogroups most involved in human disease have been isolated from slaughtered cattle in the US and cattle and beef products, including trims and ground beef, in several countries. In 2011, because of the increasing public health concern, FSIS announced to the public its intent to declare the six non-O157 STEC serogroups most involved in human illnesses, O26, O45, O103, O111, O121, and O145, as adulterants in nonintact raw beef products and product components. This rule has been enforced on 4 June 2012, and relies on the availability of a detection method developed by FSIS. The proposed detection and isolation approach for non-O157 STEC is equivalent to the one adopted in the EU and described by the international standard ISO TS 13136 (*see* Section Detection of Non-O157 STEC in Food). Similar to the ISO standard, the FSIS method is based on the real time PCR screening of food enrichment cultures for the presence of the STEC main virulence genes (*stx* and *eae*) followed by the screening for serogroup-associated genes. The whole FSIS methodology is described in chapter MLG 5B.00 of the FSIS *Microbiology Laboratory Guidebook*, available in the FSIS web site. The FSIS policy is based on the advice to the establishment to hold the sampled product and not release it pending negative test results. If test results are positive and the product has been released into commerce, FSIS will request that the producing establishment recall that product.

At present, specific microbiological criteria for STEC do not exist in the EU legislation on food safety. However, they are in the process of being introduced in the year 2013; among the specific rules for the enforcement are the hygiene of sprout production that will be adopted following the STEC O104:H4 outbreak. Such a microbiological criterion will be included in the amendment of the EU regulation 2073/2005 that recently passed the first stage of approval and should include the absence in 25 g of sprouts of STEC belonging to serogroups O157, O26, O103, O111, O145, and serotype O104:H4.

Conclusions

STEC represent one of the most dangerous foodborne pathogens, because of the severe clinical manifestations of the infection and capability to cause large, community-wide outbreaks. The epidemiology of STEC infections has remarkably evolved during the last 10 years. The organisms have been reported in a large variety of domestic and wild animals and new routes of transmission have emerged, like the direct contact with animals and a wide variety of environment-related exposures. Nonetheless, consumption of contaminated food still remains the most important route of transmission. Beside the classical foods of animal origin, an increasing role has been played by fruits and vegetables, which have been associated with several outbreaks. Contaminated sprouts have deserved particular attention, especially after the severe outbreak of *E. coli* O104:H4 infections that recently occurred in Germany. The huge human, economic, and political consequences of that outbreak prompted the European Commission to reconsider the safety rules for the production of sprouts intended for direct human consumption, that are currently under discussion.

In general, the strategies for the control of STEC infections must be based on the application of the general principles of food hygiene in all the steps of the food production chain. In particular, cross contamination between raw and ready to eat products must be avoided, bearing in mind that several outbreaks have originated by gross failures in this principle. The STEC O104:H4 outbreak has also confirmed that the genomic plasticity of *E. coli* represents a powerful engine for the emergence of new *E. coli* pathotypes, which can occupy new ecologic niches and enter in our food chains, representing a continuous threat to consumers' health, challenging the food safety systems worldwide.

Cronobacter (Enterobacter) sakazakii and Other *Cronobacter* spp.

K Abdesselam and F Pagotto, Health Canada, Ottawa, ON, Canada

Glossary

Endotoxin A substance that is released when there is destruction of the bacterial cell wall. It is a constituent of the cell membrane, synonymously associated with the lipopolysaccharide.

Enterotoxin A protein produced by an organism that affects the gastrointestinal tract. An enterotoxin is a type of exotoxin that is secreted by bacteria.

Immunocompromised A condition where the immune system is weakened or impaired.

Opportunistic Able to become pathogenic when, for example, the host's resistance is impaired. An opportunistic infection is caused by an organism that is usually harmless.

Pathogenicity The ability of an organism to cause disease.

Virulence The degree in which an organism can overcome body defenses to cause disease.

Background

Cronobacter sakazakii, formerly known as *Enterobacter sakazakii*, is a foodborne pathogen that has drawn the attention of the scientific community for the last 50 years. This organism was first characterized in 1929 as a 'yellow-pigmented coliform' and was discovered to be the causative agent of septicemia in infants. In the 1960s, the emerging concern was suspected to be involved in two cases of terminal neonatal meningitis. By the 1980s, this pathogen was classified as a new species, *E. sakazakii*, and was found to severely affect infants and neonates, causing sepsis, necrotizing enterocolitis, and meningitis. *Enterobacter sakazakii*, though found in a wide range of environmental sources, has been predominantly linked to human illness via contaminated powdered infant formula (PIF). Overall, there have been a minimum of 111 reported cases of this severe infection in infants and neonates worldwide, leading to 26 deaths.

Characteristics of the Organism

Cronobacter sakazakii belongs to the genus *Cronobacter*, which is categorized in the family Enterobacteriaceae and like most species in this family, is considered to be an opportunistic pathogen. The species *sakazakii* was named after Riichi Sakazakii, a Japanese microbiologist whose research played an important role in the understanding of enteric bacteriology. At present, there are seven species within the *Cronobacter* genus that are used to classify the 15 biogroups of the formerly known *E. sakazakii*. They include *C. sakazakii*, *Cronobacter malonaticus*, *Cronobacter turicensis*, *Cronobacter muytjensii*, *Cronobacter dublinensis*, *Cronobacter condimenti*, and *Cronobacter universalis*.

Cronobacter spp. are Gram-negative organisms that are motile, peritrichously flagellated, oxidase negative, nonspore forming, nonacid-fast, and straight and rod shaped. The organism has dimensions of 0.3–1 × 1–6.0 μm. There are two types of colonies with distinct morphologies observed on trypticase soy agar (TSA) at 26–36 °C. One type of colony is dry, rubbery, and sticky due to a heteropolysaccharide that is believed to be produced. The second type of colony is smooth and nonsticky. Both colony types can produce a yellow pigment, a previously used phenotypic marker that is now not deemed to be as useful.

Cronobacter is a facultative anaerobe that can produce adenosine triphosphate (ATP) in the presence of oxygen via aerobic respiration and can change to fermentation to produce ATP in the absence of oxygen. *Cronobacter* spp. have a wide temperature range for growth, which range from 6 to 45 °C, with an optimal range of 37–43 °C. Certain species have the ability to grow at temperatures of between 4 and 47 °C. In the Enterobacteriaceae family, *Cronobacter* spp. are amongst the most thermotolerant. A study, conducted by Edelson-Mammel *et al.* (2005), demonstrated the ability of 12 *Cronobacter* strains to survive heating in rehydrated PIF at 58 °C. The *D*-values at this specific temperature ranged from 30–35 s to 591–599 s, creating two general divisions of heat tolerance in the genus. The *D*-value for the most heat resistant strain was measured at 71 °C and was found to be 0–7 s. Iversen *et al.* (2004) predicted a 21-log reduction in the cell count of the pathogen if standard pasteurization process was used, thus indicating that the probable sources of contamination would include nonsterile equipment and/or additives.

Cronobacter spp. have the ability to survive in acidic environments with pH levels as low as 3. Of the members of the Enterobacteriaceae family, *Cronobacter* spp. also appear to be well adapted to dry stress. Lin and Beuchat conducted a study that determined the effects of water activity (a_w) and temperature on *Cronobacter* spp. recovered from infant cereal over a 12-month period. Results indicated an increase in a_w or

storage temperature increased the rate of death of *Cronobacter* spp. in dried infant cereal. Low levels, for instance 2 CFU per g of *Cronobacter* were shown to persist and survive in infant cereals for as long as 12 months in low a_w infant cereal.

There are many phenotypic differences between *Cronobacter* spp. and species belonging to the family of *Enterobacteriaceae* that have been described. The biochemical characterizations used to differentiate the currently known and/or described *Cronobacter* spp. are shown in Table 1.

Reservoirs

Cronobacter spp. are ubiquitous organisms that have been isolated from a wide variety of foods including milk, cheese, dried foods, meats, water, vegetables, rice, bread, tea, and herbs. The most common source associated with human outbreaks appears to be contaminated PIF. Clinically, this pathogen has been isolated from cerebrospinal fluid, bone marrow, blood, intestinal tract, respiratory tract, urine, ear and eye swabs, and skin wounds. At the environmental level, they have been isolated in dust, soil, plant materials, and in household environments, such as vacuum cleaner bags. It is clear that this bacterium has an ecological niche that is very broad; however, its primary reservoir has yet to be determined. There are postulations that plant material may be the primary reservoir.

PIF is the vehicle that is predominantly linked with outbreaks of *Cronobacter* infections in infants and neonates. Possible sources of contamination include ingredients that are added to PIF without prior heat treatment, and thermally sensitive ingredients that are used in the production of PIF. Thus, it appears that raw materials are an important source and possible initial step for the entry of *Cronobacter* spp. in PIF. Other sources of contamination include utensils, equipment used to handle PIF in hospitals and kitchens, and feeding tubes.

New Classification

Before *E. sakazakii* was recognized as a new species and later renamed *C. sakazakii*, it was referred to as yellow-pigmented *Enterobacter cloacae.* Deoxyribonucleic acid (DNA)–DNA hybridization results showed that *C. sakazakii* was 53–54% related to two distinct genera: *Enterobacter* and *Citrobacter*. However, pheno- and genotypic tests determined that they were closer to *E. cloacae* than *Citrobacter freundii*, thus, the new species was included in the *Enterobacter* genus. After the pathogen was classified, 15 biogroups were further identified with suggestions that they represented multiple species of *Enterobacter*. Iversen *et al.* (2008) investigated several different strains of *E. sakazakii*, and based on fluorescent amplified fragment length polymorphism (f-AFLP) fingerprints, ribotyping, and full-length 16S ribosomal ribonucleic acid (rRNA) gene analyses, proposed a reclassification of this species. Phenotypic profiling, using 14 biochemical characteristics, permitted better differentiation of the species (Table 2). Joseph *et al.* (2011) recently reported a new species, *C. condimenti*, and reclassified *Cronobacter genomospecies* 1 as *C. universalis*, while further evaluating *Cronobacter* strains 1330 (formerly *sakazakii*), NCTC 9529, 731 (formerly *genomospecies* 1), and 96 and 1435 (formerly *turicensis*) isolated from a wide range of sources from spiced meat to leg infections.

Clinical Manifestations and Features

Cronobacter is an opportunistic pathogen that has been associated most frequently with sporadic cases of life-threatening illness; in which individuals, suffering from a compromised immune system, neonates and infants less than 28-days old and/or low-birth weight are more susceptible. There are three major clinical manifestations seen in *Cronobacter* infections: necrotizing enterocolitis (NEC), septicemia and meningitis, and cerebritis.

Table 2 Draft recommendations on PIF guidance in home or professional settings such as hospitals and daycare centers

Preparation should take place in a clean environment where counters have been cleaned and sanitized Hands should be thoroughly washed using soap and lukewarm water
Bottles, spoons, and teats/nipples should be sterilized in boiling water for 2 min and then air-dried before use or storage. Bottles and equipment should be kept covered until ready-for-use
For preterm and low-birth weight infants under 2 months of age or immunocompromised infants, water for preparing PIF should be brought to a rolling boil for 2 min before dispensing into containers of a maximum of 1 l and then cooling down to no less than 70 °C, after which the powder can be added. For all other infants, previously boiled water that has been cooled to room or body temperature (37 °C) can be used to prepare PIF, but it should be served immediately to the infant
Formula that has been mixed or prepared with boiled water, which has been cooled to 70 °C, should be further cooled down to room or body temperature before serving, to avoid scalding of the infant's mouth
It is best to prepare and serve PIF immediately after cooling to body temperature. Reducing the time from preparation to consumption will reduce the risk to infants. Formula in bottles can be cooled quickly by holding the bottle under running tap water or placing in a container of cold water as long as the cooling water is below the teat/nipple
If it is not possible to serve immediately, prepared formula in bottles or other types of containers should be refrigerated at 4 °C or lower, immediately after the powder has been added and dissolved in water. The prepared formula should be used within 24 h
Owing to the possibility of the growth of harmful bacteria at temperatures above 4 °C, stored formula should be removed from the refrigerator and rewarmed to room or body temperature, only immediately before feeding and not in advance. PIF should not be left warming for more than 15 min as rewarming for extended periods means that the PIF will be held at a temperature that is ideal for the growth of bacteria
Once feeding has started, the individual bottle should be used within the next 2 h. Any leftover formula should be discarded

Abbreviation: PIF, powdered infant formula.

Several risk analyses have been conducted, with Bowen and Braden's recent results indicating the most common symptom associated with *Cronobacter* infection in neonates and infants is meningitis. Meningitis caused by *Cronobacter* is established between the fourth and fifth day after birth and can be fatal within hours to a few days. Neonatal infections have a mortality rate of 40–80%, and infants or neonates who survive the infection are often left with severe and often irreversible neurological disorders. Neurological sequelae include brain abscess, ventricle compartmentalization due to necrosis of brain tissue and liquefaction of white cerebral matter, hydrocephalus, cyst formation, and pulmonary, urinary or blood-stream infections.

The Centers for Disease Control and Prevention have estimated six new cases of *Cronobacter* infection per year, worldwide. The lack of awareness of the organism and adequate isolation methods may contribute to the under reporting. Even though the numbers of reported cases of *Cronobacter* infections are low compared to other pathogens, the outcomes of the outbreaks are severe, leading the International Commission for Microbiological Specifications for Foods to conclude that *Cronobacter* spp. are a severe hazard for restricted populations, causing life-threatening or substantial chronic sequelae.

Infants and neonates are the primary targets of the pathogen; however, immunocompromised adults, including the elderly, are also susceptible to *Cronobacter* sp. There have been at least 20 reported cases of *Cronobacter* infections in adults. The symptoms for adults included pneumonia, sepsis, foot ulcers, wound infections, osteomyelitis and splenic abscesses. Stroke patients' mouths are severely affected by *Cronobacter*. Stroke patients seem to be susceptible to Gram-negative bacilli colonization in the mouth through liquid food supplementation, such as reconstituted starch powder which at times may also contain *Cronobacter*. The generic treatment given to these stroke patients are first line antibiotics. However, *Cronobacter* can be resistant to these types of antibiotics.

Antimicrobial agents that are effective against this pathogen include acylureidopenicillins, aminoglycosides, ampicillin, antifolates, aztreonam, carbapenems, cephalosporins, chloramphenicol, nitrofurantoin, quinolones, tetracyclines, ticarcillin, and several β-lactams. *Cronobacter* spp. show resistance to oxacillin, benzylpenicillin, clindamycin, and some macrolides. If the symptoms in infants or adults are seen at an early stage of infection then antibiotics can be used to treat the patient more effectively and with minimum complications than at a later stage.

Virulence Factors and Pathogenicity

Very little is known of the virulence factors involved in the pathogenicity of *Cronobacter* spp.; however, in the past decade, much progress has been made. **Figure 1** summarizes our current model and highlights the relationship between the pathogen and the host.

The main route of entry for *Cronobacter* spp. appears to be through ingestion; therefore, factors related to contamination should be addressed. The vehicle of *Cronobacter* infections in infants and neonates is contaminated PIF. Major determinants that contribute to the presence and growth of the organism in PIF include temperature, equipment, and biofilms. PIF is normally stored at room temperature, which is approximately 23 °C. The optimal temperature for *Cronobacter* spp. is 37 °C; however, it has the ability to grow between 6 to 45 °C. PIF are nonsterile, therefore, the composition of PIF and storage temperature of reconstituted PIF can enhance the growth of the organism. Another factor that has been found in the constitution of PIF is lipopolysaccharide (LPS). LPS, a heat-stable endotoxin that has been shown to be present in PIF, appears to play a role in compromising the intestinal barrier integrity, by allowing the organism to cross the gastrointestinal (GI) tract and become bloodborne.

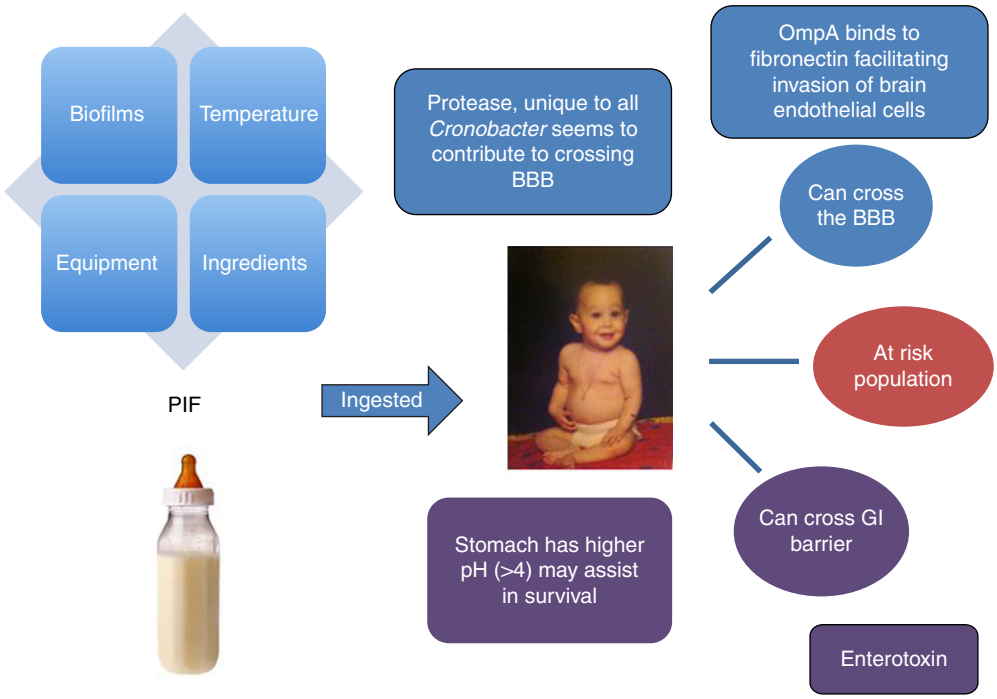

Figure 1 A current model of *Cronobacter* pathogenicity. BBB, blood–brain barrier; OmpA, outer membrane protein A.

Extrinsic contamination of reconstituted PIF can come from utensils such as blenders, brushes, and spoons. Biofilms, broadly defined as a community adhering to a surface, are an important factor in the ecology of *Cronobacter* spp.. Abiotic surfaces have been used to demonstrate *Cronobacter*'s ability to form biofilms on materials commonly associated with PIF-feeding equipment and surfaces such as glass, stainless steel, polyvinyl chloride, polycarbonate, silicone, and enteral feeding tubes.

There are three areas of focus addressing the biofilm issue in *Cronobacter*: (1) understanding the physiology and genetic basis of biofilms (i.e., identifying key genes and/or conditions), (2) determination of whether biofilm formation is a virulence factor for *Cronobacter* pathogenesis, and (3) evaluation and determination of treatments and their efficacies in reducing biofilm formation. Amalaradjou and Venkitanarayanan have recently shown that *trans*-cinnamaldehyde, an ingredient in cinnamon oil, has the ability to inhibit and inactivate *C. sakazakii* biofilms in the presence or absence of PIF on polystyrene plates, stainless steel coupons, feeding bottle coupons, and enteral feeding tube coupons at both 12 and 24 °C. Hartmann *et al.* (2010) screened a library of mutants of strain ES5 (clinical isolate of *C. sakazakii*) using the crystal violet microtiter assay and found four mutants defective in cellulose biosynthesis, three in flagellar structure, three in key metabolic functions (e.g., cell division, energy metabolism, and acid fermentation), one virulence and four unknown functions. Of the 14 mutants, two hypothetical proteins ESA_00281 and ESA_00282 proved to be important in biofilm formation structure.

One of the first efforts describing putative virulence factors was by Pagotto *et al.* (2003) where, using a suckling mouse assay, *Cronobacter* spp.' ability to produce an enterotoxin were demonstrated. Their observations were further supported by *in vitro* assays using Chinese hamster ovary (CHO), Vero, and Y-1 cells, where many *Cronobacter* strains exhibited cytopathic effects. Raghav and Aggarwal later purified and identified biochemical characteristics of the enterotoxin. The purified toxin confirmed the Pagotto *et al.* (2003) study as it demonstrated cytopathic effects in the suckling mouse assay. The toxin was reported to have a mass of 66 kDa, optimal activity at pH 6 and was heat stable, showing activity after exposure to 90 °C for 30 min. Pagotto *et al.* (2003) also described the dose–response relationships for *Cronobacter* infection using mice. Intraperitoneal injection with levels of bacteria as low as 10^5 CFU per mouse were shown to be lethal. The dose–response for the suckling mouse assay, however, may not necessarily be a good representation of the dose–response for human neonates, for which the oral infectious dose has been estimated by the World Health Organization (WHO) to range from 10^3 to 10^8 CFU.

The gastrointestinal tract is a primary target for *Cronobacter* pathogenesis and the organism's success in causing human illness is dependent on its ability to adhere to the intestinal epithelial layer. Hunter *et al.* (2008) have reported that *Cronobacter* spp. bind to enterocytes in rat pups and a cascade of host responses are triggered, which include tumor necrosis factor-alpha, nitric oxide, and interleukin-6. This was also observed when *Cronobacter* attached to the enterocytes of rat pups, where there was an increase in enterocyte apoptosis. This increase in apoptosis results in a decrease in the barrier integrity that appears to facilitate bacterial translocation. Adhesion to intestinal cells appears to be a necessary step in colonization of the intestinal tract, which induces NEC and invasion in the animal model and in IEC-6 cells, a rat

intestinal cell line. A recent study conducted by Emami *et al.* (2011) used a mouse model and Caco-2 cells to show that *C. sakazakii* damages the intestinal epithelial cells by recruiting a large amount of dendritic cells in the intestine and suppressing their maturation, which increases the transforming growth factor (TGF)-β production and results in NEC in the host.

Adhesion and invasion of the BBB and the gastrointestinal tract are crucial for infections of *Cronobacter* spp. in the host, and a better understanding of these processes would help in unraveling the mechanism(s) of pathogenesis. Mammalian tissue culture assays are a popular approach to investigate the adhesive and invasive properties. The most common cell lines used to study the adherence and invasion are HEp-2, Caco-2, and human brain microvascular endothelial cells (HBMECs). Mange *et al.* (2006) screened 50 *Cronobacter* strains and found two distinctive adherence patterns in all three cell lines tested. They were described to be either diffuse adhesion or formation of localized clusters of bacteria on the cell surface. Some strains were able to show both patterns. Mange *et al.* (2006) also demonstrated that adherence was optimal during late exponential phase of bacterial growth with a 10-fold increase in adherence cells, and also concluded that adhesion to epithelial and endothelial cells was predominantly nonfimbrial based. Townsend *et al.* (2007) studied the attachment and invasion properties of seven different *Cronobacter* strains, associated with outbreaks of different illness such as necrotizing enterocolitis, bacteremia, and meningitis, using Caco-2 cells and rat-brain capillary endothelial cells. All seven strains attached to, and invaded Caco-2 cells after 3 h. These particular isolates have the ability to replicate and adapt in macrophage cells, U937.

Bacterial translocation from the gastrointestinal barrier is critical in the pathogenesis of *Cronobacter* meningitis. Translocation from the GI tract will allow the bacteria to have access to the blood stream, which may also lead to sepsis in the host, while giving access to the BBB and eventually the central nervous system. *Cronobacter* spp. are able to overcome host defensive mechanisms, penetrate the BBB and survive in the cerebrospinal fluid. One virulence factor that has been shown to be essential in *Cronobacter* pathogenesis is OmpA. Interestingly, OmpA plays a role in the suppression of the maturation of dendritic cells. OmpA expression is also required for invasion of mammalian host cells and is necessary for *Cronobacter* resistance to blood and serum killing in newborn rats. Mittal *et al.* (2009) have shown that *Cronobacter* expression of *ompA* can successfully cross the intestinal barrier in newborn rats, multiply in the blood, and transverse the BBB; whereas *ompA* deletion mutants fail to bind to intestinal epithelial cells both *in vivo* and *in vitro*. Recent studies from Kim *et al.* (2010a) demonstrated that a protein OmpX is also required for translocation. They were the first to conduct inframe deletion mutants for OmpA and OmpX and showed that translocation does not occur in the host when both proteins are not expressed. Bioinformatic analyses of the *Cronobacter* BAA-894 genome and *E. cloacae* showed that *ompX* was found to be similar (81% identity) between the two organisms. OmpX in other bacteria, including *E. cloacae*, appears to play an important role in virulence as it assists in the invasion of the host cells and helps overcome host defenses. Kim *et al.* (2010a) have demonstrated using Caco-2 and INT-407 cells as well as rat pups that both OmpA and OmpX are required for translocation and basolateral invasion and adhesion of mammalian cells.

Singamsetty *et al.* (2008) noticed that several meningitis causing Gram-negative bacteria require the expression of OmpA to invade HBMEC. They demonstrated that OmpA was required in *Cronobacter* spp. to invade the BBB by inducing microtubule condensation and phosphoinositide (PI)3-kinase and PKC-α activation. Both Nair *et al.* (2009) and Mittal *et al.* (2009) have shown that OmpA binds to fibronectin, thereby facilitating the invasion of brain endothelial cells. Mittal *et al.* (2009) were the first to demonstrate that OmpA expression affects the onset of meningitis in newborn rats. Mortality rate was 100% when newborn rats were infected with OmpA positive strains whereas no pathological symptoms were observed when *ompA* deletion mutant strains were used.

Kothary *et al.* (2007) examined 135 different *Cronobacter* strains and identified a cell bound, zinc-containing metalloprotease encoded by a *zpx* gene. The protease was found to be active against azocasein, as well as causing the rounding of Chinese hamster ovarian cells. The *zpx* gene product may be responsible for allowing the organism to cross the BBB and may contribute to cellular destruction in neonates with NEC.

A virulence mechanism that seems to be common to species belonging to the family of Enterobacteriaceae is their active efflux. This active efflux ejects a range of xenobiotic compounds from the cell, including bile salts, antibiotics, disinfectants, and dyes.

Detection Methods

In 2002, the US Food and Drug Administration (FDA) described a modified method, based on work conducted by Muytjens *et al.* (1988) in detecting and isolating *Cronobacter* spp. from PIF. The protocol consists of several steps using multiple growth conditions in broth followed by plating on selective agar media. The first step requires enriching the PIF samples in water overnight. Second step is to further enrich the samples in Enterobacteriaceae enrichment (EE) broth for up to 24 h. Samples are plated on violet red bile glucose agar for overnight incubation and presumptive colonies purified onto TSA in which the incubation period ranges from 48 to 72 h. The resulting yellow-pigmented colonies are selected for biochemical tests using analytical profile index (API) 20E test strips. This method was lengthy, was not specific to *Cronobacter* spp., and was unable to discriminate between *Cronobacter* and other *Enterobacter* spp.

The International Organization for Standardization published a method in 2006 to isolate *Cronobacter* spp. from milk-based powdered formula. The method consists of preenriching the PIF samples in buffered peptone water at 37 °C overnight. The samples are then enriched in modified lauryl sulfate (addition of vancomycin) at 44 °C overnight. The samples are then plated on to chromogenic agar at 25 °C for a period of 48–72 h. For confirmation of *Cronobacter* spp., approved biochemical identification kits can be used. However, not all strains of *Cronobacter* have the ability to grow in the modified lauryl sulfate broth.

The FDA revised their 2002 method to incorporate both culture on chromogenic media and real-time polymerase chain reaction (PCR) for detection, which proved to be significantly better ($p < .05$) than the original method for detection of *Cronobacter* spp. The chromogenic media, developed by Iversen *et al.* (2004) was based on the work of Muytjens *et al.* on the α-glucosidase enzyme. Muytjens *et al.* identified a unique enzyme that was present in all 129 *Cronobacter* isolates tested. This enzyme appears to be unique to only *Cronobacter*, as the closely-related species *E. cloacae*, *Enterobacter aerogenes*, and *Pantoea agglomerans* were all negative for the enzyme. Media with the chromogenic substrate 5-Bromo-4-chloro-3-indolyl α-D-glucopyranoside (X-αGlc), yield *Cronobacter* colonies appearing blue–green on Druggan, Fosythe, and Iversen agar plate. The α-glucosidase present in *Cronobacter* spp. hydrolyzes X-αGlc to form a bromo–chloro indigo pigment, resulting in blue–green colonies.

In 2009, O'Brien *et al.* developed a one-step method for detection, to help address issues of lengthy and multiple enrichments. Their method consisted of a combined preenrichment/enrichment broth, *Cronobacter* enrichment broth ((CEB) formerly known as *Enterobacter sakazakii* enrichment (ESE) broth) combined with a selective-differential agar. The recovery of *Cronobacter* spp. from PIF using this protocol was significantly higher when compared with other enrichment broths. The advantage of this protocol is that it removes the need for separate preenrichment and enrichment steps, reducing the time for detection of *Cronobacter* in PIF. Al-Holy *et al.* (2011) evaluated a new enrichment broth known as Al-Holy–Rasco (AR) medium, which consists of a generic brain heart infusion broth with the addition of 1% NaCl, 15% sucrose, and 0.8 g l^{-1} sodium deoxycholate as selective ingredients. They used 10 different strains of *Cronobacter* to compare their enrichment media to EE, CEB, modified lauryl sulfate broth, and milk. AR media seem to support the growth of *Cronobacter* and suppress non-*Cronobacter* spp. better than the other media. Malorny and Wagner developed a reverse transcriptase (RT)–PCR specific for *Cronobacter* which targets 16S rRNA gene. This molecular assay is quick, shortening the process from 2 days to 2 h, and can detect *Cronobacter* at population levels of 10^3 CFU per ml in foods after enrichment. Seo and Brackett developed a more specific RT–PCR in which the principal of this technique was targeting a sequence within the macromolecular synthesis operon. The advantage of this method is that it can differentiate *Cronobacter* spp. from species belonging to the family Enterobacteriaceae. Its sensitivity of detection is approximately 100 CFU per ml in rehydrated PIF. If a 24 h enrichment step was included, then the sensitivity of the detection can be reduced to 0.6 CFU per g of PIF. Other target genes for RT–PCR detection methods for *Cronobacter* spp. have been described, which include the internal transcribed spacer sequence of the 16S–23S ribosomal DNA (rDNA), α-glucosidase gene (*gluA*), OmpA, and a zinc-containing metalloprotease. A recent PCR-based method was developed to differentiate the various species of *Cronobacter* that targets the *rpoB* gene, a β-subunit of RNA polymerase. This assay relies on single nucleotide polymorphisms in the *rpoB* gene using mismatch PCR.

Fluorescence *in situ* hybridization (FISH) has been applied in PIF for detection of low population levels of *Cronobacter* spp. The group described the use of a peptide nucleic acid probe combined with FISH to detect cells of *Cronobacter* in 10 g of PIF following an 8-h enrichment period. This was possible even when there were other bacterial populations present.

Preventive Measures

PIF is not a sterile product, and microbiological criteria to help food manufacturers minimize the risk of infections have been implemented. In 2004, the Food and Agriculture Organization of the United Nations and the WHO convened a joint meeting to discuss *Cronobacter* and other important microbial contaminants of PIF, with the aim to revise the 1979 Recommended International Code of Hygienic Infant Formula. In 2005, the document was released, and later updated in 2007. Highlights of the guidelines are based on infants that are more susceptible to infection and those that are not at risk. Infants who have a higher chance of infection are advised to consume sterile liquid infant formula, whereas infants who are not at risk have several options of PIF. Preparing PIF with water at a temperature of 70 °C is suggested as it was shown to reduce the potential for disease-causing organisms to survive. The 'hang-time,' the amount of time PIF is at room temperature in the feeding bag and accompanying lines during enteral tube feeding, has been recommended to not exceed 4 h. Reducing the time from preparation to consumption and storing the PIF at temperatures no higher than 5 °C for a maximum of 24 h have also been shown to be useful in minimizing the risk.

Health Canada has PIF guidance documents that are publicly available. These general recommendations are meant to assist individuals at home or in a professional setting, such as hospitals and daycare centers. A preliminary summary is shown in **Table 2**.

Disinfectants used to clean surfaces and reduce contamination are effective against planktonic cells. However, they appear less effective in decreasing survival of the organism when cells are part of a biofilm. Contamination can be associated with the utensils or machinery used to make PIF and *Cronobacter* spp. have been shown to form biofilms in those environments or surfaces associated with handling of PIF. Bacteriophages, viruses that infect bacteria, have been suggested to inhibit the growth of pathogenic microorganisms. Using sewage or ultraviolet irradiation of pure cultures, six bacteriophages were isolated by Kim *et al.* (2007). Two bacteriophages were demonstrated to control growth in both laboratory media and in reconstituted infant formula at 12, 24, and 37 °C. Phages at 10^7, 10^8, or 10^9 PFU per ml were used to demonstrate that higher temperatures (24 and 37 °C) and high titers (10^9) were required for contamination levels equivalent to 73 000 CFU per 100 g of PIF. Zuber *et al.* isolated 67 phages and reported that a cocktail of 5 phages were successful in preventing growth of 35 (of the 40) strains in artificially contaminated formula. Another strategy described by Hayes *et al.* (2009) was to use antimicrobial peptides produced by the fermentation of sodium caseinate using a proteolytic strain of *Lactobacillus acidophilus*. They identified two peptides derived from milk proteins, caseicins A and B, which may play a role as a bioprotective agent in dairy-based food products such as PIF.

A variety of phenolic compounds have been shown to have antimicrobial activity. A study by Amalaradjou and Venkitanarayanan (2011) demonstrated that malic, tartaric, and tannic acids have antimicrobial activity against *Cronobacter* sp. Kim *et al.* (2010b) have also shown that red muscadine juice can cause a 6-log reduction of *C. sakazakii* in commercial baby juices in approximately 2 h. Their results suggest that red muscadine could be used to prevent and/or control *C. sakazakii* in baby food formula. Recently, Yemis *et al.* (2011) investigated the antibacterial activity of vanillin, ethyl vanillin, and vanillic acid as possible preservatives in the intervention strategy for control of *Cronobacter* spp. They evaluated the effectiveness of the compounds on the growth and heat resistance. Vanillin, ethyl vanillin, and vanillic acid were shown to have bactericidal effects, prevented the growth of the organism and reduce the heat resistance in microbiological media.

When possible, mothers should be encouraged to breast feed and learn about health risks associated with infant formula. Human milk has been shown to prevent the growth of certain pathogens and protects infants and neonates from infections that can be achieved by protozoans, viruses, and bacteria such as *Staphylococcus*, Group B *Streptococcus*, *Escherichia coli*, and *Cronobacter* spp., in addition to providing maternal antibodies. Studies suggest that breastfed infants have lower chances of getting gastrointestinal, respiratory, and meningeal infections. Interestingly, work by Lenati *et al.* (2008) has shown that, *in vitro*, *Cronobacter* growth can occur in human breast milk.

Conclusion

Cronobacter spp. are important, emerging opportunistic pathogens that have the ability to survive in a variety of different environmental conditions. The number of reported cases of *Cronobacter* infections, although low compared to other foodborne diseases, primarily target high-risk populations, with a high mortality rate in infants and neonates. Our knowledge of the ecology, biology, and pathogenicity of this fascinating foodborne pathogen will no doubt continue to increase, resulting in improved detection and characterization, along with better intervention strategies, guidelines, and policies, for reducing the risk to human health.

Glossary

β-Lactam antibiotics A broad class of antibiotics, consisting of all antibiotic agents that contains a β-lactam nucleus in its molecular structure. This includes penicillin derivatives (penams), cephalosporins (cephems), monobactams, and carbapenems.
Cholecystitis A painful inflammation of the gallbladder's wall.
Infection, nosocomial An infection acquired in a hospital. Specifically an infection that was not present or incubating before the patient was admitted to the hospital, but occurred within 72 h after admittance to the hospital.
Septicemia Systemic illness with toxicity due to invasion of the bloodstream by virulent bacteria coming from a local seat of infection.
Spondylodiscitis Inflammation of an intervertebral disc or disc space which may lead to disc erosion.

Enterobacter species

Background to the Genus *Enterobacter*

The genus *Enterobacter* was first proposed by Hormaeche and Edwards in 1960 when the motile and ornithine decarboxylase (ODC) positive members of the genus *Aerobacter* were separated out as *Enterobacter* in order to distinguish them from the nonmotile and ODC negative *Klebsiella* strains. Since then taxonomic complications have led to the further reclassification of several *Enterobacter* species and the transfer of the following bacteria *Enterobacter intermedius* to the genus *Kluyvera* as *Kluyvera intermedia*, Enterobacter agglomerans to the genus *Pantoea*, and *Enterobacter sakazakii* to the recently described genus *Cronobacter*.

One of the most challenging issues associated with the genus *Enterobacter* relates to those strains misidentified as *Enterobacter cloacae*. *Enterobacter asburiae*, *Enterobacter cancerogenus*, *Enterobacter dissolvens*, *Enterobacter hormaechei*, *Enterobacter kobei*, and *Enterobacter nimipressurali* are all closely related to *E. cloacae* and are part of the '*E. cloacae* complex'. The taxonomy of this *E. cloacae* complex is mainly based on the assessment of DNA–DNA hybridization of the whole genome along with associated phenotypic characteristics. All species within this complex are of clinical significance and are increasingly being implicated as the causative agent(s) of local and systemic infections in humans.

Characteristics of the Genus *Enterobacter*

Enterobacter species are widely dispersed in nature and exist in a diverse range of environments including soil, water, domestic and food processing establishments, vegetation, vertebrate and invertebrate hosts, and in the feces of humans and animals. These bacteria generally grow well, aerobically and anaerobically, at temperatures ranging between 20 and 37 °C on general laboratory media at neutral pH. Although motility has been a distinguishing characteristic used to differentiate between *Klebsiella* and *Enterobacter*, some *Enterobacter* species are nonmotile (and these include *E. asburiae*, *E. dissolvens*, *E. nimipressuralis*) whereas others demonstrate a variable motility (such as *Enterobacter gergoviae*, *E. hormaechei*, *E. intermedius*, *Enterobacter pyrinus*). Fermentation by *Enterobacter* species is more limited when compared to some *Klebsiella* species. For example, *Enterobacter* produce gas from cellobiose and ferment rhamnose, a feature that distinguishes them from most species of *Serratia*. All *Enterobacter* are nonpigmented with the exception of the newly reclassified *Cronobacter* genus, formerly known as *Enterobacter sakazakii*.

Enterobacter Linked to Food Contamination

Enterobacter species can be cultured from a wide range of foods (Table 1). *Enterobacter cloacae* is a recognized contaminant of raw milk and dairy products such as yoghurt and cheese. *Enterobacter* have been identified in pasteurized milk and cream and in dried dairy products; possibly due to postprocess contamination, as these bacteria do not survive pasteurization. Powdered infant formula (PIF) is not sterile food and may contain low levels of pathogenic microorganisms. The most frequently isolated Enterobacteriaceae species include *E. cloacae*, *Cronobacter* species, *E. pulveris*, *Enterobacter helveticus*, *Pantoea agglomerans*, and *Klebsiella pneumoniae*. To a large extent research has been carried out on *Cronobacter* species (*E. sakazakii*) in PIF, with contamination by other *Enterobacter* receiving lesser consideration. Nevertheless *Enterobacter* species have the ability to cause infections and are a known contaminant of PIF;

Table 1 A summary of bacterial genera, species, and food matrices from where these bacteria were recovered

Genus	*Species*	*Food Sources*
Enterobacter	*aerogenes* *cancerogenous* *cloacae*[a] *cowanii* *gergoviae* *helveticus* *hormaechei* *ludwigii* *oryzae* *pulveris* *radicincitans* *turicensis*	Animal feed (dried pellets), beverages, chocolate, cream, cucumber, dairy products, eggs, fish, flour, fresh frozen or powdered fruit and vegetables, grains, herbs, infant food, legume products, meat, mulberry plants, nuts, parenteral nutrition, pasta, plants, sugar beets, pork, powdered infant formula (PIF), sausage, seeds, spices, tea, water, and wild rice
Klebsiella	*granulomatis* *ornithinolytica* *oxytoca* *planticola* *pneumoniae*[a] subsp. *ozaenae* subsp. *rhinoscleromatis* subsp. *pneumoniae* *variicola*	Alfalfa, bananas, bean sprouts, cold meat, hamburgers, ice creams, infant food, milk shakes, nasogastric food, powdered milk, rice, salads, sugar cane, sweets, and maize
Pantoea	*agglomerans*[a] *anthophila* *ananatis* *calida* *citrea* *deleyi* *dispersa* *eucalypti* *gaviniae* *punctata* *stewartii* *terrea* *vagans*	Banana, beetroot, bean plant leaf, carrot juice, mango, cereal, cluster bean, corn, foxtail millet, maize, mandarin, millet, pearl millet, pineapple, plants, roses, seeds, snail vine, soil, sorghum, and water
Serratia	*entomophila* *ficaria* *fonticol* *grimesi* *liquefaciens* *odorifera* *marcescens*[a] *plymuthica* *proteamaculans* *quinivorans* *rubidaea*	Cream, fruit, meat, milk, mushrooms, salads, starchy foodstuffs, and other vegetables
Cedecea	*davisae*[a] *lapegei* *species* 3 *species* 5	Mushrooms, salads, and vegetables
Edwardsiella	*hoshinae* *ictaluri* *tarda*[a]	Fish and water
Hafnia	*alvei*	Beef, cheese, cream, freshwater fish, honey, milk, pork products, vegetables, and water
Kluyvera	*ascorbata*[a] *cochleae* *cryocrescens* *georgina*	Milk and other foods
Leclercia	*adecarboxylata*	Water and other foods

[a]Denotes type species.

therefore these bacteria pose a food safety threat to public health and the PIF manufacturing industry alike.

Clinical Manifestation of Infections Linked to *Enterobacter*

Enterobacter species are now recognized as important nosocomial pathogens responsible for bacteremia, lower respiratory tract infections, pneumonia, skin and soft tissue infections, urinary tract infection (UTI), intra-abdominal and ophthalmic infections, endocarditis, septic arthritis, and osteomyelitis. Most occurrences of *Enterobacter*-associated infections are described as hospital-acquired where these bacteria are common contaminants of hospital surfaces, medical equipment, and hospital personnel. With the exception of *E. sakazakii* (*Cronobacter* species) the former sole member of this genus to be linked epidemiologically to food-borne infections, in general, *Enterobacter* species are more commonly associated with nosocomial infections. These bacteria can affect people of all ages, but are particularly relevant to immunocompromised individuals. *Enterobacter cloacae*, along with *Enterobacter aerogenes*, *E. hormaechei*, and *E. gergoviae* have been associated with infections in neonates. Risk factors in neonates include premature birth and low birth weight, which predisposes these vulnerable individuals to developing serious conditions and sometimes fatal outcomes.

Enterobacter cloacae, followed by *E. aerogenes*, are the two most common *Enterobacter* species cultured from clinical specimens in human infections, and are responsible for more than 90% of all cases. *Enterobacter asburiae*, *E. cancerogenous*, and *Enterobacter amnigenus* have also been reported to cause bacteraemia in adults. Risk factors associated with *Enterobacter* sepsis in children include parenteral nutrition, use of antimicrobial compounds, and indwelling catheters. Low birth weight, prematurity, length of hospital stay, invasive procedure(s), and overuse of antibiotics may put infants at an increased risk of infection.

Antimicrobial Resistance Among *Enterobacter* Species

Over the years many Enterobacteriaceae have become resistant to commonly used antimicrobial compounds and antimicrobial resistance among these organisms is an emerging problem. Use of antimicrobial agents in hospitals has resulted in an increase in resistance to many β-lactam antibiotics, particularly extended-spectrum β-lactamases (ESβLs) with approximately 25% of all *Enterobacter* species now being resistant to ESβL, due to the presence of a Bush group 1 chromosomal cephalosporinase. In a recent study by Sharma *et al.* (2008), 73.68% of isolates studied were found to be ESβL producers and the *ampC*-encoding gene was identified in all isolates tested. AmpC β-lactamase producing bacterial pathogens may cause major therapeutic failure if they remain undetected. Resistance to new cephalosporins, aminopenicillins, and cephamycins is due to mutants that can express large amounts of this enzyme. This limits the choice of a suitable antimicrobial agent to treat invasive infection. Antibiotic resistance can also be plasmid mediated with five aminoglycoside-modifying enzymes being detected on the same R-plasmid.

Among the *Enterobacter* species, *E. aerogenes* has emerged as an important hospital pathogen during the past 20 years due to its ability to adapt to environmental stresses. This bacterium now accounts for more than half of all Gram-negative organisms that produce ESβLs. The overexpression of genes that regulate and encode efflux pumps, may further contribute to the resistance profile of *E. aerogenes*.

Epidemiology of *Enterobacter*

Several methods have been developed to characterize strains of *Enterobacter* including antibiogram profiling, biotyping, serotyping, plasmid profiling, ribotyping, random amplification of polymorphic DNA (RAPD), arbitrarily primed-PCR (AP-PCR), repetitive sequence-based PCR (rep-PCR), enterobacterial repetitive intergenic consensus (ERIC) PCR, amplified fragment length polymorphism (AFLP), and pulsed-field gel electrophoresis (PFGE). PFGE has been used to investigate outbreaks in neonatal intensive care units (NICUs) involving *E. cloacae*, *E. aerogenes*, *E. gergoviae* and is currently regarded as the gold standard method for molecular subtyping of food-borne pathogens.

Culture Methods used for Isolation of *Enterobacter* Species

Most *Enterobacter* strains will grow on selective media for Enterobacteriaceae, including Violet Red Bile Agar (containing glucose or lactose), Hektoen, or MacConkey agar. Some *Enterobacter* species are reported to be susceptible to antimicrobial agents commonly used in media designed for the selection of Enterobacteriaceae. These selective formulations may include antimicrobial compounds, brilliant green or crystal violet dyes, bile salts, and sodium lauryl sulfate. No selective media has been developed for the specific isolation of *Enterobacter*. To ensure the safety of PIF and also to reduce any unnecessary disposal of product, it is important to distinguish between *Cronobacter* and *Enterobacter* species. *Cronobacter* can generally be distinguished from *Enterobacter* based on the hydrolysis of the chromogenic substrate of α-glucosidase, 5-bromo, 4-chloro, 3-indolyl α-D-glucopyranoside (α-Glu), ODC activity, and the use of the 2,3-butanediol fermentation pathway (as determined by Methyl Red and Voges–Proskauer reactions). Interestingly *Enterobacter hormaechi* is an example of an organism that has been previously misidentified as *Cronobacter*. Therefore, numbers of cases of *E. hormaechi* infection in neonates may be underreported. Townsend *et al.* (2008) showed that *E. hormachei* could invade the gut and blood–brain barrier epithelial cells and these bacteria could also persist in macrophages.

Control and Preventative Measures to Limit Dissemination of *Enterobacter*

ESβL producing species such as *E. cloacae* are increasingly reported and can cause outbreaks in susceptible populations. Bacterial infections caused by antibiotic resistant organisms result in higher morbidity and mortality and increased health-economic costs compared to those infections involving susceptible bacteria. Understanding the physiology and

survival mechanisms of *Enterobacter* will help toward developing effective strategies to reduce the prevalence of these bacteria in a clinical setting. Controlling the ecology in the food production environment would be a key step in limiting the further dissemination of these bacteria through the food chain.

Klebsiella Species

Background to the Genus *Klebsiella*

The genus *Klebsiella* was named after the German pathologist, Edwin Klebs in 1885 in honor of his work. This genus has undergone extensive changes in recent years. *Klebsiella pneumoniae* and *Klebsiella oxytoca* are the two clinically and epidemiologically most important species of this genus. Organisms such as *K. pneumoniae*, *Klebsiella ozaenae*, and *Klebsiella rhinoscleromatis* are now accepted as subspecies within the *K. pneumoniae* species. *Klebsiella terrigena* has been transferred to the genus *Raoutella*. Furthermore, *Klebsiella variicola* a newly defined species in 2004 was cultured from a range of plants including banana, rice, sugar cane, and maize and from the hospital environment. *Calymmatobacterium granulomatis* produces granulomatous lesions in humans and was renamed as *Klebsiella granulomatis* based on 16S rRNA analysis and *phoE* sequencing.

Characteristics of the Genus *Klebsiella*

Klebsiella are ubiquitous in nature and can be isolated from food (Table 1), sewage, soil, plants, and these bacteria colonize the mucosal surfaces of animals and humans. *Klebsiella* are nonmotile organisms and are usually capsulated. Microscopically, they appear as straight rods of approximately 1–2 μm in length with a diameter of 0.5–0.8 μm. These bacterial cells can be arranged singly, in pairs, or short chains. Diplobacilli, very similar to pneumococci are commonly seen in the body. *Klebsiella* are facultative anaerobes but their growth under strict anaerobic conditions can be poor. Most have fimbriae but this may not be the case for some respiratory strains. These bacteria have no special growth factor requirements. Their optimum temperature for growth is 37 °C with a growth range between 4 and 43 °C. They are killed by moist heat at 55 °C and can survive for several months in a desiccated environment. Most strains can use citrate and glucose as sole sources of carbon, but cannot use L-sorbose as a sole carbon source. They produce gas from sugars with gas production from starch being an important diagnostic characteristic. The gastrointestinal tracts of warm-blooded animals and humans can be colonized with *Klebsiella* with bacterial cell numbers reaching up to 10^8 CFU per gram in the feces. Carriage rates of 50% have been reported in premature infants in NICUs and these organisms can persist for one month or longer in infant feces.

Clinical Manifestation of Infections Linked to *Klebsiella*

Klebsiella can be disseminated following consumption of a contaminated food (Table 1), contact with a contaminated water supply during bathing and by person-to-person contact in the hospital environment. This genus is a common pathogen in the community but more importantly it is a major cause of morbidity and mortality in NICUs. It is responsible for a significant proportion of hospital-acquired infections such as necrotizing enterocolitis (NEC), septicemia, UTIs, soft tissue infections, and pneumonia. *Klebsiella* is a cause of community-acquired pneumoniae (CAP). CAP manifests as a sudden onset of breathing problems, hemoptysis, toxemia, and high fever. Early treatment with antibiotics can improve the prognosis; nevertheless CAP remains a leading cause of death especially in patients at the extremes of age. Clinically, the most important member of the genus is *K. pneumoniae*. In many developing countries, *Klebsiella* are one of the leading causes of meningitis in newborns. Between 1997 and 2002 *Klebsiella* was responsible for 7–10% of all hospital-acquired bloodstream infections across Europe, Latin American, and North America.

Klebsiella can cause serious infections in animals that can lead to a significant economic loss. They can cause mastitis in cows, leading to poor milk yields and result in the death of the animal and contagious equine metritis in horses, which can be costly to eradicate.

Antimicrobial Resistance Among *Klebsiella* Species

In recent years *Klebsiella* species have become resistant to a wide range of antibiotics. *Klebsiella* are reported to have exhibited resistance to penicillins, especially ampicillin and carbenicillin via the penicillinase enzyme SHV-1. Historically these organisms were susceptible to cephalosporins and gentamicin; more recently however *K. pneumoniae* has developed a novel mechanism of resistance to carbapenems, known as *K. pneumoniae* carbapenemases (KPCs). KPC represent a new class of bacterial enzyme capable of inactivating carbapenems. High-level antibiotic resistance is conferred by a plasmid-encoded KPC that can hydrolyze all cephalosporins, monobactams, and carbapenems. Spread of these resistance plasmids into other Gram-negative bacteria such as *Enterobacter*, *K. oxytoca*, *E. coli*, *Serratia marcescens*, and among *Pseudomonas* species has been reported. The first isolate of KPC-producing bacteria was described in a *K. pneumoniae* isolate recovered from a hospital in North Carolina in 2001. However, KPC-mediated resistance is now a worldwide problem and has been reported in China, Colombia, Brazil, France, Israel, and the US.

Epidemiology of *Klebsiella*

Should *Klebsiella* species be implicated in one or more cases of food-borne illness an investigation would be necessary to describe the associated epidemiology. This approach would include the genotyping of isolates recovered from patients and the implicated food source. Various foodstuffs especially those high in sugar content can harbor *Klebsiella* and are capable of colonizing the bowel. Its presence at low levels in PIF makes it a bacterial pathogen of concern due to the susceptibility of vulnerable neonates. *Klebsiella* species may be detected in food or water as a coliform along with other Enterobacteriaceae; however, as *Klebsiella* is also found throughout the

environment it may not necessarily indicate fecal contamination. Enteral feeding contamination by *K. oxytoca* has been recognized as a source of colonization of the throat and stool in premature infants. *Klebsiella* in food may give rise to the subsequent colonization of the gastrointestinal tracts of patients in hospitals, an important first step in the development of systemic infection.

In one study over a four-week period discriminatory typing was used to trace *Klebsiella* isolates through a hospital environment. A correlation was reported between food and fecal serotypes, and patient clinical isolates. This study explored more fully the role of contaminated food as a source for *Klebsiella* colonization and subsequent infection. An investigation, including environmental sampling, was undertaken after four leukemia patients in the same hospital ward developed serious infections with *Klebsiella aerogenes*, the source of this organism, was found to be a food blender used for preparing milk-based drinks on the ward, common to all four patients.

Culture Methods Used for Isolation of *Klebsiella* Species

The majority of *Klebsiella* strains grow well on Simmons' Citrate Agar and Møller's KCN medium. Some respiring strains grow very poorly on MacConkey agar. Chromogenic agar can be used for the isolation and enumeration of *Klebsiella* species, such as HiCrome *Klebsiella* Selective Agar. A chromogenic substrate in the media is cleaved specifically by *Klebsiella* to produce purple-magenta colored colonies.

Control and Preventative Measures to Limit Dissemination of *Klebsiella*

Klebsiella are well adapted to survival in the environment, even more so than other enteric bacteria. The main route of transmission of this pathogen within the hospital setting is through poor hand hygiene. Of concern to public health is the increase in antibiotic resistance reported among isolates of this genus. The high mortality rates associated with infectious pathogens will continue to increase due to the expanding antibiotic resistance profiles reported and the increased risks of therapeutic failures. Therefore, the ability of *Klebsiella* to adapt to new antimicrobial compounds requires new approaches to better manage hospital infections with *Klebsiella* species.

The restriction on the use of third generation cephalosporins and effective and consistent hand hygiene will help to reduce the prevalence of healthcare-associated infections.

Pantoea Species

Background to the Genus *Pantoea*

The genus *Pantoea* was proposed in 1989 to include several species that had formally resided in other genera of the *Erwinia herbicola–Enterobacter agglomerans* complex. The creation of the genus *Pantoea* allowed strains previously known as *E. agglomerans* and *E. herbicola* to be assigned to this new genus. Until recently the species of the genus included *Pantoea agglomerans, Pantoea ananatis*, *Pantoea citrea*, *Pantoea dispersa*, *Pantoea punctata*, *Pantoea stewartii*, and *Pantoea terrea*. In 2009, four new *Pantoea* species were described following their isolation from eucalyptus leaves and shoots showing symptoms of blight and die-back. These species were named: *Pantoea vagans*, *Pantoea eucalypti*, *Pantoea deleyi*, and *Pantoea anthophila*.

More recently, three new *Pantoea* species were discovered: *Pantoea gaviniae, and Pantoea calida* were isolated from infant formula and an infant formula production environment. *Pantoea allii* was recovered from onion and onion seed. There remains considerable taxonomic diversity within the *Pantoea* genus with some isolates of the *Erwinia herbicola–Enterobacter agglomerans* remaining ungrouped. Much work remains to be done to clarify the phylogenic classification of this genus.

Characteristics of the Genus *Pantoea*

Pantoea species share most of the general phenotypic characteristics associated with other genera within the Enterobacteriaceae. Most strains grow well at 4 °C and *P. dispersa* grows well at 41 °C where most other strains do not. *Pantoea* species are lysine, ODC, and arginine dihydrolase negative. They usually ferment glucose, lactose, mannitol, and sucrose, and are indole- and urease-negative. Most clinical isolates produce a yellow pigment. The genus *Pantoea* meaning all sorts and sources is intended to designate bacteria from diverse geographical and ecological sources. These bacteria are widely distributed in nature and have been found in soil, water, food (Table 1), humans, and animals. *Pantoea agglomerans* is associated with plants as an epiphyte or an endophyte and some isolates have been reported to be tumorogenic pathogens. They can easily be recovered from cotton and have been linked to cotton fever among intravenous drug abusers. Cotton pledgets are continuously used by nurses and physicians in a hospital environment, which can become contaminated in several ways.

Pantoea ananatis is considered an emerging plant pathogen as it has shown an increase in incidence, host and geographical range. Its occurrence in plants and trees can lead to sporadic plant disease outbreaks resulting in severe economic losses in eucalyptus, corn melons, Sudan grass rice, pineapple, and total losses have been reported in the case of onions. This bacterium may not be pathogenic to all plants, as some may possess both antibacterial and antifungal activities. *Pantoea ananatis* have been observed to increase root and shoot growth in papaya plants and promote growth and induce systemic resistance against *Xanthomonas axonopodis* pv. *vesicatoria* in pepper.

Clinical Manifestation of Infections Linked to *Pantoea*

Because of its confusing taxonomy and the difficulty in designating *Pantoea* species, little is known about their pathogenicity. *Pantoea agglomerans* is both a commensal and pathogen of animals and humans and is commonly isolated in hospitals. The latter is also the most commonly isolated *Pantoea* species in humans. They are considered an opportunistic pathogen that rarely causes disease in healthy individuals. The role of other *Pantoea* species is relatively unknown. The most common infection caused by *P. agglomerans* is septic arthritis or synovitis,

which has been traditionally reported after thorn injury. *Pantoea agglomerans* is also associated with pondylodiscitis, tibial osteitis, colelithiasis, occupational respiratory infections, skin allergy and has been linked with other organisms in polymicrobial peritonitis. It has been associated with contaminated intravenous products, a parental nutrition outbreak, the anesthetic agent propofol, blood products and contamination of transference tubes. In the 1970s *P. agglomerans* (then referred to as *E. agglomerans*) was implicated in a nationwide epidemic of septicemia caused by contaminated bottles of infusion fluids: 25 hospitals were affected with 378 cases reported. In 2002 it was reported that a *P. dispersa*-like strain was the only detectable microorganism cultured from an immunocompromised female with a rare combination of acute myeloid leukemia (AML) and multiple myeloma (MM).

Antimicrobial Resistance Among *Pantoea* Species

Limited information is available on the prevalence of antimicrobial resistance among members of this genus. Some *Pantoea* species have been reported to be resistant to most antibiotics used in an NICU. In 2000, a clinical isolate of *P. agglomerans* recovered from an individual with septic arthritis was reported to be highly resistant to fosfomycin and mecillinam.

Epidemiology of *Pantoea*

The epidemiology of plant diseases caused by *P. ananatis* on different hosts is relatively unknown. Environmental factors affect the severity of the disease caused by *P. ananatis*. Strain subtyping of *Pantoea* is important for epidemiological purposes and to identify those strains that are pathogenic to plants or cause infection in humans. Molecular subtyping methods including fluorescent- AFLP (F-AFLP) and PFGE have been successful for typing *Pantoea* strains.

Culture Methods Used for Isolation of *Pantoea* Species

Pantoea species generally grow well on most laboratory media, such as blood agar, nutrient agar, tryptic soy agar, and some media specifically designed for the isolation of the Enterobacteriaceae. However, *P. agglomerans* grows poorly on MacConkey agar and is not hemolytic on blood agar. A selective medium PA 20 was developed for the isolation and enumeration of *P. ananatis* from plant material, specifically from onion seed. It was reported to inhibit the growth of most of the common saprophytes associated with the seed. Phenotypic identification of *Pantoea* species may be difficult as they share many similar characteristics. The most promising approach for the speciation of *Pantoea* is the use of multilocus sequence analysis (MLSA). By using four housekeeping genes, MLSA could clearly differentiate between *Pantoea* species.

Other Information Relevant to the Genus *Pantoea*

Pantoea agglomerans are among the most promising biocontrol agents for a variety of bacterial and fungal plant diseases, particularly fire blight in apples and pears. However, this species is designated as a biosafety level 2 organism because it is an opportunistic human pathogen which hiders its commercial registration as a biocontrol product. These bacterial strains are also effective against other bacterioses, such as basal kernel blight of barley and postharvest fungal diseases of pome fruits.

Serratia Species

Background to the Genus *Serratia*

The first member of the Enterobacteriaceae family was discovered by a Venetian pharmacist Bartolomeo Bizio in 1823, who identified *S. marcescens*, growing on an Italian barley dish. The red-pigmented organism was described as a case of bleeding polenta. *Serratia marcescens* was the first species recognized within this genus and it is the primary pathogenic species. Rare reports of infection have been documented with *Serratia plymuthica*, *Serratia liquefaciens*, *Serratia rubidaea*, *Serratia odorifera*, and *Serratia fonticola*. All species with the exception of *Serratia entomophila* have been isolated from humans.

Characteristics of the Genus *Serratia*

Serratia are considered to be ubiquitous in the environment and the organism is found in water, soil, plants, insects, animals, mammals including humans and food (**Table 1**), particularly those rich in starch. Most *Serratia* isolates are motile with petrichous flagella. Optimum growth of *Serratia* has been observed at pH 9 and at temperatures ranging from 20 to 37 °C. Only *S. marcescens* and *S. rubidaea* fail to grow at 4 °C. The former is smaller in size when compared to the average coliform bacteria. *Serratia* can produce alternate forms of flagella that can provide the cell with different types of motility; depending on what medium the organism is grown on.

Serratia species can be distinguished from other genera by its production of three enzymes DNAase, lipase, and gelatinase. Members of this genus give positive reactions for citrate, Vogues–Proskuer, ortho-nitrophenyl-β-D-galactoside (ONPG) and can ferment mannitol and trehalose. If present, lactose fermentation occurs slowly. *Serratia marcescens* is unique among enteric bacteria in many respects as it is one of the most effective bacteria capable of degrading chitin, through the production of chintenases and a wetting agent or surfactant called serrawettin, which assists in the colonization of surfaces. Swim and swarming motility along with extracellular enzymes including nucleases, proteases, and haemolysin may contribute to pathogenesis. *Serratia* produce two types of bacteriocins. Group A bacteriocin producing strains are resistant to chloroform, heat, proteolytic enzymes, and active against other *Serratia* strains. Group B bacteriocin producing strains are susceptible to these latter agents but are active against other enterobacteria but not against other *Serratia* strains.

Serratia produce a cell-associated red color pigment called prodigiosin or 2-methyl-3-amyl-6-methoxy-prodigiosene. Pigmented strains have caused alarm by simulating the appearance of drops of blood on starchy foodstuffs. Production

of prodigiosin is highly variable between strains and it is only formed under aerobic conditions at specific temperatures. There is no correlation between optimum growth conditions and pigment production. Some isolates may grow at optimum temperature producing no pigment whereas at a lower temperature pigment production may be in abundance. Although some *S. marcescens* strains produce a red pigment, a majority of clinical strains are nonpigmented (>90%) and are usually found in various ecological niches.

The elaboration of fimbriae, production of potent sidreophores, presence of cell wall antigens, production of proteases, and the ability to resist the bactericidal action of serum have all been identified as potential virulence factors in *Serratia*.

Clinical Manifestation of Infections Linked to *Serratia*

Until the 1950s, *S. marcescens* was believed to be a nonpathogenic saprophyte and rarely isolated from human patients. In the past 30 years there has been an increase in nosocomial infections linked to *S. marcescens*. The first report of *S. marcescens* infection occurred in 1951 in Stanford University Hospital where 11 cases were reported over a 6-month period. This bacterium is now recognized as an opportunistic pathogen in humans and may spread in epidemic proportions causing nosocomial infections in hospitalized patients. Clinically *S. marcescens* causes a range of infections including cystitis, arthritis, eye infections, respiratory tract infections, UTIs, septicemia, meningitis, and wound infections.

Serratia marcescens has been reported to cause endocarditis in hospitals and in the community and affects the left hand side of the heart, which is in contrast to other Gram-negative bacteria. The bacterium is relatively uncommon accounting for only 1% of bloodstream infections reported to the National Healthcare Safety Network (NNIS) between 1986 and 1989. However, the mortality rate of *Serratia* is high and has been reported to be between 33% and 52%. *Serratia* infection linked to meningitis is also very rare but its high mortality rate (45%) exceeds that of other Gram-negative bacteria with surviving patients usually having neurological deficits. *Serratia marcescens* nasopharyngeal colonization in hospitalized patients commonly leads to respiratory infections. According to the NNIS, *Serratia* are responsible for 4% of nosocomially-acquired pneumonia.

Antimicrobial Resistance Among *Serratia* Species

Serratia marcescens can utilize a wide range of nutrients, which aids its ability to survive and grow under extreme conditions, including in the presence of disinfectants and antiseptics such as those used in contact lens washing solutions containing chlorhexidine, cotton balls and antiseptic solutions containing benzalkonium chloride and antiseptic soaps containing triclosan. Antibiotic resistance has been reported against several antimicrobial classes including penicillins (first- and second-generation cephalosporins, β-lactamase-mediated carbapenem resistance), aminoglycosides, and polymyxins. Infections with *S. marcescens* may be difficult to treat due to its resistance to multiple antibiotics. Nonpigmented strains are generally more resistant as they usually harbor resistance plasmids.

Epidemiology of *Serratia*

Several methods have been described for successfully subtyping *S. marcescens*, including PFGE, serotyping, phage typing, biotyping, one-dimensional sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis (PAGE), bacteriocin typing, antimicrobial susceptibility testing, and plasmid analysis (which is limited by the fact that only 25% of strains contain plasmids). Multilocus enzyme electrophoresis (MLEE) and electrophoresis of periplasmic proteins are alternative typing methods.

Culture Methods for the Isolation of *Serratia*

Differential and selective media have been developed for the isolation and presumptive identification of *Serratia*. These bacteria can readily grow on routine microbiological culture media (such as brain heart infusion broth, trypticase soy, nutrient agars). Isolation of *Serratia* from nonsterile sources such as food, environmental habitats, and hospital samples may require more specialized culture media. In this case deoxyribonuclease-toluidine blue-cephalothin agar (DTC) and caprylate-thallous (CT) agar may be required.

Control and Preventive Measures to Limit the Dissemination of *Serratia*

Major recalls involving *Serratia* include a recall in early 2008 by the US Food and Drug Administration (FDA) who issued a nationwide recall of one lot of Pre-Filled Heparin and Normal Saline Flushes that were contaminated by *S. marcescens*. The primary reservoir for *S. marcescens* is hospitalized patients, usually those with UTIs, or those individuals colonized or presenting with infected respiratory tracts. Infections transmitted from person-to-person are the most common dissemination route and are generally very difficult to control. Hospital infection control recommendations should stress the importance of strict adherence to hand-hygiene guidelines. More research is required to understand the relationship between *Serratia* species cultured from foods.

Other Information Relevant to the Genus *Serratia*

The production of the red pigment prodigiosin is a valuable marker and has been used in experiments such as the transmission of aerosols. In the US *S. marcescens* has been used in biological warfare population-vulnerability experiments. Prodigiosins display immunosuppressive, proapoptotic and anticancer properties and can therefore be potentially interesting candidates for drug development. *Serratia*-elaborated chintenase can be used in the treatment of chitin containing wastes, biocontrol agents against pathogenic fungi, production of adhesives and wound dressings, heavy metal recovery from waters, and dialysis membranes.

Other Genera Less Often Encountered

This section briefly describes the less frequently encountered pathogenic genera in the Enterobacteriaceae family including *Cedecea*, *Edwardsiella*, *Hafnia*, *Kluyvera*, and *Leclercia*.

Cedecea Species

The name of this genus was derived from the letters CDC, the abbreviation used for the Center for Disease Control and Prevention in Atlanta, where the organism was originally discovered. *Cedecea* species, based on their biochemical characteristics most closely resemble *Serratia*. Three species have been named (*Cedecea davisae*, *Cedecea lapagei*, and *Cedecea neteri*) and a further two species remain to be named (and are referred to as *Cedecea* species 3 and 5). These bacteria are usually motile and produce gas from glucose. *Cedecea* grow well on nonselective laboratory media producing convex colonies at 37 °C. *Cedecea* are predominately isolated from the respiratory tract but their importance in causing disease has not yet been demonstrated, although *C. davisae* and *C. neteri* have been reported to cause bacteremia and pneumonia.

Edwardsiella Species

The genus *Edwardsiella* originally consisted of only a single member (*Edwardsiella tarda*), however currently, at least three species are now known to exist (and are denoted as *Edwardsiella hoshinae*, *Edwardsiella ictaluri*, *Edwardsiella tarda*). *Edwardsiella* have a limited environmental habitat and host range. These bacteria are frequently isolated from freshwater and marine environments. They may be pathogenic for animals associated with these ecological niches especially cold-blooded vertebrates including, catfish, eels, lizards, and birds sometimes causing an economic loss.

Edwardsiella tarda is the only species in this genus, known to be pathogenic for humans where it is primarily associated with sporadic cases of gastroenteritis. *Edwardsiella* isolated from the gastrointestinal tract accounts for more than 80% of all clinical strains. Other infections associated with this bacterium include wound infections and systemic diseases such as cholecytitis, meningitis, osteomyelitis, and septicemia. *Edwardsiella tarda* is rarely found in the feces of healthy individuals. Risk factors associated with *E. tarda* are exposure to aquatic environments, exotic animals, people with underlying illness, including liver disease and the ingestion of raw fish. Studies have shown the invasive properties of *E. tarda* where most strains invaded HEp-2 cell monolyers, produced hemolysin and siderophores, and bound Congo red dye. Furthermore, *Edwardsiella* species are susceptible to commonly used antibiotics, including penicillin a feature that is unusual for genera such as Enterobacteriaceae. A serotyping scheme has been developed to further identify these bacteria. This serotyping system comprises of 61 O-groups and 45 H-antigens. Some *E. tarda* isolates produce bacteriocins that are effective against other *E. tarda* strains and some *Yersinia* species.

Hafnia Species

The current *Hafnia* genus consists of only one species, *Hafnia alvei*. This bacterium was previously known as *Enterobacter hafnia* or *Enterobacter alvei*. *Hafnia alvei* have been isolated from different environmental and clinical sources. Food products that commonly yield *Hafnia* include ground (minced) beef and vacuum-packed beef, pork products, dairy products, freshwater fish, and honey (Table 1). These organisms do not ferment lactose and can resemble *Salmonella* on specific *Salmonella* isolation agar. *Hafnia* species demonstrate biochemical reactions that are similar to those of *Enterobacter* and *Serratia*. No specific media has been developed for their isolation and detection. *Hafnia* is often isolated from clinical material yet its role in infection is poorly understood. They have been associated with extraintestinal disease usually in immunocompromised individuals. However, the majority of *Hafnia* strains are not considered pathogenic. They are usually isolated from feces and rarely recovered from other body sites.

Kluyvera Species

Kluyvera was first proposed as a genus in 1956 by Asai and coworkers, with two species *Kluyvera citrophila* and *Kluyvera noncitrophila*. However, the genus *Kluyvera* was not defined completely until 1981 when Farmer *et al*. used DNA–DNA hybridization technique to fully characterize the genus. The original species names proposed by Aasi and coworkers were not used, as they did not fit the CDC's species descriptions. Previously known as enteric group 8 and API group 1, the current genus consists of four species, *Kluyvera ascorbata*, *Kluyvera cryocrescens*, *Kluyvera georgiana* (formerly species group 3), and *Kluyvera cochleae*. *Kluyvera* have been isolated from milk, sewage, soil, water, kitchen food (Table 1), an oriental fruit fly, and a hospital sink. Human isolations are more common with the organism being cultured from sputum, urine, stool, blood cultures, peritoneal fluid, wound specimen, and a Broviac catheter. Clinical signs related to *Kluyvera* infection can vary and affect a wide range of age groups. Each of these species has been isolated from human clinical specimens except *K. cochleae*. *Kluyvera* species can cause bacteremia, soft tissue infections, intra-abdominal abscesses, and UTIs. Reports suggest that this organism can also cause disease in healthy immunocompetent children. *Kluyvera* isolates can demonstrate resistance to penicillin and some first- and second-generation cephalosporins (cefalotin and cefuroxime) due to the production of β-lactamase enzymes.

Leclercia Species

The genus *Leclercia* was proposed for those species previously known as *Escherichia adecarboxylata* or CDC Enteric group 41. Even though *Leclercia adecarboxylata* has been isolated from a variety of sources its natural habitat is unknown. Most of the early isolates studied were recovered from food, water, and environmental sources. However, *Leclercia* has also been found in human clinical specimens including blood, feces, sputum, urine, and wounds with cases reported from around the world. Some strains are known to produce a yellow pigment and grow well on general laboratory media. Although *Leclercia* are generally susceptible to most antibiotics in clinical use today, there are reports of resistant strains.

Francisella tularensis

M Gyuranecz, Centre for Agricultural Research, HAS, Budapest, Hungary

Glossary

Biological warfare agent An agent (bacteria, viruses, or fungi) that could be used to kill or incapacitate humans, animals, or plants.

Coagulation necrosis A type of necrosis that develops when the protein elements coagulate and thus the affected cells or tissue form a dry and homogeneous eosinophilic mass.

Colony-forming unit The viable number of a bacterium or a fungus.

Enzyme-linked immunosorbent assay An immunoassay that uses an enzyme linked to an antigen or antibody as a marker for the demonstration of a specific protein, generally an antibody or antigen.

Fluorescent antibody test A test for the demonstration of agents expressing a specific protein by binding antibodies specific for the protein and visualizing these complexes by fluorescent labeling of the antibody.

***Francisella*-like endosymbiont** These are *Francisella* variants with unknown pathogenicity which are harbored by ticks.

Granuloma A structured nodular aggregation of mononuclear inflammatory cells and connective tissue.

Immunohistochemistry This is a method for the detection of specific antigens in tissue sections by staining with antibodies marked with pigmented or fluorescent material.

Lethal dose 50 (LD_{50}) The dose of a substance that would be expected to kill half of a population of exposed organisms.

Polymerase chain reaction A molecular technique for amplifying a single or a few copies of deoxyribonucleic acid (DNA) by separating the DNA into two strands and incubating it with oligonucleotide primers and DNA polymerase to generate millions of copies of that particular DNA sequence.

Background

Francisella tularensis is the etiological agent of tularemia, a lethal zoonotic disease and potential biological warfare agent. It was first isolated and characterized by McCoy and Chapin in 1912 during an outbreak of a 'plague-like' disease in ground squirrels in Tulare County, CA, USA. The genus designation honors the American pathologist, Edward Francis, who examined tularemia during the 1920s and 1930s; the name of the disease and species name derived from Tulare County.

Characteristics of the Organism

Four subspecies of *F. tularensis* are recognized: the highly virulent *F. tularensis* ssp. *tularensis* (type A), moderately virulent *F. tularensis* ssp. *holarctica* (type B), and *F. tularensis* ssp. *mediasiatica*, and low virulent *F. tularensis* ssp. *novicida*. The *F. tularensis* ssp. *tularensis* is found in North America; *F. tularensis* ssp. *holarctica* is found throughout Europe, Asia, and North America, and was recently discovered in Tasmania; *F. tularensis* ssp. *mediasiatica* has been isolated only in Kazakhstan and Turkmenistan, whereas *F. tularensis* ssp. *novicida* has been linked to waterborne transmission in Australia and the US.

Francisella tularensis is an intracellular bacterium. It is an obligate aerobe, small (0.2–0.7 μm × 0.2–1.7 μm), Gram-negative, nonmotile, and pleomorphic coccobacillus covered by a carbohydrate-rich capsule. *Francisella tularensis* is oxidase negative, weakly catalase positive, and cysteine is required for its growth. Utilization of glycerol is an effective tool to differentiate *F. tularensis* ssp. *tularensis* (glycerol positive) and *F. tularensis* ssp. *holarctica* (glycerol negative).

Survival of *F. tularensis* in nature is dependent on a variety of factors such as temperature (1 h at 60 °C) or direct exposure to sunlight (3 h at 29 °C). General survival in carcass tissues is 3–4 weeks and 4 months in water at 4–6 °C. *Francisella tularensis* does not form resistant structures and is relatively sensitive to all standard inactivation procedures. Therefore, autoclaving is suitable for the inactivation of *F. tularensis*. The bacterium is sensitive to hypochlorite and other commonly used chemical decontaminants and readily inactivated on exposure to ultraviolet irradiation.

Francisella tularensis has ~1.9 mega base pair size genome (*F. tularensis* ssp. *holarctica* LVS NC_007880 and *F. tularensis* ssp. *tularensis* SCHU S4 NC_006570). It is a highly clonal bacterium, which means that it inherits deoxyribonucleic acid (DNA) in a vertical manner and does not transfer DNA laterally between cells.

 doi:10.1016/B978-0-12-378612-8.00099-8

Epidemiology

Natural infections with *F. tularensis* have been reported in a range of vertebrates including mammals, birds, amphibians, and fish. Despite its broad host range, tularemia is primarily a disease of the orders Lagomorpha and Rodentia. In the New World, the cottontail rabbit (*Sylvilagus* spp.), black-tailed jackrabbit (*Lepus californicus*), and snowshoe hare (*Lepus americanus*) are important in the ecology of tularemia, whereas the European brown hare (*Lepus europaeus*), mountain hare (*Lepus timidus*), and Japanese hare (*Lepus brachyurus*) are associated with tularemia in the Old World. Voles (*Microtus* spp., *Arvicola amphibius*, and *Myodes glareolus*) are most frequently involved in tularemia epizootics but other rodent species are also infected. Hematophagous arthropods have substantial role both in maintaining *F. tularensis* in the nature and disease transmission. Ticks are believed to be the most important arthropods (biological vectors) in the ecology of tularemia throughout the Northern Hemisphere, but other bloodsucking arthropods (e.g., mosquitoes – Scandinavia and Russia, and horseflies – Russia and the US) transmit *F. tularensis* mechanically. There are two known cycles of tularemia: the terrestrial and aquatic. In the terrestrial cycle, hares and rodents are the most important mammalian hosts, whereas hematophagous arthropods play a role as vectors. In the aquatic cycle, voles and maybe muskrats and beavers serve as the main host species, shedding live bacteria into the environment. It was found that a protozoon species (*Acanthamoeba castellanii*) can be an important aquatic-environment reservoir of *F. tularensis.*

Humans are highly susceptible to *F. tularensis*. People can get infected in several ways such as direct contact, through wounds or small cuts, ingestion, inhalation, or via the conjunctiva. *Francisella tularensis* can be transmitted by the infected animals' tissues or fluids, contaminated water or food, aerosols, or by the bites of infected arthropods.

Through ingestion of contaminated water or food, the oropharyngeal form (see section 'Clinical Manifestation and Pathology') of tularemia can be acquired. The water of streams and wells may become contaminated with *F. tularensis* and remain contaminated for more than a month when carcasses of infected mammals (e.g., rodents or lagomorphs) remain in the water. The meat of several animals (e.g., hares and rabbits) may be infected but other food items could also be contaminated with the feces of *F. tularensis* infected animals (e.g., rodent). In Turkish tularemia outbreaks between 1936 and 2004, 387 out of 507 cases (77%) were referred to as the oropharyngeal form, while 32 out of 1100 recorded human tularemia cases in Finland between 1967 and 1983 were diagnosed as oropharyngeal form. In Italy in 1982, consumption of water from an unchlorinated water system caused a waterborne tularemia outbreak with 49 human cases. In early 2000, 327 food- and water-related human tularemia cases were recorded in Kosovo , at the end of a 10-year-long political crisis and war. The rodent population increased during wartime, which allowed epizootic spread of *F. tularensis* infection among rodents and resulted in the contamination of food and water sources.

Pathogenesis

Francisella tularensis is a highly infectious agent but its virulence factors have not been well characterized. As low as 10 colony-forming unit (CFU) of *F. tularensis* ssp. *tularensis* is enough to cause fatal infection in mice, guinea pigs, or rabbits and a similarly small dose is enough to induce a severe or sometimes fatal infection in humans. *Francisella tularensis* ssp. *holarctica* causes lethal infection in mice and guinea pigs at a similarly small inoculation dose, however, a higher dose is needed to induce the disease in rabbits (lethal dose 50 (LD_{50}): $>10^6$ CFU) or humans (LD_{50}: $>10^3$ CFU).

After entering the body (via inoculation by hematophagous arthropods or wounds, through the conjunctiva, by inhalation of infected aerosols, by ingestion of contaminated meat, or by water), bacteria multiply locally causing ulceration and necrosis and then invade the blood and lymph vessels and spread to the lymph nodes and organs such as liver, spleen, lung, kidney, serosal membranes, and bone marrow, causing multiple foci of coagulation necrosis. *Francisella tularensis* is a typical intracellular pathogen with a high predilection not only to growin macrophages but it can also infect many other cell types, such as epithelial cells, hepatocytes, muscle cells, and neutrophils. *Francisella tularensis* septicemia occurs at the end stage of the disease when bacteria invade the blood vessels without causing lesions indicative of tissue response. Only this septicemic form is seen in highly sensitive animals, which die within 2–10 days. Relatively resistant animals and humans can survive the infection and develop protective immunity. Synergy between phagocytes, antibodies, and T cell-derived cytokines appears to be critical for achieving immunity against *F. tularensis* and clearing infection. In humans, the antibody response is measurable by the second week postinfection. Antibody levels are highest during the second month after infection and decline gradually thereafter.

Clinical Manifestation and Pathology

Clinical cases of tularemia are infrequently observed in free-ranging wildlife as infected animals are usually found moribund or dead. Nonspecific signs include depression and pyrexia. Local inflammation or ulceration at the portal of entry and enlargement of the regional lymph nodes may be observed. Highly sensitive animals develop fatal septicemia and may be nonresponsive before death. In hares, depression, stupor, loss of body weight and lack of fear, and facilitating capture are observed in the late stages of the disease. The pathology of tularemia differs considerably between different animal species. In highly sensitive species with acute disease (e.g., mouse), the usual macroscopic finding is the enlarged spleen and, less frequently, liver. Pinpoint white foci could be seen in these organs showing multifocal coagulation necrosis by histology. In moderately sensitive species (e.g., European brown hare) a more chronic form of disease can be observed and characterized by granulomatous lesions with central necrosis, particularly in the lungs and kidneys and occasionally in the liver, spleen, bone marrow, and lymph nodes. The granulomas contain heterophils, macrophages, and giant cells.

Seven clinicopathological forms of tularemia have been described in human medicine: ulceroglandular, glandular, oculoglandular, oropharyngeal (after food- or waterborne infection), pneumonic, typhoidal, and septicemic. The most frequent clinical signs in humans are inflammation and later ulceration at the primary site of infection, with swelling of regional lymph nodes, which may become abscessed. Generally, the course of the clinical disease includes sudden onset of fever, generalized aches, inflammation of the upper respiratory tract with nasal discharge, vomiting, malaise, and anorexia. In oropharyngeal tularemia, people show an ulcerative–exudative stomatitis and pharyngitis, with or without tonsillar involvement, and excessive regional neck lymphadenitis.

Analytical Methods

Field examination of pathological samples is not recommended when there is a suspicion of tularemia because of the potential for human exposure and risk of contaminating the environment. Special precautions, including wearing gloves, masks, and eyeshields are advised when handling infective materials. Procedures should be performed within appropriate biosafety containment facilities (biosafety level 2 or 3).

Francisella tularensis appears as numerous Gram-negative small-sized bacteria in impression smears or in histological sections of spleen, liver, lung, kidney, bone marrow, lymph node as well as in blood smears. *Francisella tularensis* can be detected specifically by direct or indirect fluorescent antibody tests. Immunohistochemical assay is a very useful and sensitive method for the detection of *F. tularensis* in domestic and wild animals.

Francisella tularensis can be identified by culture. The most adequate samples for culture are, in acute cases, heart blood, spleen, liver, or bone marrow, whereas in chronic cases, granulomatous lesions should be examined. Owing to the highly fastidious culture requirements of *F. tularensis*, isolation can be difficult as it grows poorly in conventional culture media. Francis medium, McCoy and Chapin medium, or modified Thayer-Martin agar are recommended. Isolation of *F. tularensis* from carcasses may be difficult due to the overgrowth of contaminant bacteria. Selective culture media can be prepared by adding penicillin, polymyxin B, and cycloheximide. When the primary isolation of *F. tularensis* is difficult, it may be isolated following inoculation of tissue suspension from suspect cases into laboratory animals such as mice. The colonies of *F. tularensis* are small, round, and they do not appear within the first 48 h of incubation at 37 °C and 5% CO_2. Because *F. tularensis* ssp. *tularensis* and *holarctica* differ in citrulline ureidase activity and glycerol fermentation, biochemical assays can be used for differentiation based on glycerol fermentation or citrulline ureidase activity.

Several polymerase chain reaction (PCR) methods have been described for the detection of *F. tularensis* DNA in both environmental and clinical specimens. Conventional PCR assays target the 16S ribosomal ribonucleic acid gene and genes encoding the outer membrane proteins, *fopA* or *tul4*, they show good specificity and allow rapid detection of *F. tularensis* in specimens. However, *Francisella*-like endosymbionts of ticks can produce nonspecific positive results in these assays. Real-time PCR methods show no evidence of cross reactivity with non-*F. tularensis* agents (other vectorborne and environmental organisms) and the high sensitivity increases the chance of detecting very low numbers of *F. tularensis* organisms in environmental samples. Molecular methods are also applied to *F. tularensis* isolates to provide resolution among the *Francisella* species, subspecies, and within-subspecies strains.

Serology can be carried out for investigating exposure to *F. tularensis*. A slide agglutination test, using one drop of stained bacteria and one drop of whole blood, is a widely used field method. The standard serological tests are the tube agglutination and microagglutination tests. Cross reaction with *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, *Legionella* spp., and *Yersinia* spp. may occur. The enzyme-linked immunosorbent assay allows an early diagnosis of tularemia. Western blotting, indirect immunofluorescence assay, and flow cytometry have also been assessed for the serological diagnosis of tularemia.

Control/Preventive Measures

Francisella tularensis has an extremely broad host range and very complex ecological transmission cycles, therefore it is difficult to control. Monitoring of wildlife, arthropod vectors, and surface water for tularemia activity in enzootic areas provide useful information for public health authorities, veterinarians, and wildlife managers.

Infection in humans with *F. tularensis* can be treated with antibiotics such as quinolones (ciprofloxacin and levofloxacin), aminoglycosides (streptomycin and gentamicin), and tetracyclines (tetracycline and doxycycline). Publication of epizootic events and providing information on treatment and protection are important. Rubber gloves should be worn by trappers or hunters when skinning carcasses of species commonly associated with tularemia to prevent contact transmission. The use of insect repellent, protective clothing, and frequent body searches for prompt removal of ticks can greatly reduce the risk of infection. Meat from potentially infected animals (e.g., hares and rabbits) should be well cooked. The food which may be contaminated with animal feces should be avoided. Untreated water from lakes and streams should not be consumed, used for washing, or for brushing teeth. Food stores and water sources should be protected from contact with possibly infected animals (e.g., rodents and lagomorphs). Diagnostic laboratory procedures should be performed within secure biosafety containment facilities (biosafety level 2 or 3) observing appropriate biosafety procedures.

Generally vaccination has not been widely applied but it has been used under high-risk situations, typically for laboratory researchers. Many vaccine candidates including acellular subunit, killed whole cell, and live attenuated vaccines have been developed in the recent years but none of them have been licensed yet.

Helicobacter pylori

E Bergogne-Bérézin, University Bichat-Claude Bernard, Paris, France

Glossary

Achlorhydric Absence of chlorhydric acid (gastric fluid).
Cag PAI *Cag* pathogenicity island.
Ferrets Used as wild hunters for rats and mice, they are today domesticated mammals.
Lymphoma General term for malignant neoplasms from lymph and reticuloendothelial tissues.
MALT lymphoma Gastric mucosa-associated lymphoma: Extensive lymphoma formed of large B cells with a high malignant degree of pathogenicity.
Microaerophilic A bacteria that does not require a high rate of oxygen supply.
Omeprazole A proton pump inhibitor.

History, Background, and Taxonomy

For a long time before the discovery of the potential role of an unknown bacteria, gastric ulcers were considered to be the result of hyper acidic gastric mechanism. Patients were treated with drugs neutralizing acidic content, such as bismuth subsalicylate that was efficient and has been used for long. However, bismuth being a toxic metal, this treatment has been limited. The hypotheses of bacterial potential role in peptic ulcer were suggested by several authors at the end of the nineteenth century. In early 1950s, several microbiologists described a bacterium in gastric acid secretions and in mucosal biopsies, until Robin Warren and Barry Marshall identified in 1982 a Gram-negative, microaerophilic organism, named initially *Campylobacter pyloridis* and later *Helicobacter pylori*. It is helix-shaped with 3 mM lengh and it possesses 4–6 flagella that confer motility to pathogenic strains. It produces oxidase, catalase, and urease. *H. pylori* strains can form biofilms, capable of converting to viable coccoid form, which is a potential epidemiological factor and contributes to resistance of the organism in acidic conditions. Its taxonomy has been defined as that of a completely new Genus, belonging to Family '*Helicobacteriaceae*' Genus *Helicobacter*, Species *H. pylori*. In the late twentieth century with the development of molecular biology, sequencing of the *H. pylori* genome contributed to establishing taxonomy bases on the deoxyribonucleic acid (DNA) level and to understanding virulence factors. Moreover, genomic analyses have unraveled a large diversity of strains: Genetic differences should further permit a better understanding of pathogenesis of *H. pylori*. Some Helicobacter-like organisms (HLOs) have been detected by PCR (specific tests). The first HLOs have been described in ferrets (*Helicobacter mustelae*) and in Syrian hamsters (*Helicobacter hepaticus*). Thus, some taxonomic changes should be expected in the near future.

Bacteriology of *H. pylori*

In Microbiology laboratories classical techniques can be applied for isolation and identification of Helicobacter, as have been done early in the 1980s, by Robin Warren and Barry Marshall. Bacteriological cultures have been achieved by using bacterial growth from biopsies taken from gastric mucosa (of both the body and the antrum). Culture methods have been described by specialists but not standardized: The biopsy specimens must be homogenized and then sowed in selective media (Agar Pylori, BioMérieux) or nonselective media (such as Columbia III Agar with 5% sheep blood). Incubation requires microaerophilic conditions for 10–14 days (37 °C) and then further techniques require experience to identify colonies and carry out subcultures for identification tests. However, bacteriological and molecular methods remain limited to specialized expert centers: Positive or negative results based on invasive methods must be confirmed by noninvasive methods, such as detection of *H. pylori* antigens. The latter methods have been applied to stools of patients, confirming the potential intestinal carriage or occasional excretion of the pathogen in stools.

Epidemiology, Contamination, and Transmission

Investigations carried out after the discovery by Marshall and Warren have shown that *H. pylori* is a common organism found in more than 50% of the world's population, and 80% of individuals infected with the organism are asymptomatic. This bacterium lives probably exclusively in human stomach and is the only bacterial species capable of surviving in such an acidic environment. The habitat of *H. pylori* is mainly the upper digestive tract. By using appropriate techniques, *H. pylori* can be isolated in stools, saliva, and dental plaques, which suggests transmission by several routes, such as

 doi:10.1016/B978-0-12-378612-8.00100-1

contaminated water or foods. Despite that it is not classified among foodborne organisms, its transmission may occur *via* stools contaminated from foods and water, as well as by oral–oral route or fecal–oral route.

Recent research has shown the presence of other helicobacter species in mammal animals (*Helicobacter felis, Helicobacter muridarum)* and in some species of birds (*Helicobacter pullorum*). Another specific helicobacter species is *H. mustelae* widespread in ferrets (*Mustela putorius*): These wild animals, known since Ancient Egypt, used for hunting rats and mice, have become popular as domestic pets: They can develop ulcerative gastritis due to *H. mustelae (*isolated from feces of ferrets, which support fecal–oral transmission of gastric *Helicobacter*). An interesting discovery resulting from an archeology research group has shown the presence of *H. pylori* in the stomach of *Homo sapiens* 58 000 years ago, before the large migrations of Africans to Asia and Europe; they observed that the genetic diversity of strains reduces as much as the people move far from East Africa.

In the western area, the level of carriage of *H. pylori* varies significantly with the countries. In developing countries higher levels of incidence have been determined, probably due to poor hygiene conditions, contaminated water and food, as well as promiscuous conditions of living. Contaminated children have been found in those countries, as mentioned in the Maastricht 2-2000 Consensus Report. In the US, the predominant contaminated population is that of elderly people **(** >60 years old), whereas the incidence is $<20\%$ in people below 40 years. This apparently contradictory statement can be explained by an early contamination of elderly people at the time when Helicobacter was unknown, or related to intestinal disorders or mucosal diminished immune defense to bacterial adhesion described in older population, even in developed countries.

Clinical Profile, Signs and Symptoms, and Associated Diseases

Helicobacter infection can be either clinically silent or symptomatic. Several symptoms associated with the presence of *H. pylori* can be nonspecific, varying with time. When inflammation of the gastric mucosa develops, gastric or abdominal pain, acidic reflux, regurgitation, vomiting, and nausea constitute the majority of visible symptoms. However, 70 or 80% of infections remain asymptomatic.

Besides the classical peptic ulcer or gastro-duodenal ulcer, several syndromes have been related to the infection with *H. pylori*, such as chronic gastritis and atrophic gastritis associated with achlorhydric syndrome. Several extragastric diseases have been attributed to *H. pylori*: mucosa-associated lymphoma (MALT lymphoma), coronaritis, gastro-oesophageal reflux disease, iron deficiency anemia, skin disease, and rheumatological manifestations. The association of chronic helicobacter infection with alterations in gastric mucosal cell proliferation is recognized worldwide as well as association between *H. pylori* infection with gastric adenocarcinoma and gastric lymphoma. The role of helicobacter in those associations remains uncertain and needs confirmation of its potential responsibility in gastric and extragastric diseases.

Inflammatory Factors

H. pylori infections are a source of inflammatory processes mediated by disulfide-bridged proteins: helicobacter cysteine-rich proteins (*Hcp*), particularly Hcpa (*hp0211*), triggers an immune response through the differentiation of monocytes into macrophages. They interfere with host cell functions, change the monocyte morphology, the expression of surface marker protein (CD11b), phagocytic activity, and cell adherence. Colonization of the stomach by *H. pylori* results in chronic inflammatory process of the stomach lining and the severity of the inflammation forms the basis for *H. pylori*-related diseases. Resulting from severe inflammation, acid and pepsine in the stomach lumen overwhelm the mechanisms of protection of stomach and duodenal mucosa, which results in duodenal and stomach ulcers. In people producing large amounts of acid, *H. pylori* colonizes the antrum of the stomach where *H. pylori* avoids the acid secreting parietal cells located in the main body of the stomach. The inflammatory response to the bacteria induces G cells in the antrum to secrete *gastrin*, and the latter product stimulates the parietal cells to secrete even more acid in the stomach lumen. The increased acid load can damage the duodenum with production of an ulcer. Chronic inflammation induced by bacteria is associated with further diminished acid production, atrophy of the stomach lining resulting in gastric ulcer, and the risk of gastric cancer.

Structure, Genome, and Pathogenesis

Some structural characteristics of helicobacter contribute to the pathogenicity of this organism. Like other Gram-negative bacteria, *H. pylori* possesses an outer membrane (OM) comprising phospholipids, a lipopolysaccharide (LPS), and the O antigen of LPS (toxin) may be fucosylated, mimicing Lewis blood group antigens found on the gastric epithelium. The OM also contains cholesterol, glucosides as found in few other bacteria. Genetic studies have shown genetic differences between strains. Approximately 29% of the loci in the pathogenetic strains have a 40 kb-long *Cag* pathogenicity island (*cagA* gene) that contains 40 genes: This pathogenicity island is not found in strains from asymptomatic carriers of *H. pylori*. *CagA* gene codes for one of the major virulence proteins and those strains having *CagA* gene are associated with the ability to cause ulcers.

To colonize the stomach, *H. pylori* avoids the acidic pH of the lumen by means of its flagella, burrows in the mucus to reach the stomach epithelial cell layer, and swims to the neutral environment of the epithelial cell surface. *H. pylori* can also be found on the inner surface of the gastric epithelial cells and produces adhesins, which permit attachment of the bacteria to epithelial cells. One important characteristic of *H. pylori* is its abundant production of the enzyme *urease,* which is present inside and outside the bacteria. The *urease* destroys *urea* normally secreted in the stomach: This results in carbon dioxide and ammonia, converted to ammonium neutralizing gastric acid: Therefore, the survival of *H. pylori* is dependent on its urease production. In addition, the ammonia produced is toxic to the epithelial cells, as well as other products of *H. pylori*, such as proteases, cytotoxin A (Vac A), and certain phospholipases.

The addition of the roles of urease production, ammonium, and toxic products are convergent factors in favor of persistence and growth of *H. pylori* in the gastric area.

H. pylori and Cancers

The *Cag pathogenicity island* (*cag* PAI) predominates in approximately 50–70% *H. pylori* strains in Western countries. Patients infected with those strains have a strong inflammatory response in the stomach with a higher risk of developing ulcers and gastric cancers. Type IV secretion system expressed by the *cag* PAI strains, 'injects' peptidoglycan, the inflammation-inducing agent, from their cell wall into the epithelial cells, followed by expression of cytokines (promoting inflammation). The same system disrupts cytoskeleton, adherence to adjacent cells, cell polarity, and once inside the cell, the *CagA* protein allosterically activates *phosphatase/protooncogene Shp2*. Pathogenic *H. pylori* can activate the Epidermal Growth Factor (EGFR), a membrane protein with a tyrosine kinase domain. Activation of EGFR by *H. pylori* is associated with altered functions of epithelial cells and their contribution to pathogenesis.

Among those complex mechanisms of pathogenesis, with a great diversity of *H. pylori* strains, two related mechanisms by which the organism may promote cancer are being studied: one mechanism involves increased production of free radicals near *H. pylori* with an increased rate of host cell mutation; the other mechanism called 'a perigenetic pathway' involves enhancement of transformed host cell phenotype by alterations in cell proteins (adhesins). *H. pylori* induces inflammation, local high levels of tumor necrosis factor-α, alteration of gastric epithelial cells, dispersion and mutation of cells (without additional mutations in tumor suppressor genes). Further studies will permit a better understanding of cancer development related to *H. pylori*.

Detection Methods

The detection and evaluation of the incidence of a disease such as *H. pylori* infection is necessary to develop measures for the control of a potential spread of the infection. In different populations the variability of the incidence is a function of hygiene and contamination conditions. Thus the control of the incidence requires development of means for detection of the organism and this needs to proceed to diagnostic tests, such as detection of antibodies, reliable to diagnose the infection in a series of patients. Serological tests can also control the efficacy of the treatment with antibodies persisting for months after a potential eradication of *H. pylori*. However, none of the methods are totally reliable. They must be chosen as a function of clinical profiles of patients and of availability of diagnostic tests.

The test with radioactive 13C- or 14C-labeled urea metabolized by the bacteria (resulting in labeled carbon dioxide detected in the patient's breath) requires hospitalized patients and cannot be used in large groups of populations for evaluation of the incidence and developing methods for control of transmission. Similarly, detecting the presence of *H. pylori* in a biopsy check during endoscopy, histology, and microbial culture should permit the control of treatment efficacy, but is only applicable in patients examined while in hospital. Few other tests encounter the same limits and do not permit a significant control of the patients' conditions and incidence in a given population.

Prevention and Control Measures

Prevention of contamination by *H. pylori* requires detection in potentially contaminated populations. As modes of transmission have been established and carriage of the bacteria in the upper gastrointestinal tract being silent in many cases, the contamination may occur by means of water or food in close contact with such contaminated population. The lack of hygiene contributes to such transfer (oral–oral or fecal–oral routes). Therefore detection is important for prevention, but suitable methods may not be available in developing countries with highly contaminated population. Rising antibiotic resistance does not permit empirical antibiotic treatments in those populations. Vaccine studies have been approached in mouse models with promising results. Different routes and adjuvants have been assayed to find the most appropriate mode of immunization. However, although attempts are promising in animals, trials in humans were only recently conducted. Prophylactic vaccines seem to be more appropriate than vaccines to cure the infection and to eradicate *H. pylori* or to reduce the bacterial density from gastric mucosa. New directions for immunization are studied with growing interest in the use of DNA or living vectors, but they are still at an early stage. An intramuscular vaccine against *H. pylori* infection is being investigated in Phase I clinical trials. Presently the most effective method of prevention remains education of public in food and water hygiene.

Omeprazole (or derivatives) combined with active antibiotics have proven therapeutic efficacy and decreasing incidence in developed countries.

Conclusion

Analyzing the knowledge acquired during recent years, the late discovery (1980) of *H. pylori* has resulted in a relatively limited knowledge of the organism: in terms of characteristics of the bacteria, growth, metabolism, chemical, and genetics, requirements for *in vitro* culture and *in vivo* behavior. The literature on *H. pylori* is limited and mainly devoted to pathogenicity and mode of clinical pathogenesis. There is still more research to be done in the years to come.

Omeprazole (or derivatives combined with active antibiotics have proven therapeutic efficacy and decreasing incidence in developed countries.

BACTERIA

Listeria monocytogenes

R Magalhães, C Mena, V Ferreira, J Silva, G Almeida, P Gibbs, and P Teixeira, Universidade Católica Portuguesa, Porto, Portugal

Glossary

Biofilm An aggregation of microorganisms attached to a surface and embedded in an extra-cellular polymeric matrix.
Epidemic clone Group of individuals with a common ancestor that are evolved clonally.
Invasion Mechanism by which pathogenic microorganisms infect human host cells.
Outbreak A group of at least two cases of a single illness that are demonstrated by epidemiological investigation to have a single common exposure or source.
Water activity or a_w The amount of water that is available to microorganisms.

Background

Listeria monocytogenes is a foodborne pathogen that causes the disease known as listeriosis in humans and in several animal species. The official discovery of *Listeria* dates back to 1924, when Murray, Webb, and Swann isolated *L. monocytogenes* as the etiological agent of a septicemic disease affecting rabbits and guinea pigs in their laboratory at Cambridge in England. This strain was named *Bacterium monocytogenes*, as it was observed to infect monocytes of the blood. The following year, Pirie isolated an identical bacterium from the liver of several gerbils, also known as the African jumping mouse. He named it *Listerella hepatolytica*. Until 1940, there was considerable confusion in the nomenclature of *L. monocytogenes*. Pirie chose *Listerella* as the generic name in honor of Lord Lister, the well-known pioneer in the field of bacteriology. However, this name had already been applied to a group of slime molds (Mycetozoaire). The generic name *Bacterium* as applied by Murray and collaborators was undesirable because the organism does not possess the characteristics of this genus. The resolution of the Committee on Nomenclature, Third International Congress for Microbiology, New York, 1939, was that in all duplications of generic names, only the one first applied should be considered valid, invalidating the generic name proposed by Pirie, and thus he suggested the name *Listeria* in 1940. *Listeria* was adopted in the sixth edition of *Bergey's Manual of Determinative Bacteriology* and approved by the Judicial Commission on Bacteriological Nomenclature and Taxonomy, and it is now the official genus name.

Although the first cases of human listeriosis were reported in 1929 in Denmark, the oldest preserved laboratory culture of *L. monocytogenes* dates from 1921, isolated from a patient with meningitis by Dumont and Cotoni in France. For many years, clinical *Listeria* isolates were a laboratory rarity, and the epidemiology of the disease was an unresolved mystery. However, at the end of the 1970s and the start of the 1980s, the number of reports on *Listeria* isolations began to increase and, in 1983, the first outbreak in human directly linked to the consumption of *L. monocytogenes* contaminated foodstuffs (coleslaw salad) in Canada was reported. Subsequent investigations of a series of epidemic outbreaks in humans in North America and Europe clearly established *L. monocytogenes* as a foodborne pathogen.

Characteristics of *Listeria monocytogenes*

The Organism

Listeria monocytogenes is a member of the genus *Listeria*, a group of Gram-positive bacteria with low G + C content closely related to *Bacillus* and *Staphylococcus*. The genus *Listeria* includes seven other species: *Listeria ivanovii*, *Listeria welshimeri*, *Listeria innocua*, *Listeria seeligeri*, *Listeria grayi*, *Listeria marthii*, and *Listeria rocourtii*, the latter two having been described in 2009. Although *L. monocytogenes* is recognized as the causative agent of listeriosis in humans, rare cases of infection by *L. innocua*, *L. ivanovii*, and *L. seeligeri* have also been reported.

Listeria monocytogenes is catalase-positive, oxidase-negative, regular short rod with a diameter of approximately 0.5 μm and a length of 0.5–2.0 μm (Figure 1). They are facultative anaerobes that do not form a capsule, do not form spores, and are motile by peritrichous flagella when cultured at 20–25 °C and nonmotile at 37 °C. They have the capacity to hydrolyze aesculin and sodium hippurate but not urea, gelatin, or casein. Production of acid is observed when *L. monocytogenes* is cultured in media with L-rhamnose, but not D-mannitol or D-xylose.

Through examination of group-specific surface proteins, such as somatic (O) and flagellar (H) antigens, at least 13

 doi:10.1016/B978-0-12-378612-8.00101-3

serotypes (i.e., 1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4ab, 4b, 4c, 4d, 4e, and 7) have been recognized in *L. monocytogenes*.

Factors Affecting Survival and Growth

The organism's ability to grow and reproduce in harsh conditions makes it a foodborne pathogen of great concern. In common with other organisms, the environmental conditions like temperature, pH, water activity, and the atmospheric environment are the main factors affecting the growth of *L. monocytogenes* in foods (Table 1).

Figure 1 Gram staining of *Listeria monocytogenes*.

Temperature

Listeria monocytogenes can grow over the temperature range of −1.5 to 45 °C, with an optimum between 30 and 37 °C.

Listeria monocytogenes is not considered as a heat-resistant organism, being eliminated by conventional milk pasteurization. As with other organisms, heat resistance increases with decreasing water activity and after exposure to some sublethal treatments. A list of *D*-values reported for *L. monocytogenes* in the scientific literature is presented in Table 2. It is important to note that these values may vary according to the experimental methodology and the strains tested. Significant differences in the resistance of different strains of *L. monocytogenes* to different stress conditions have been observed.

Listeria monocytogenes has been isolated from several frozen foods, including dairy products, meats, vegetables, and fish products. Cell numbers of *L. monocytogenes* Scott A inoculated into ice cream did not alter during storage at −18 °C for 5 months.

Table 1 Reported generation times for growth of *Listeria monocytogenes* under different conditions

Temperature (°C)	*pH*	*Media*	*Generation time (h)*
−1.5	NR	Vacuum-packaged sliced roast beef	100
0.0	6.6	UHT milk	77
2.5	6.6	UHT milk	24
5	NR	Vacuum packed ham	33.1
5	6.41	Anthotyros cheese	20.2
10	NR	Shredded lettuce (chlorine treated and modified atmosphere storage)	10.8
10	NR	Melon pulp	7.12
10	4.9	Papaya	15.1
10	NR	Vacuum-packed ham	13.4
20	NR	Melon pulp	1.74
20	4.9	Papaya	6.4
30	NR	Melon pulp	0.84
30	4.9	Papaya	1.2

NR, not reported.

Table 2 Reported *D*-values for *Listeria monocytogenes* under different conditions

Temperature (°C)	*pH*	*Media*	*Water activity*	D-*value (min)*
60	5.5	Beef	NR	3.8
61	NR	Surface-pasteurized turkey bologna	NR	2.1
63.3	NR	Liquid egg yolk	0.989	0.20
63.3	NR	Liquid egg yolk plus 10% w/v sucrose	0.978	0.72
63.3	NR	Liquid egg yolk plus 10% w/v NaCl	0.865	11.5
66.1	NR	Raw milk	NR	0.25
70	NR	Beef	NR	0.13
71.1	NR	Raw milk	NR	2.7×10^{-2} (1.62 s)
71.7	NR	Sterile whole bovine milk	NR	5.0×10^{-2} (3.0 s)
71.7 (prior heat shock at 48 °C 15 min)	NR	Sterile whole bovine milk	NR	7.7×10^{-2} (4.62 s)

NR, not reported.

pH

Listeria monocytogenes grows over a wide range of pH values (4.3 to 9.6) with an optimum between 6 and 8. These values, however, may vary with the acidulant used and temperature.

When inoculated into orange serum or cut strawberries (pH 3.6–3.8), log reductions of 0.5–1 cfu g^{-1} were observed during storage for 7 days at 4 °C. However, 4 to 5 log reductions were observed from 2 to 5 days when orange serum was incubated at 30 °C. Similarly, when inoculated into apple juice at pH 3.42 (initial cell concentration 10^6 cfu ml^{-1}), no bacteria were recovered after 48 h of incubation at 26 °C.

Prior adaptation of *L. monocytogenes* to mildly acidic conditions has been demonstrated to enhance the survival of the pathogen in low-pH foods. As an example, when inoculated into Crescenza cheese (pH 5.0–5.6), cells previously exposed to pH 3.5 increased by 3 log cycles, whereas nonadapted cells decreased 0.8 log cycles after 14 days storage at 4 °C.

Water Activity

In optimum conditions of pH and temperature, the minimum water activity (a_w) value that allows growth is 0.90. However, it has been recovered from the sludge in cheese brines (at salt saturation, ca. 26% w/w, a_w 0.75, and cool ambient temperature of 14–16 °C) over a long period of time, showing considerable resistance to very low water activities. In a saturated salt solution in (TSB) at 8 °C, survival was 50% after 1 year, but at 22 °C survival was ca. 45% after only 4 months. In dry-cured fermented salami with water activities from 0.79 to 0.86, *L. monocytogenes* survived for 12 weeks at 5 °C.

Atmosphere

Growth of *L. monocytogenes* occurs in aerobic conditions, but is improved by anaerobic conditions and the bacteria can tolerate up to ca. 20% CO_2; however, CO_2 concentrations approximately above 50% are considered inhibitory.

Irradiation

Although there is limited information available, it is generally assumed that *L. monocytogenes* exhibits a resistance to gamma and UV irradiation similar to and lower than, respectively, other Gram-positive bacteria, and is more resistant to irradiation than Gram-negative bacteria. As with other organisms, irradiation in air is more lethal than in vacuum or modified atmospheres (low O_2 tension). A 6 to 7 log reduction can be achieved by 2–4 kGy.

Listeria monocytogenes in Food-Processing Environments

Listeria monocytogenes is generally found widely distributed in natural environments and has been isolated from soil, decaying vegetation, stream water, sewage, urban environments, and human and animal feces. This common environmental distribution and its unusual ability to adapt and survive under extreme conditions, when compared to other pathogens, make *L. monocytogenes* a considerable challenge in terms of eradication and control in the food-processing environment, and a great concern for the food industry. Although methods of basic quality assurance have been developed and implemented to control *L. monocytogenes* contamination throughout the food processing stages, several studies indicate that the most important source of food product contamination is cross-contamination from equipment and the general environment after the foods have been processed. Moreover, it has also been shown that *L. monocytogenes* can persist – a specific subtype of a strain is repeatedly isolated over an extended period of time – in food processing plants. A number of studies support the observation that persistent strains can often be isolated from the environment of food-processing plants (e.g., drains, equipment, etc.), and particularly from the sites close to food-contact surfaces (e.g., slicing machines), rather than raw materials. The finding that persistent strains are often recovered from the environment and equipment after cleaning and sanitizing, emphasizes the risk of growth and establishment of *L. monocytogenes*, particularly in sites difficult to access leading to ongoing food product contamination. The reasons why certain *L. monocytogenes* strains are able to persist is not well understood. Some authors consider that these strains are better adapted to the processing environment and possess characteristics that influence survival against stresses in the processing environment, such as resistance to sanitizers and improved ability to adhere to food-contact surfaces to form biofilms. Although it has been demonstrated that *L. monocytogenes* is capable of rapid attachment to different food-processing surfaces like buna-N rubber, cast iron, stainless steel, nylon, Teflon®, polyester floor sealant, and glass, few studies have provided strong evidence of the ability of this pathogen to actually form biofilms. Therefore, there is still some controversy as to whether or not *L. monocytogenes* forms a classic biofilm, or if the more common methods used to quantify biofilm formation (e.g., enumeration or crystal violet staining of adhered cells) merely reflects the cell adsorption to a surface (a reversible state, as the bacteria can be removed from the surface by moderate washing), rather than a true biofilm (adherence of planktonic cells followed by production of extracellular polysaccharides and resistance to cleaning and sanitizing).

Listeria monocytogenes Control in the Food-Processing Environment

Sanitizers

No unusual resistance to biocides has been reported for *L. monocytogenes* and, in general, it is considered less resistant than *Pseudomonas* spp. The efficacy of biocides, however, decreases when they are tested against attached cells. Previous work on the evaluation of eight commercial disinfectants demonstrated that aldehyde and acid/peroxide-based products were ineffective at the recommended concentrations. Only three products, those containing an amine, quaternary ammonium compound, and peroxide and chlorine-based products caused 5 log reductions in *L. monocytogenes* cell numbers. Acquired resistance to biocides in *L. monocytogenes* has been considered a very rare event, but during the last few years, resistance to different agents has been increasingly documented for this species.

Antilisterial Bacteriophages

In October 2006, the FDA proclaimed the 'generally regarded as safe' (GRAS) status for LISTEX™ P100 (MICREOS Food Safety, the Netherlands), a commercial preparation of antilisterial phages, against *L. monocytogenes* in cheese. The extension to all products susceptible to *Listeria* opens the door for the meat and fish industry to apply LISTEX™. Recently, the Dutch designated inspection office SKAL confirmed the 'organic' status of LISTEX™ under the EU law, as a result of which it can be used in the EU in regular and organic products. Natural bacteriophages may prove to be a unique solution, where increased safety does not come at the expense of product characteristics. US food processors can now benefit from LISTEX™, like their European counterparts.

Natural Antimicrobials, Bacteriocins

Bacteriocins are simply defined as biologically active protein moieties with an antibacterial mode of action. The family includes a diversity of proteins in terms of size, microbial targets, modes of action, and immunity mechanisms. They differ from traditional antibiotics in one critical way: they are ribosomally synthesized rather than from secondary metabolites, they have a relatively narrow spectrum of activity, are only toxic to bacteria closely related to the producing strain, and the genes responsible for production and immunity are generally found clustered in operons. They have been found in all major lineages of bacteria, but are most generally found and studied in lactic acid bacteria (LAB). These bacteriocins can serve as natural food preservatives and processing aids that are GRAS.

To date, the only commercially produced bacteriocins are nisin, produced by *Lactococcus lactis*, (marketed as Nisaplin™), pediocin PA-1, produced by *Pediococcus acidilactici*, (Danisco, Copenhagen, Denmark), and ALTA™ 2431 (Kerry Bioscience, Ireland). Nisin is used in more than 48 countries and has the Food and Drug Administration approval. Nisaplin™ is sold as a natural food protectant and has been shown to be effective in a number of food systems, inhibiting the growth of a wide range of Gram-positive bacteria, including *L. monocytogenes*. The possibility of including live bacteriocin-producing LAB in foods has been a promising area: protective culture concept. Bioprotective cultures may act as starter cultures in the food fermentation process, such as dry sausage manufacturing process, or they may protect foods without any detrimental organoleptic changes. This system of incorporating a bacteriocin-producing culture into a food provides it with its own built-in biopreservation, thereby returning to a more natural method of shelf-life extension and improving the safety of food. This concept has been studied in cold-smoked fish and in some artisanal meat sausages.

Listeriosis: Epidemiology and Clinical Features

Listeriosis had generally been thought of as a veterinary disease until the 1980s when the rise in the numbers of human cases of listeriosis in several countries, together with evidence for foodborne transmission, renewed interest in this disease. Listeriosis is an atypical foodborne illness of major public health concern because of its severity, the high case-fatality rate, the long incubation period, and the predilection for individuals who have an underlying condition which leads to impairment of T-cell-mediated immunity. Most cases of human listeriosis are foodborne; however, the disease process is complex with multiple routes of infection.

Clinical Manifestations

Listeriosis in humans caused by the consumption of contaminated food can occur in two forms: the more severe, invasive systemic disease, or a febrile gastroenteritis (Table 3). The establishment of the disease depends on three major variables: the number of bacteria ingested with food, the pathogenic potential of the strain, and the immunological status of the host. For example, only 4 of the 13 serotypes (i.e., 1/2a, 1/2b, 1/2c, and 4b) have been involved in the majority of human listeriosis cases reported.

Listeria monocytogenes has the ability to cross the intestinal, blood–brain, and fetoplacental barriers; septicemia, central nervous system infections, miscarriages, and stillbirths are the most common forms of the invasive infection.

Several outbreaks of listeriosis associated with consumption of foods with high levels of *L. monocytogenes*, in which the symptoms are confused with those of other foodborne gastroenteritis, have been reported.

Listerial dermatitis, appearing as papular or pustular lesions on the arms or hands of veterinarians or other people, can occasionally occur as an occupational hazard from infected animals.

Mechanism of Infection

Host cell infection begins with the internalization of the bacteria either by phagocytosis in the case of macrophages or induced phagocytosis (invasion) in the case of normal nonphagocytic cells. *Listeria monocytogenes* displays a large variety of surface proteins, known as internalins, that mediate bacterial invasion into human cells. The surface protein internalin A (InlA) was identified as the main bacterial factor involved in the invasion of polarized cells. The cellular receptor for InlA in epithelial cells is E-cadherin, present in several human barriers. It has been demonstrated that the E-cadherin/InlA interaction is critical for the bacteria to cross barriers such as the intestinal, the feto-placental, or the blood–brain barrier. The protein InlB is also critical for *L. monocytogenes* invasion, exhibiting, however, a broader range of target cells than InlA. The main signaling receptor for InlB is the hepatocyte growth factor (HGF) receptor Met, a ubiquitous tyrosine kinase receptor involved in the development of organs such as the liver or placenta. Escape of the pathogen from the vacuole within infected cells requires the expression of listeriolysin O (LLO), a pore-forming toxin which induces the lysis of this compartment, which in some cells can function synergistically with, or be replaced by a phosphatidylinositol-specic phospholipase C (PI-PLC). Once the phagosome is broken, the bacteria are freed into the cytoplasm. Intracellular movement requires expression of the bacterial surface protein ActA, required for the polymerization of actin-enriched structures that

Table 3 Clinical manifestations, diagnosis, and treatment of foodborne listeriosis

Types of listeriosis	*Sources*	*Incubation period for the disease*	*Clinical manifestations*	*Diagnosis*	*Treatment*
Severe gastroenteritis (generally occurs in healthy individuals)	Consumption of foods contaminated with high levels of *L. monocytogenes*	A few hours to 2 days	Fever, vomiting, and diarrhea, sometimes progressing to septicemia	Isolation of *L. monocytogenes* from blood (severe cases) Isolation of *L. monocytogenes* from suspected foods Isolation of *L. monocytogenes* from feces is of little relevance	Ampicillin or ampicillin in combination with aminoglyco-side or cotrimoxazole
Adult infections (more common in elderly and immunocompromised)	Consumption of foods contaminated with *L. monocytogenes*	A few days to several months	Asymptomatic or flu-like symptoms, may progress to meningitis, encephalitis, or septicemia	Isolation of *L. monocytogenes* from blood, CSF, or affected organs; observation of Gram-positive bacilli in the CSF	
Infection during pregnancy (more frequent in the third trimester of pregnancy)	Consumption of foods contaminated with *L. monocytogenes*	A few days to several months	Asymptomatic or flu-like symptoms associated or not, with gastrointestinal disorders, uterine infection, miscarriage, stillbirth, or neonate infection	Isolation of *L. monocytogenes* from blood, amniotic fluid, or vaginal fluids	
Neonatal infection	Transplacental dissemination	A few hours after birth to 48 h (early-onset syndrome)	Early neonatal septicemia (similar to infection caused by group B *streptococci*)	Isolation of *L. monocytogenes* from blood, CSF, umbilical cord, gastric exudates, or affected organs; observation of Gram-positive bacilli in the CSF	
	Contamination during delivery	1–2 weeks (late-onset syndrome)	Meningitis, encephalitis, and septicemia (closely associated with prematurity)	Isolation of *L. monocytogenes* from blood, CSF, or affected organs; observation of Gram-positive bacilli in the CSF	
	Hospital-acquired infection (by contact with infected newborns or with contaminated postnatal environment)				

CSF, cerebrospinal fluid.

enable *L. monocytogenes* to move from one infected cell to adjacent cells, without being exposed to the extracellular environment. Lysis of the second vacuole is performed by a lecithinase (PC-PLC) and LLO.

Six of the crucial virulence genes, involved in the different steps of *L. monocytogenes* infectious cycle, are clustered on a pathogenicity island known as 'positive regulatory factor A (PrfA)'-dependent virulence gene cluster. These genes are: *hly* (encoding LLO); *plcA* (encoding PI-PLC); *actA* (encoding ActA); *plcB* (encoding PLCB); *mpl* (encoding a metalloprotease involved in the maturation of pro-PlcB); and *prfA* (encoding, PrfA) that activates the transcription of all genes located in this pathogenicity island, including its own. The internalins InlA and InlB are encoded by the *inlAB* operon located in another gene cluster. PrfA is also involved in the regulation of the expression of other genes involved in *L. monocytogenes* virulence that are dispersed on the chromosome, including the internalin locus *inlAB*. Mutants lacking a functional PrfA protein are avirulent and present significantly reduced transcript levels of the virulence genes.

Listeria monocytogenes is well adapted to survive both as a saprophyte, in soil and decaying organic matter, and as a pathogen inside eukaryotic host cells. A variety of physicochemical signals such as temperature, pH, salt, carbon sources, and several stress conditions seem to play a crucial role in the expression of the *L. monocytogenes* virulence genes and in the efficient transition between extracellular and intracellular lifestyles. Outside host cells, *L. monocytogenes* represses the synthesis of PrfA, considered the master regulator of the virulence genes, resulting in the reduction of virulence gene expression. Following ingestion by a mammalian host, the increased temperature and reduced pH of the stomach results in increased production of stress-response proteins, internalins, and PrfA, initiating the transition to virulence. The alternative sigma factor σ^B, encoded by *sigB*, also contributes to the regulation of PrfA expression as a response to several types of stresses such as low pH (~pH 2) of the stomach, high osmolarity and activity of bile in the upper intestine, and thereby *L. monocytogenes* virulence gene transcription. After surviving the acidity of stomach, the bacteria are able to cross the intestinal barrier and are thought to disseminate from the mesenteric lymph nodes to the spleen and the liver.

Epidemiology

Statistical Data on Prevalence and Incidence of the Disease

Listeriosis is reported mainly in the industrialized countries, and data from Africa, Asia, and South America are scarce. The absence of diagnostic and surveillance systems or testing facilities, the high incidence of other pathogens and pathologies, different consumption patterns and dietary habits, or different host susceptibilities are the possible reasons for the lack of data in these continents.

In Europe, the incidence of listeriosis in 2008 was three cases per million inhabitants. A decrease was observed in 2007 and 2008. However, in recent years, an increase in the rate of listeriosis has been reported in countries such as Estonia, Germany, Ireland, Italy, Latvia, Lithuania, Netherlands, Poland, Spain, Sweden, and the UK.

In Canada and in the USA the reported incidence is approximately four and three cases per million inhabitants per year, respectively.

Although listeriosis can cause disease in all populations, the majority of cases (more than 50%) occur in those aged 65 years and more, but most elderly patients often have an underlying immunocompromising condition.

Reservoir of Pathogens, Vehicle of Transmission, Examples of Food Incriminated and Data on Prevalence of Contamination or Distribution in Nature

Listeriae are ubiquitous microorganisms that have been isolated from a diversity of sources, including soil, water, effluents, a large variety of foods, and human or animal feces. They live as saprophytes in decomposing plant matter, which appears to be their natural habitat. However, the prevalence of *L. monocytogenes* in urban sites is higher than in natural sites. It has been isolated in low numbers from a variety of environmental samples associated with the primary production of food.

A wide range of food types has been associated with the transmission of listeriosis, namely milk and dairy products, meat products (cooked chicken, sausages, paté and rilletes, pork tongue, hot dogs, ham, salami, chicken wraps, and deli turkey breast), fish products (shrimp, smoked fish, smoked trout mousse, shellfish, and smoked mussels), vegetables (coleslaw salad, alfalfa, rice salads, and celery), and other products like sandwiches. Generally, these foods have an extended shelf life, do not require further cooking at home, and can support the growth of high levels of *L. monocytogenes*.

The prevalence of *L. monocytogenes* in foods has been evaluated by many researchers and food authorities or food inspection agencies. Each year, The European Food Safety Authority publishes a report with the data collected in each country.

Causes of the Outbreaks/Incidences

Food products were not considered as a vehicle of listeriosis until the outbreak which occurred in Canada in 1981 was investigated, and provided evidence to link ingestion of food contaminated with *L. monocytogenes* with listeriosis. Since then, severe outbreaks have been reported worldwide (Table 4), although the investigation of invasive listeriosis outbreaks is complex due to the long incubation period (5–70 days). This makes it very difficult to obtain accurate food histories from case-patients and also because listeriosis primarily affects persons with an immunocompromised status.

Specific Factors of Risk

Listeriosis is a rare disease among the general population with a reported incidence much lower than many other foodborne diseases. Certain groups within the general population which have an underlying condition which leads to impairment of T-cell-mediated immunity are particularly susceptible to infection, namely immunocompromised persons by medication

Table 4 Food products implicated in invasive listeriosis outbreaks occurring worldwide between 1981 and 2009; number of cases and deaths reported and serotype involved

NR, not reported.

or disease (e.g., organ transplant or cancer patients), HIV-infected individuals, pregnant women, fetuses/newborn babies, and the elderly. In these higher risk groups, associated mortality rate can reach 40%. Within these susceptible populations, bone marrow transplant patients, those with blood-borne cancers, and individuals with full-blown AIDS are at the highest risk of severe listeriosis resulting in a fatal outcome. However, cases in individuals not showing any apparent predisposition have been reported.

Demographic changes and medical advances have resulted in an increase in the size of certain at-risk groups, namely the elderly and immunocompromised patients; therefore, an increase in listeriosis in older patients is likely to occur. In fact, the majority of the cases are already being reported worldwide in those aged 65 years and more.

Analytical Methods for Organism and Toxins

Detection, Isolation, and Enumeration of *Listeria monocytogenes*

The analysis of *L. monocytogenes* is performed to determine compliance of the food industry with standards and guidelines, to assess the safety of foods, or to support foodborne disease investigation.

There are several established culture-based methods for the detection of *L. monocytogenes*, all of them requiring an initial step to increase the viable cell count to detectable numbers. This is generally achieved using a selective enrichment in liquid medium, which usually takes from 24 to 72 h. Enrichment media include University of Vermont I broth (UVM I), buffered Listeria enrichment broth (BLEB), Fraser broth, and 1/2 Fraser broth, in which the inhibitory components acriflavine and nalidixic acid are used in similar concentrations; Fraser broth also has lithium chloride as a selective agent. Enrichment steps are followed by plating onto agars containing selective/differential agents. Oxford agar (OXA) was the medium of choice of the International Organization for Standardization (ISO) until 1998, when it was replaced by PALCAM agar (**Figure 2**). In 2004, it was replaced by a chromogenic agar, ALOA, (agar Listeria acc. to Ottaviani & Agosti), which allows the differentiation of *L. monocytogenes* and *L. innocua* (**Figure 3**). The detection in the first two plating media is based on the hydrolysis of aesculin which does not differentiate between species. In ALOA, the detection is based on the phosphatidylinositol phospholipase C enzyme (PI-PLC) activity, present in *L. monocytogenes* and in *L. ivanovii*, and β-glucosidase activity detected by a chromogenic substrate. The confirmation of suspected colonies can be performed by testing a limited number of biochemical markers such as hemolytic activity (CAMP test, **Figure 4**) and sugar fermentation patterns.

Figure 2 Growth of *Listeria monocytogenes* in PALCAM agar.

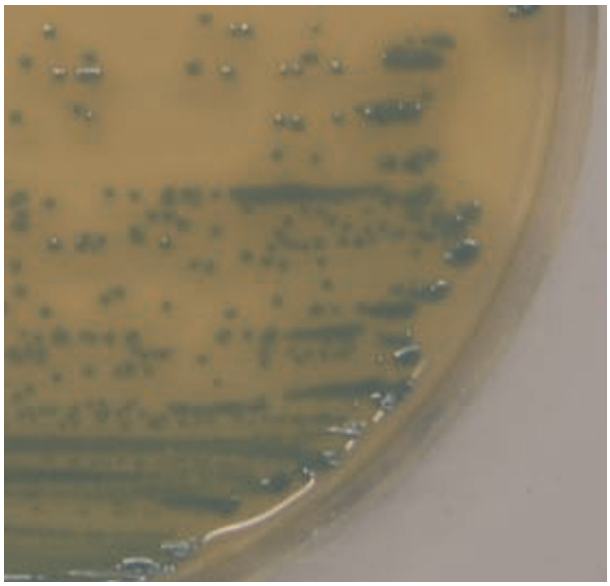

Figure 3 Growth of *Listeria monocytogenes* in ALOA plates.

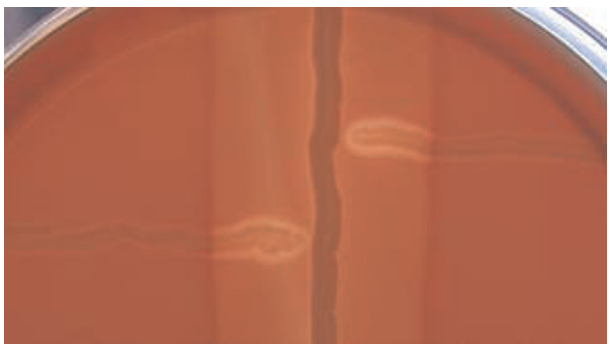

Figure 4 CAMP test for *Listeria monocytogenes*.

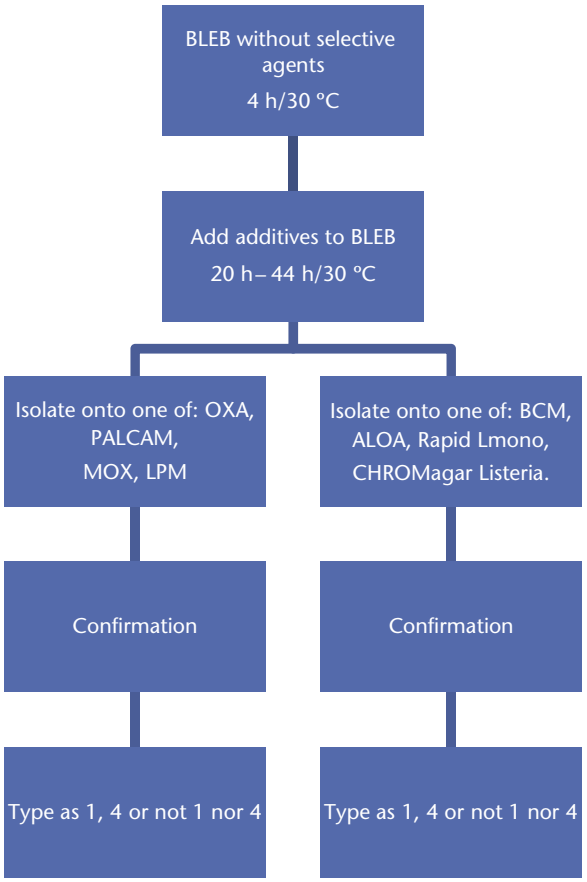

Figure 5 Schematic representation of FDA BAM method for the detection of *Listeria monocytogenes* in foods.

The FDA Bateriological Analytical Manual (BAM) method, as shown in Figure 5, uses one enrichment medium (BLEB) which has a first step of incubation of 4 h without selective agents, followed by an incubation of 20–44 h in the complete medium at 30 °C. After this step, subculturing by streaking is performed on selective solid media. There is a recommendation to use a second medium to differentiate species. After biochemical confirmation, the method requires serological subtyping (using commercial antisera) in order to characterize isolates as type 1, 4, or neither type 1 nor 4 (types 3, 5, 6, etc.).

The ISO method is summarized in Figure 6. The methodology includes two enrichment steps in 1/2 Fraser and in Fraser broth, and the use of two solid media for isolation of *L. monocytogenes*, ALOA and the second solid medium are chosen by the laboratory. Some alternative methodologies based on the ISO method are available in the market, such as the VIDAS LMO II (bioMérieux, France) or 'short protocols' AFNOR validated (Figure 7).

Enzyme-linked fluorescent assay (ELFA) is the basis of the method used by the automated VIDAS for the detection of antigens of *L. monocytogenes*. Results are obtained in 48 h if negative. Otherwise, further confirmation has to be performed following the reference method or through another alternative method.

More recently, a set of kits has been launched based on real-time PCR methods, such as the iQ-Check *L. monocytogenes*

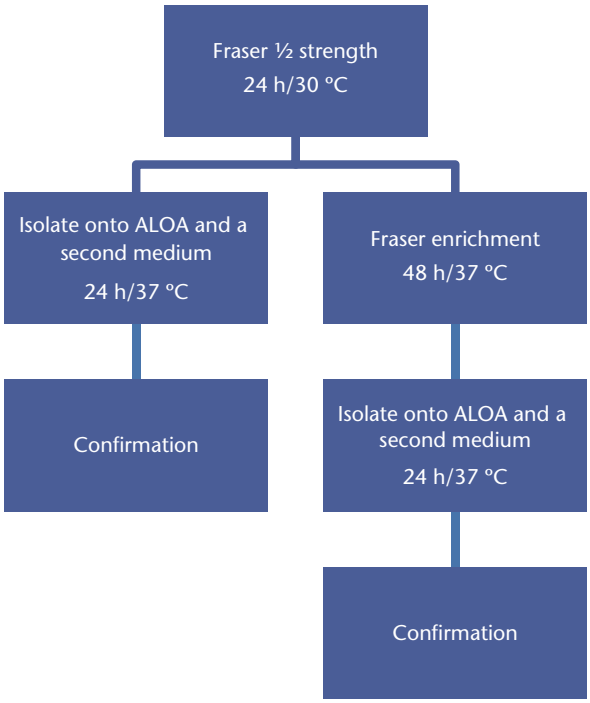

Figure 6 Schematic representation of ISO 11290-1:1996, amended. 1:2004 method for the detection of *Listeria monocytogenes* in foods.

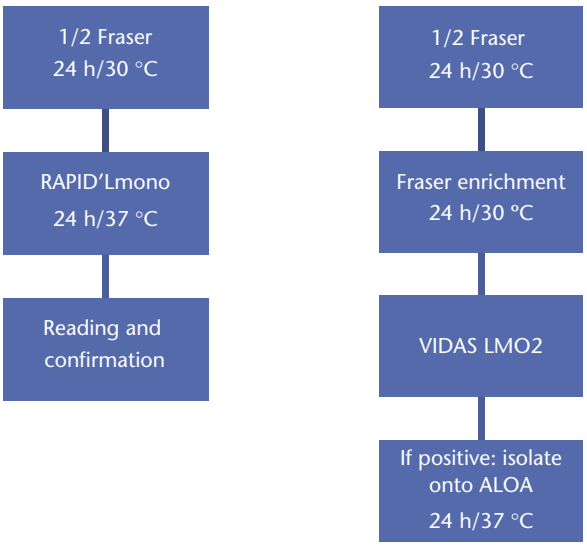

Figure 7 Schematic representation of protocols AFNOR validated using Rapid'Lmono (left) and VIDAS bioMérieux (right) for the detection of *Listeria monocytogenes*.

from Bio-Rad which has AFNOR validation according to ISO 16140 (Figure 8). After the enrichment steps in 1/2 Fraser or in Listeria special broth (LSB) for 24 h at 30 °C, lysis of bacteria and DNA extraction are performed using reagents included in the kit and finally, a PCR is run. Results are obtained in 24 h. According to AFNOR validation, positive results

Figure 8 Schematic representation for the detection method of *Listeria monocytogenes* by real-time PCR.

should be confirmed by the reference method or using another alternative method.

The most probable number (MPN) is a procedure to estimate the microbial concentration in a test sample; it is particularly useful when low numbers of organisms are present. Generally, three 10-fold serial dilutions are used in either a three- or five-tube MPN series. Based on positive results achieved, an MPN table is used to calculate the concentration of bacteria in the original sample.

Direct counts of *L. monocytogenes* can be performed following the reference method described in ISO 11290-2, Amd. 2004. It should be noted that due to the low pH and high salt concentration in cheeses, some cells may be in an injured state and therefore unable to grow on selective media such as PALCAM, which was the major plating media used until 2004. This direct method is also characterized by a detection limit of 10–100 cfu g^{-1} and, therefore, is not well adapted to the enumeration of low levels of *L. monocytogenes* in foods.

Subtyping of *Listeria monocytogenes*

Several methods of subtyping of isolates of *L. monocytogenes* have been used over the past decades. These include serotyping, antimicrobial resistance testing (e.g., arsenic, cadmium, and tetracycline resistance), bacteriocin typing, phage-typing, multilocus enzyme electrophoresis (MEE), and more recently, several molecular, genetic methods such as amplified fragment length polymorphisms (AFLPs), random amplification of polymorphic DNA (RAPD), and ribotyping, but the current and internationally accepted method is pulsed-field gel electrophoresis (PFGE), although gene sequencing techniques (multilocus sequence typing (MLST) and multiple-locus variable-number tandem repeat analysis (MLVA)) are being developed as a supplement to PFGE.

Through characterization by phylogenetic and population genetic studies, *L. monocytogenes* isolates can be grouped into major evolutionary lineages, namely, lineage I (that includes isolates belonging to serotypes 1/2b, 3b, 4b, 4d, and 4e), lineage II (that includes isolates belonging to serotypes 1/2a, 1/2c, 3a, and 3c), and lineage III that subdivides into lineages IIIA, IIIB, and IIIC (all of which contain serotype 4a, 4c, and atypical serotype 4b isolates). Phylogenetic studies have

demonstrated that isolates classified as subgroup IIIB represent a distinct fourth lineage of *L. monocytogenes.* Although isolates from all four lineages have been associated with human listeriosis, lineage I isolates are significantly overrepresented among human listeriosis cases, in particular, those of serotype 4b. Lineage II strains have a higher prevalence among isolates from environmental samples and foods, and lineage III strains are rare and mainly associated with listeriosis in animals.

Subtype characterization of *L. monocytogenes* isolates from listeriosis outbreaks that have occurred over the past three decades has suggested that many outbreaks have been caused by a small number of *L. monocytogenes* epidemic clones (ECs), i.e., a group of closely related individuals with a common ancestor. Four *L. monocytogenes* ECs have been reported to date, designated as ECI, ECII, ECIII, and ECIa (ECIa has also been referred to as ECIV) (Table 4).

Level of Characterization Needed to Link Human Cases to the Implicated Food or to Each Other

Typing of bacterial isolates, that is the generation of patterns of parameters which can contribute to the differentiation between closely related taxa, reveals the relationship between them. Typing can be used for a number of purposes, including the determination of the primary sources of contamination and to link people who are ill following the consumption of contaminated foods, to the sources of bacterial contamination. Also, the differentiation beyond the species level provides a tool to better understand the ecology of *L. monocytogenes* strains and subtypes, including differences in their ability to cause human foodborne disease. The characterization of bacterial isolates can be based on their phenotypic traits, such as metabolic reaction profiles, antibiotic susceptibility profiles, and serotypes, or by the nature of the DNA of the genome, by using molecular typing techniques.

Serotyping

Serotyping is most often an early step in a typing scheme and, although not being highly discriminatory, it can be useful in preliminary investigations. Under the sponsorship of the World Health Organization, serotyping was one of the first typing methods to be studied, evaluated, and standardized. Although the methodology is easy and simple to perform, problems with serovars that are neither 1/2a nor 4b were found and related to the difficulty in preparing good-quality antisera.

A commercial serotyping kit: *Listeria* antiserum Seiken kit (Denka Seiken Co., Tokyo, Japan) is available in the market and widely used instead of antisera produced by individual laboratories, which are used in only a small number of reference laboratories. Palumbo *et al.* (2003) developed an enzyme-linked immunosorbent assay (ELISA) to be used in conjunction with the Denka Seiken kit that made the process more efficient.

More recently, a multiplex PCR was developed allowing the molecular segregation of isolates into four groups: IIa, which includes serotypes 1/2a and 3a; IIb, which includes serotypes 1/2b, 3b, and 7; IIc, which includes serotypes 1/2c and 3c; and IVb which includes serotypes 4b, 4d, and 4e.

Pulsed Field Gel Electrophoresis Typing

PFGE is a method that has been successfully used in typing *L. monocytogenes.* Restriction enzymes cut genomic DNA infrequently producing simple profiles that could be easily compared. PFGE is considered the standard subtyping method to detect listeriosis outbreaks.

PFGE, which was used for the first time in 1991, uses a standardized DNA macrorestriction analysis by PFGE for *L. monocytogenes* using restriction enzymes *Asc*I and *Apa*I, and the establishment of a universal size standard strain for use with the standardized PFGE protocols. With the aid of computerized gel scanning and analysis, software data banks of PFGE patterns have been created enabling the comparison of strains and identifying its phylogenetic relationship with other strains.

In the USA, PulseNet is the national molecular surveillance network for foodborne infections (*Escherichia coli* O157:H7, nontyphoidal *Salmonella* serotypes, *L. monocytogenes,* and *Shigella*) and was established in 1996. The establishment of international surveillance networks, like PulseNet, in Canada, Europe, the Asia Pacific region, and Latin America, would be crucial for early warnings on foodborne disease outbreaks.

One of the disadvantages of PFGE is the time needed to complete the analysis (3–4 days). To analyze large numbers of samples, the use of a more rapid typing method, although less discriminatory, is of practical importance.

Ribotyping

This technique also uses infrequently cutting restriction enzymes, but targets ribosomal DNA. Ribosomal genes are relatively conserved across the bacteria. This allows tracing of lineages through the appearance of mutations over time. For ribosomal typing of *L. monocytogenes*, the restriction enzyme *Eco*RI is used and the DNA fragments are separated by electrophoresis. The bands are then probed with DNA probes that specifically detect those DNA fragments that code for ribosomal RNA (rRNA). A fully automated ribotyping system (Riboprinter®, Dupont Qualicon) has enabled large-scale typing of isolates with less effort and expertise than PFGE. The technique can also be used with other restriction enzymes, improving the discrimination of strains.

DNA Sequencing-Based Molecular Subtyping Methods

In recent years, DNA sequencing-based molecular subtyping methods for *L. monocytogenes* have been developed as alternatives for band-based molecular subtyping techniques (e.g., PFGE). These approaches have been used not only to assess genetic diversity among isolates, but also to study the evolution and phylogeny of *L. monocytogenes*.

Multilocus Sequence Typing

MLST is based on the DNA sequencing of multiple genes (usually seven) or gene fragments to uncover allelic variants in conserved genes of bacterial species. Sequences of each gene obtained for the isolates to be characterized are aligned and the differences observed, even at a single nucleotide, are

assigned as distinct alleles. An MLST type is then assigned to each isolate according to the unique combination of polymorphisms observed for each of the loci. MLST schemes involving sequencing of multiple housekeeping genes, of multiple virulence genes, or of a combination of housekeeping and virulence genes have been used to characterize *L. monocytogenes* isolates.

One of the advantages of MLST over other molecular typing methods is that sequence data are unambiguous and are portable between different laboratories, being easily compared with web-based databases.

Multiple-Locus Variable-Number Tandem Repeat Analysis

MLVA takes advantage of the polymorphism of tandem-repeat DNA sequences (TRs). Bacterial genomes are rich in TRs. In each repeat sequence locus, the repeat copy number can vary between different strains, therefore these sequences are often referred to as 'variable-number tandem repeats' or VNTRs. In MLVA, the VNTR array is amplified using PCR. Forward primers are fluorescently labeled so that the PCR product can be detected and sized using high-resolution capillary electrophoresis (automatic sequencer). Use of multiple different fluorescent tags enables multiplexing targets with overlapping fragment sizes. At each locus, the number of copies of each repeat is assigned based on the observed fragment sizes (allele type). Owing to the rapid accumulation of changes in VNTR regions, MLVA is particularly useful in short-term evolution studies of bacterial species.

Whole genome sequences of several *L. monocytogenes* isolates have been crucial for the identification VNTRs and the development of MVLA typing schemes for *L. monocytogenes* isolates.

PFGE is still considered the more discriminatory typing technique for *L. monocytogenes* and the selected routine typing technique for surveillance and listeriosis outbreak investigations. However, its cost, labor-intensive, and difficult interlaboratory comparisons of results lead to the constant search for other subtyping methods. MLVA has already become the preferred typing technique for other foodborne pathogens, for example, *E. coli* O157:H7, and has proven to be more discriminatory than PFGE in some cases. Therefore, in the future, this technique may replace or complement PFGE typing of *L. monocytogenes*.

Control Measures

Control of *L. monocytogenes* in the food-processing environment has been the subject of a number of research projects. Owing to its ubiquitous nature and growth capability at refrigeration temperatures, it is impossible to assure its absence in all ready-to-eat (RTE) foods at the time of consumption. Therefore, it is unanimously accepted that an integrated multipartner approach – the government, the trade, and the consumers – is required to control this organism.

Regulatory Control

The microbiological criteria for *L. monocytogenes* are a matter of discussion between several international food safety authorities. Commercialization of foods in a globalized world makes it absolutely necessary that regulations relating to *Listeria* in foods be harmonized.

A 'zero-tolerance' policy is applied in the US. The EU, Australia, and Canada permit less than 100 cfu g^{-1} in specific foodstuffs depending on the risk associated or the capability of the bacterium to grow during the shelf life of the product in question.

Concerning *L. monocytogenes*, three relevant categories of foodstuffs with different limits were established by the EU Regulation 2073/2005, amended by EU Regulation 1441/2007: RTE foods intended for infants or for special medical purposes (absence in 25 g for products placed in the market during their shelf-life); RTE foods able to support the growth of *L. monocytogenes*, other than those intended for infants and for special medical purposes (absence in 25 g before the food has left the immediate control of the food business operator, who has produced it, and the product will not exceed the limit of 100 cfu g^{-1} throughout the shelf-life); and RTE foods unable to support the growth of *L. monocytogenes*, other than those intended for infants and for special medical purposes (100 cfu g^{-1} for products placed in the market during their shelf-life).

Control at Industry Level

The regulator's efforts to control *L. monocytogenes* in foods will be not effective, if the indusrty is not committed to ensuring the production and distribution of safe food. Control strategies are needed at all stages in the food chain (farm, processing, retail, foodservice, and domestic environment) with the following objectives: (1) to prevent contamination and growth in raw materials; (2) to destroy/reduce the pathogen if present in raw materials; (3) to prevent recontamination after a listericidal process; and (4) and to prevent/reduce the growth when present in final products to avoid levels considered unsafe at the time of consumption. The most effective strategies to reach these objectives include: implementation of environmental controls and using effective disinfection systems; implementation of Hazard Analysis and Critical Control Points (HACCP) programs at all stages of the food industry, giving particular attention to time/temperature controls and cross-contamination during processing and at retail; frequent revision of the HACCP programs so that they can more accurately identify the critical control points along the production line; combination of factors that are more effective in controlling listeria growth in RTE foods, for example, lactic acid, bacteriocins, and starter cultures; and application of post-packaging treatments (e.g., high-pressure processing) to inactivate *L. monocytogenes*.

Food Safety Education

In addition to regulatory and industry changes, educational initiatives on listeriosis prevention are needed.

The education of at-risk individuals, of their food preparers, and of the health professionals providing care for them is proposed as a key strategy in the reduction of the incidence of listeriosis – information on high-risk foods to be avoided,

and education on the four simple practices (clean, separate, cook, and chill) that can help reduce the risk of foodborne illness in general and listeriosis in particular.

Costs

A report published by the Centers for Disease Control and Prevention (CDC, USA) estimated that 2518 cases of listeriosis occurred every year in the USA, which result in 2322 hospitalizations and 504 deaths in the US each year. However, these results are based on a 1999 report and, therefore, are outdated because the food industry has invested heavily in improving its food safety practices. In the EU, the reported cases in 2008 (data from 25 countries) were 1389 and 134 deaths.

Illness caused by the consumption of contaminated foods has a considerable economic and public health impact worldwide, which are difficult to quantify. Generated costs include health-related expenses (e.g., medical costs and quality-of-life losses), and expenses related to food-processing companies, for example, food product recalls and bad publicity. A recent and illustrative example was the listeriosis outbreak that occurred in Canada in 2008 caused by hams and charcuterie products, which had a direct cost of $19 million to the company (Maple Leaf Foods) due to the recall of contaminated meat.

Glossary

High temperature short time pasteurization 71.7–72°C for at least 15 s for high temperature short time (HTST) pasteurized milk products, which is a continuous pasteurization process as compared with batch pasteurization at lower temperatures for a longer time. This results in five log (99.999%) or greater reduction in harmful bacteria. HTST is also used for beverages, such as fruit juices. Currently, many milk processing plants exceed these minimum requirements for fluid milk products. Compared to other pasteurization processes, HTST pasteurization maintains color and flavor better, but some cheeses are found to have varying responses to the process. For fluids, HTST must be used in conjunction with sterile fill technology to prevent postpasteurization contamination.

Lymph nodes Small bean-shaped scattered masses of tissue in the lymphatic system that act as filters and immune monitors, removing fluids, bacteria, or cancer cells along the route of the system.

Macrophage Any large, mononuclear, highly phagocytic cells derived from monocytes that occur in the walls of blood vessels and in loose connective tissue. They are components of the reticuloendothelial system. Macrophages are usually immobile but become actively mobile when stimulated by inflammation; they also interact with lymphocytes to facilitate antibody production.

Nucleotide-binding oligomerization domain-containing protein 2 (NOD2) The official name of the *NOD2* gene is nucleotide-binding oligomerization domain containing 2 on chromosome 16 in humans. The *NOD2* gene provides instructions for making a NOD2 also known as caspase recruitment domain-containing protein 15 (CARD15) or inflammatory bowel disease protein 1 (IBD1). NOD2 plays an important role in the immune system. It recognizes bacterial molecules (peptidoglycans) and stimulates an immune reaction.

Phagocytosis The process includes five steps by phagocytes (white blood cells): (1) invagination, (2) engulfment, (3) internalization and formation of the phagocyte vacuole, (4) fusing of lysosomes to digest the phagocytosed material, and (5) release of digested microbial products.

Polymerase chain reaction In polymerase chain reaction testing, numerous copies of a gene are made by a rapid technique for *in vitro* amplification of specific DNA or RNA sequences, allowing small quantities of short sequences to be analyzed. The two strands of DNA containing the gene segment are separated, using DNA polymerase to make a copy, and then continuously replicating the copies.

Pulsed-field gel electrophoresis (PFGE) PFGE is used especially to separate large DNA fragments through agarose gels by periodic changing the direction of the electric current in order to minimize overlap of the bands.

Restriction fragment length polymorphism (RFLP) Fragments of DNA, cut by restriction enzymes, are different in length and the restriction fragments are separated according to their lengths by gel electrophoresis. RFLP analysis is used to trace relationships among organisms.

Subclinical infection Infection associated with no detectable symptoms although caused by microorganisms capable of producing easily recognizable diseases. This may occur in an early stage, with signs and symptoms appearing during the later stage of the infection, or the symptoms and signs may never appear (asymptomatic). Such infections can only be detected by laboratory testing.

Subpasteurization Slightly lower temperatures and/or shorter times than for the standard milk pasteurization temperatures, typically used to retain flavor in cheese making but with a risk of pathogen survival.

Background

Mycobacterium avium subspecies *paratuberculosis* (MAP) was first identified in 1895, Germany, by Johne and Frothingham at the Veterinary Pathology Institute in Dresden. The organism was causing chronic inflammation of the intestine in a cow, and this condition affecting the ruminants (cows, sheep, and goats) subsequently bore the title of Johne's disease (JD). This disease was later diagnosed in nonruminants: dogs, pigs, horses, chickens, primates, and, occasionally, carnivores like weasels. Clinical JD in dairy cattle typically causes loss of condition, a reduction in milk yield, weight loss, and periodic episodes of diarrhea. In a cattle herd with one or two clinically diseased animals, up to 50% of the other apparently healthy

 doi:10.1016/B978-0-12-378612-8.00102-5

animals will be subclinically infected. Infections are most likely to occur in calves and young cattle, because MAP is transmitted from cow to calf through the colostrum and milk, and directly between animals in crowded and contaminated farm environments. MAP can persist in the intestinal tract of subclinically infected animals for years without causing clinical disease, only to manifest itself when the animal undergoes physical or psychological stress such as calving or overcrowding, respectively. There is no treatment and the disease is invariably fatal, domestic animals are usually euthanized once the disease has progressed to the point of rendering them unproductive. There is increasing evidence today that Crohn's disease (CD) in humans, being somewhat similar to JD in animals, is also probably because of MAP.

Characteristics

As the name indicates, MAP is a member of the *M. avium* complex (MAC) (Nichols *et al.*, 2004). MAP is a small mycobacterium of approximately 0.5 μm by 1–2 μm in size and is an obligate intracellular pathogen that can cause chronic inflammation of the intestine in many animals. It is Gram- and acid-fast positive, and MAP cells also have intracellular vacuoles or inclusions common to mycobacteria. The environmental distribution of MAP is markedly different from that of most other members of the MAC. Although the DNA of MAP is >99% identical with that of *M. avium*, MAP only occurs in environments contaminated by feces of infected animals. MAP compensates for its inability to assimilate iron and replicate in the environment (due to lack of mycobactin) by producing an extra tough waxy rough cell wall (made of lipids and polysaccharides) thus enabling its prolonged survival until ingestion by a susceptible host. Like other mycobacteria, MAP has the capacity to replicate inside host macrophages (white blood cells). As part of the immune system, macrophages are capable of destroying a wide variety of bacterial pathogens. Mycobacteria, including MAP, however, are one of the few types of bacteria that not only can survive the antibacterial effects of macrophages, these facultative intracellular bacterial pathogens are able to replicate inside macrophages and cause disease. MAPs accomplish this by secreting factors that avoid or neutralize the production of antibacterial chemicals inside macrophages, and they are also able to suppress or modulate the host's immune response.

MAP grows very slowly under culture and is difficult to identify (see under Analytical Methods for MAP). Like many mycobacteria, MAPs demonstrate both environmental and heat resistance. Pasteurization of milk (typically 72 °C for 15 s) was designed to destroy *Mycobacterium bovis* (and *tuberculosis*) excreted from cattle into milk. However, MAP is more thermotolerant than *M. bovis*, and experimental work has shown that pasteurization at 72 °C for 15 or 25 s would reduce the number of viable organisms, but may allow some survivors. This conclusion may be supported by surveys of pasteurized milk where MAP has been found at low prevalence (see under Epidemiology of JD in Animals). Some MAP species can colonize swimming pools, aquaria, and cold water distribution systems, whilst others are more commonly associated with hot water systems. If liquids of injections contain mycobacteria, these can cause abscesses, whereas other iatrogenic infections are linked to contaminated endoscope washers and renal dialysis fluid.

Epidemiology of JD in Animals

JD, or paratuberculosis, is a disease concerning domestic livestock of cattle, sheep, and goats, that was first noticed a little over 100 years ago in Europe and North America, but is likely to be much more widespread today. The risk of infection is not only an economic one for farmers but also a human health concern because there is evidence that MAP is also pathogenic for people. Most work with MAP has been focused on cattle, and less is known about its presence in other species (Eltholth *et al.*, 2009). In beef cattle, herd prevalence from several studies is higher, as to be expected, than for individual cows (2–54% vs. 0·4–19%). For dairy cattle, herd prevalence is 3–70%, and for individual animals, 1–18%. Although these data reveal much variability between studies, the overall results indicate that MAP is frequent in both beef and dairy cattle. MAP has been isolated from the intestinal mucosa, mesenteric, head and lymph nodes, liver and spleen from naturally infected animals, and thus the contamination of the milk could be from direct shedding of the MAP in the udder or fecal contamination from an infected animal during or after milking. MAP has been detected in raw and pasteurized milk from cows, sheep, and goats, and in cheeses made thereof. In raw cow milk, the prevalence of polymerase chain reaction (PCR) and culture positive samples in several studies has ranged between 2–49% and 0.3–1.6%, respectively. In a Swiss survey of bulk milk, 23% sheep samples and 24% of goat samples were MAP positive. Meat may also be contaminated though transmission from systemically infected animals as surfaces of beef carcasses have shown the presence of MAP DNA. All this indicates that humans may be potentially exposed to MAP through consumption of dairy products (less likely from meat) or working with infected animals. Different studies have been applied to investigate the effect of different time temperature combinations on MAP inactivation. It has been estimated that MAP inactivation by high temperature short time pasteurization at 72 °C for 15 s ranges from 4 to 7 log. The rate of inactivation may depend on the primary concentration of MAP in raw milk. Subpasteurization temperature of milk for cheese production may not be sufficient for complete inactivation of MAP (65.58 °C for 16 s; Stabel and Lambertz, 2004) and MAP is not completely destroyed in milk that is artificially contaminated with a high inoculum even after a combination of high pressure (600 MPa) and pasteurization. Surveys of pasteurized milk indicate survival does occur (up to 3% culture and 15% positive by PCR). Survival may depend on the level of MAP present at pasteurization but this was not measured in the surveys. A more limited set of surveys of cheeses have shown that these may be contaminated (up to 4% culture positive and 32% by PCR).

There are also concerns for MAP in infant formula. Fifty one dried milk baby food products from 10 producers operating in seven European Union countries were tested by competitive real time quantitative PCR (Hruska *et al.*, 2011). From 48 to 32 500 MAP cells g^{-1} of powdered infant milk were found in 18 out of the 51 samples (35%). More than

10 000 cells g^{-1} were present in four samples (7.8%). Such concentrations mean that one package of milk could contain 5 million MAP cells, which is ingested by a bottle-fed infant over the course of several days. Even though they do not suffer from an immediate infection, premature babies and bottle-fed newborns can be affected by pro-inflammatory triggers from the muramyldipeptide and other components of the mycobacterial cell wall arising from the MAP present that later develop into chronic inflammatory diseases, such as CD.

In many countries, clinically diseased JD ruminants may be slaughtered and the meat and offal used for human consumption. During the slaughter and processing of the animals, large numbers of MAP, particularly in the lymph nodes and liver, would be released into the slaughterhouse environment to contaminate other carcasses, and possibly infect the workers. Any manure or slurry from the holding pens or slaughterhouse area may be sold as fertilizer and, thus, produce grown in soils containing this manure would expose the crops and their consumers to viable MAP, because pathogen survives well in the environment and may resist mild cooking.

Epidemiology of CD in Humans

CD is named after Burrill B. Crohn, an American gastroenterologist, for identifying the disease in 1932, although the disease has been recognized as early as 1913 by a Scottish surgeon, who has documented at least nine cases of inflamed intestinal tract. Typically affecting $<1\%$ of the population, CD is a chronic intestinal inflammation of humans, of which there is some evidence that MAP is a possible cause, or at least a contributor. Metaanalysis studies indicate that there is an association between MAP and CD, even though the etiology of CD is not yet clear. CD was first recognized in the past century, initially appearing in developed societies in temperate regions with intensive farming, more commonly in northern regions of Europe and North America, and less so in Asia and Africa. However, CD seems to be increasing in countries such as Iran, India Brazil, China, and Japan, which have substantially increased production and consumption of dairy products. This rising trend may also be linked to both the westernization of lifestyles such as changes in dietary habits and environmental changes such as improved sanitation plus industrialization (Thia *et al.*, 2008). Distinct regions of Canada (Prairie provinces and Nova Scotia), UK (Scotland, particularly west and north), France (Amiens), the Netherlands (Maastricht), Scandinavian region (Stockholm), and New Zealand (Canterbury) represent the highest incidence areas (Economou and Pappas, 2008). The highest levels of CD worldwide seem to be in Canada with an incidence rate of 20.2/100 000 in Nova Scotia (Bernstein *et al.*, 2006). Reasons for this specific distribution is not known. A convincing link between MAP and CD has been found from long-term studies up to the 1990s in Iceland (Hermon-Taylor and El-Zaatari, 2004). Before 1930, MAP infection and JD in Iceland were virtually unknown. Then in 1933, a few subclinically infected sheep were imported from Germany and distributed to 14 farms. By the late 1950s, the disease became an epidemic in Iceland with almost 30% of sheep farms affected. The mean incidence of CD (number of cases 100 000^{-1} $year^{-1}$) rose each decade, from 0.4 in1950–59 to 5.6 in the early 1990s, with the highest annual figure of 8.2 in 1992. Young people were particularly affected. This upward trend would probably continue (**Figure 1**).

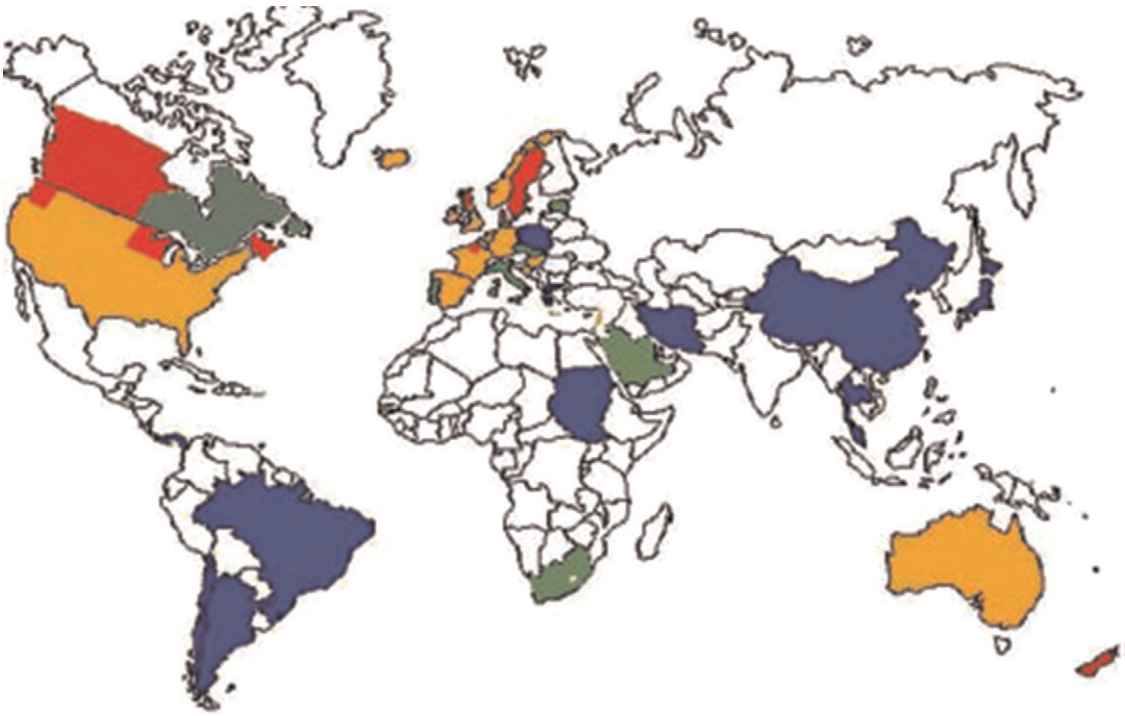

Figure 1 The global map of CD: Red refers to annual incidence above 7/100 000, orange to incidence 4–7/100 000, green to incidence 1–4/100 000, blue to incidence <1/100 000. Absence of color indicates absence of data. Reproduced from Economou M and Pappas G (2008) New global map of Crohn's disease: Genetic, environmental, and socioeconomic correlations. *Inflammatory Bowel Diseases* 14(5), 709–720.

CD affects any part of the gastrointestinal tract (GI) from mouth (nonhealing sores) to anus (itchiness or abscesses), but particularly the ileum and the colon. Symptoms vary in relation to abdominal pain, diarrhea, vomiting, and weight loss, which is classified on the whole as a type of inflammatory bowel disease. Flatulence, bloating, and blood in the stool may also occur. Associated problems are skin rashes, arthritis, inflammation of the eye, tiredness, and lack of concentration. CD also increases the risk of cancer, particularly colon cancer, where there is inflammation in the GI. The usual onset is between 15 and 30 years of age, but it is not easy to diagnose and may begin at earlier ages. There can be periods of remission followed by painful symptoms. Most people seem to be asymptomatic because of frequent exposure during a lifetime; some of these may be colonized with a risk for later acute symptoms resulting from a stress event if they are susceptible. The disease is probably underdiagnosed, and is present worldwide; it is now recognized as a major healthcare problem. CD is now known to be caused by interactions between environmental, immunological, and bacterial factors in genetically susceptible individuals. The chronic inflammation of CD is caused when the adaptive immune system tries to compensate for a deficient innate immune system. Over 30 gene mutations have been associated with CD that runs in families, and a biological function is known for most of them. An impaired cytokine secretion by macrophages contributes to impaired innate immunity, and leads to a sustained microbial-induced inflammatory response in the colon where there are billions of bacteria. NOD2, a gene toward CD genetic susceptibility, is associated with less effective macrophage destruction by MAP. Those with CD have polymorphisms that change the amino acids in the protein NOD2, each impairing the responses to peptidoglycan, which is a component of bacterial cell walls (Abraham and Cho, 2009). These polymorphisms occur with increased frequency in persons of European ancestry but are not present in Asian patients, and are significantly less frequent in African Americans with CD. Also, MAP produces mannins, which protect both itself and various bacteria from phagocytosis, and may allow it to cause a variety of secondary infections thereof. However, other bacteria could be implicated in CD (independently or synergistically with MAP) such as adherent invasive *Escherichia coli*, because they are found more frequently in CD patients than in controls. An interesting argument for the recent rise in CD is the possible exposure to large numbers of psychrotrophic bacteria such as *Yersinia* and *Listeria*, which are more likely to be in foods because of the widespread use of refrigerators. The protozoan *Blastocystis* may also be an important facilitator of infection. Environmental components that could play a role in risks for CD are increased consumption of animal protein, milk protein, and an increased ratio of omega-6 to omega-3 polyunsaturated fatty acids, but not vegetable protein and fish. Smoking and the use of contraception hormone pills also seem to increase the risk of CD or exacerbate the symptoms. There is no cure for CD and remission would neither be possible nor prolonged if achieved. In cases where remission is possible, relapses can be prevented and symptoms can be controlled with medication, lifestyle and dietary changes, changes to eating habits (e.g., eating smaller amounts more often), reduction of stress, moderate activity, and exercise.

Analytical Methods for MAP

The principal diagnostic tests for MAP infection in animals are individual or pooled fecal culture, ELISA, and IFNγ release from activated white cells in response to MAP antigens. Even though PCR diagnostics have also been introduced, ELISA remains as the cheapest and most convenient screening test hitherto. However, commercially available ELISA kits lack the sensitivity and specificity to diagnose subclinical MAP infection at an early stage. Although fecal cultures are among the preferred confirmation methods, fecal MAP is historically difficult to isolate, and strains from sheep or humans may require months or years of incubation before their gradual emergence becomes visible – and bovine strains can be even slower to demonstrate colonial growth. Some strains of MAP cannot be grown at all. If they can be cultivated, MAP may take an initial 16 weeks or longer to produce visible colonies on primary cultures, and requires exogenous mycobactin an iron-transport protein for *in vitro* growth. On solid media such as Middlebrook 7H11, MAP colonies appear rough and translucent; on Herrold's media containing egg yolk, they are smooth and opaque. As the cultures become older and the medium dries, the colonies take on a crumbly appearance. In liquid media, MAP grows in characteristic tight clumps. Culturing has been improved by the commercial availability of BD BACTEC™ and the Mycobacteria Growth Indicator Tube System (BD MGIT™) media (Becton Dickinson). More than 30 different MAP strains have been identified using methods such as restriction endonuclease analysis, IS900 restriction fragment length polymorphism (RFLP), and pulsed-field gel electrophoresis (PFGE). Typing of MAP isolates obtained from all over the world indicating that there are differences between ovine and bovine strains, signify a host adaption. Because most strains grow very slowly or not at all, PCR-based typing procedures for MAP are highly desirable, and success has been found with random amplified polymorphic DNA patterns and a multiplex PCR with a common IS900 primer and a locus-specific primer.

Routes of Transmission

Apart from consumption of milk and other foods being contaminated with MAP, these mycobacteria can infect persons from environmental sources too. As MAP survives well in the environment, it may be transmitted to people through water; this can be directly through consumption of potable water and also possibly from exposure to aerosols because of flooding, irrigation of fields, misting of plants indoors, besides that due to greenhouses, and shower heads. When lakes and rivers are contaminated by agriculture runoff from heavily grazed pastures, MAP will be present as cells within protozoa. Bacterial pathogens such as *Legionella pneumophila* and members of the MAC can be taken up by protozoa like amoebae and ciliates without undergoing digestion.

Bacterial proliferation in laboratory cultures was noticeably enhanced in the presence of amoebae, and biofilms rapidly formed in mixed amoebae and bacteria cultures (Marciano-Cabral *et al.*, 2010). This indicates that synergistic effects may occur in the environment to enhance the survival and growth of MAP in water systems. Filtration may remove some of these

if they are trapped in the larger particles but those passing through any filtration systems may not be destroyed by chlorination. These pathogens can form biofilms in distribution pipes arriving at both industrial and domestic outlets, and MAP can accumulate over time in cold and hot water storage and delivery systems. There have been anecdotal reports to link clusters of CD cases with water supplies. In a rural English community, 12 persons developed CD between 1960 and 1983, which is higher than normal prevalence. With its own water supply from local springs, the village was in a hollow surrounded by upland pastures that were grazed by cattle in which clinical JD was evident. The second CD cluster occurred in a Minnesota town, where there were 7 cases of CD amongst 285 graduates of the high school class of 1980. All seven had been swimming in local ponds and lakes where there was rich agricultural grazing land, and high fecal coliform counts indicated extensive contamination with cattle fecal runoff; unfortunately, no testing for MAP was done.

Prevention and Control

Because MAP may survive in milk at subpasteurization and even in pasteurization temperatures due to its heat resistance, the best way to prevent exposure of consumers to MAP, is the eradication of the JD and by sourcing milk and meat from JD free herds. In particular, since powdered or liquid milk substitutes the breast feeding of premature babies and newborns, it should be produced from MAP-free milk.

On the medical side, research on linking MAP with CD should continue, including possible synergistic effects with other pathogens. Less is known regarding the source and extent of MAP in the food supply. New methods are required for early detection of infected animals in order to decrease infection between animals as well as contamination of the environment, particularly in milking parlors, dairy plants, slaughterhouses, and meat processors. Although estimates of the prevalence of JD are scarce, particularly for nondairy herds, the available data suggest that the likelihood of contamination of raw milk with MAP in most studied regions is substantial. These locations are, therefore, critical points in reducing the risk of MAP contamination. Along the food production chain from farm to processor, certain steps are likely to increase or decrease the level of MAP contamination in the final product. There are many data gaps that need to be filled before more specific prevention and control procedures can be implemented. These include estimating: (1) the extent of dissemination of MAP in tissues of infected animals; (2) the amount of MAP shedding in milk and feces; (3) the level of fecal contamination of milk and carcasses; (4) to what extent farm and slaughterhouse workers could be infected; and (5) effect of different processing steps of milk and other dairy products and meat on the inactivation of MAP. There should be a careful comparison in prevalence and concentration of MAP at different steps in the processing of milk and meat products from known JD infected farms and those apparently unaffected by the disease.

Those who are immunocompromised (young, elderly, and ill) are more likely to be infected, if exposed. Although mass immunization of these persons cannot yet be considered feasible or practical (an improved and enhanced TB vaccine could be effective against MAP as well as *M. bovis* and *M. tuberculosis*), risks can be reduced by limiting their exposures to some potential sources, such as unpasteurized dairy products, undercooked meat, farms with ruminants and slaughterhouses, whirlpool baths, and showers. However, it would seem that MAP is so widespread in the environment that everybody is exposed to low levels of these organisms on a regular basis and most people seem to be able to cope without developing acute symptoms.

BACTERIA

Mycobacterium bovis

AJ Rodriguez-Morales, Universidad Tecnológica de Pereira and Office of Scientific Research, Pereira, Risaralda, Colombia
DM Castañeda-Hernández, Fundación Universitaria del Área Andina, Pereira, Colombia

Glossary

Anthroponosis An infectious disease in which the etiological agent is carried by humans and is transferred to other humans and animals.
Foodborne disease Any disease resulting from the consumption of contaminated food, pathogenic bacteria, fungus, viruses, or parasites that contaminate food, as well as chemical or natural toxins such as poisonous mushrooms.
Organism life cycle A period involving all different generations of a species succeeding each other through means of reproduction, whether through asexual reproduction or sexual reproduction (a period from one generation of organisms to the same point in the next).
Surveillance In public health and epidemiology, the discipline of continuously gathering, analyzing, and interpreting data about diseases, and disseminating conclusions of the analyses to relevant organizations, to intervene in their patterns in order to control and prevent them.
Taxonomy The science of classification, in microbiology the arrangement of microorganisms into a classification.
Zoonosis Any infectious disease that can be transmitted between species (by different ways, by a vector or by their products, food) from animals to humans or from humans to animals (less common).

Introduction

Mycobacterium bovis is a slow-growing (16–20 h generation time), aerobic bacterium, Gram positive and acid-fast, and the causative agent of tuberculosis (TB) in cattle (known as bovine TB) (ICD-10 A16), although it can produce infection in other animals (in addition to cattle, important maintenance hosts of the pathogen include goats, bison, deer, and badgers in Ireland and the UK; buffalo in Africa; moose in Canada; and the common brushtail possum in New Zealand).

Characterisitics of the Pathogen

Mycobacterium bovis is a member of the *Mycobacterium tuberculosis* complex (Table 1), which includes *M. tuberculosis*. Related to *M. tuberculosis* – the bacterium which causes TB in humans – *M. bovis* can also jump the species barrier and cause TB in humans. Bovine TB is not only a relevant zoonosis, with an important economic burden (up to hundreds of millions of euro annually in Europe), but also a relevant human health threat that can spread to humans through inhalation of infectious droplet nuclei and by ingestion of raw milk, than being relevant for public health. This human health threat, however, has been largely neglected for many reasons, which will be discussed later. Both species share genetic identity of over 99% at the whole genome level, although according to recent data *Mycobacterium microti* is more closer phylogenetically than *M. bovis* to *M. tuberculosis*.

Additionally, *M. bovis* and *M. tuberculosis* also share key aspects such as developing similar lesions and immune responses, which often result in colonization and spread to the same organs, namely lungs and lymphatic tissues.

Besides its occurrence in humans and cattle, in the past two decades domestic outbreaks of *M. bovis* infection have also been reported in pigs and other animals. *Mycobacterium bovis* often does not produce acute disease, persists in the carrier stage, has multiple nonhuman reservoirs, and easily crosses species.

In general, animal TB is a disease of high economic relevance within the context of livestock farming as it directly affects animal productivity and also influences international trade of animal products. Bovine TB was completely eradicated in many USA herds at a cost of USD $450 million over a period of 50 years using a 'test and slaughter' program combined with meat inspection. However, data suggest that in states bordering Mexico, over 70% of TB cases would still be due to *M. bovis*. *Mycobacterium bovis* infections have also been detected in wildlife and can have severe consequences for the ecosystem. For example in Canada, TB was endemic in plains bison and occurred in elk, moose, and mule deer in Buffalo National Park (BNP), Alberta during the 1920s and 1930s. Bison were moved from BNP to Wood BNP (WBNP), where TB became, and remains, endemic in bison, posing a challenge to efforts to restore bison in northern Canada. TB was found in a white-tailed deer

in Ontario in 1959, and in an infected elk near Riding Mountain National Park (RMNP), Manitoba in 1992. Intense surveillance has resulted in detection of 40 elk, 8 white-tailed deer, and 7 cattle herds infected between 1997 and 2008 in the RMNP area. Moreover, animal TB bears a zoonotic potential and is therefore of public health concern currently.

Like in humans, aerosolized bacteria are the most common source of infectious organisms in cattle, and the primary site of natural infection is the respiratory tract (Figure 1). In bovine TB, airborne infection is considered the most common route of transmission, and more than 20% of cattle with bovine TB shed the mycobacteria, mainly during early infection (Figure 1). The intermittent nature of bacilli shedding from infected animals, after a short initial postinfection period has been documented. Several studies indicate that between 5% and 30% of naturally infected animals release mycobacteria in clinical samples, but the precise duration of the secretion period is unknown. In humans, transmission can occur due to the consumption of contaminated milk from infected cattle, which has not been pasteurized or boiled (Figure 1).

Different studies in the world have supported the fact that although slight differences are found in the genome sequence of *M. tuberculosis* and *M. bovis*, the physiology and host range spectrum are quite different. In recent years, using multiple approaches, progress has been made regarding the molecular basis that might, at least partially, explain how mycobacteria are able to remain as a persistent or latent infection in its human host, and it has also been suggested that this particular stage of disease exists in cattle, by analogy with human TB; nevertheless, until now little attention has been paid to this form of infection in bovine hosts, either from the academy or from government sectors.

TB produced by *M. bovis* is an important human zoonosis associated with the consumption of dairy products contaminated with the bacilli, and to labor risk (such as direct contact or droplet transmission) in farms or slaughterhouses (Figure 1). In developed countries eradication programs have significantly reduced the prevalence of this disease, but reservoirs in wildlife make complete eradication difficult. *Mycobacterium bovis* is classified as a Risk 3 pathogen for public health. Close to 40% of the Latin American and Caribbean countries have reported the occurrence of TB due to *M. bovis*, and a conservative estimate would be that it causes 5% of the total pulmonary TB cases (considering that in many developing countries only radiological and clinical diagnosis of human TB is made in many cases). Of the approximately 375 million cattle in Latin America and the Caribbean, 70% are held in areas where rates of *Mycobacterium bovis* infection in cattle are higher than 1%. The remaining 30% are in countries where infection affects less than 1% of the cattle, including 65 million in countries where bovine TB infection is virtually nil. For example, it is estimated that in certain endemic areas of Mexico more than 15% of cattle would be infected.

Historically, *M. bovis* has been associated with extrapulmonary TB in infants and children, usually occurring due to the consumption of milk from infected cattle, which had not been pasteurized or boiled. It could be estimated that *M. bovis* can cause up to 10% of the extrapulmonary TB cases, particularly in these epidemiological settings. Despite the low reported cases of *M. bovis* infections in humans, it is accepted that zoonotic transmission is negligible in most of the developed world, but not in developing countries, and this deserves and should be investigated in many places over the world.

The World Health Organization (WHO) in conjunction with the Food and Agriculture Organization and the World Animal Health Organization (*Office International des Epizooties* (OIE)) recently classified bovine TB as a neglected zoonosis, with special reference to developing countries. In the world's most vulnerable communities, animal diseases, which are transmissible between livestock and humans, not only have the potential to impact human health directly but also threaten human livelihoods by compromising sustainable food supply, income, and social status.

According to the OIE data available at the World Animal Health Information System which is coupled with the World

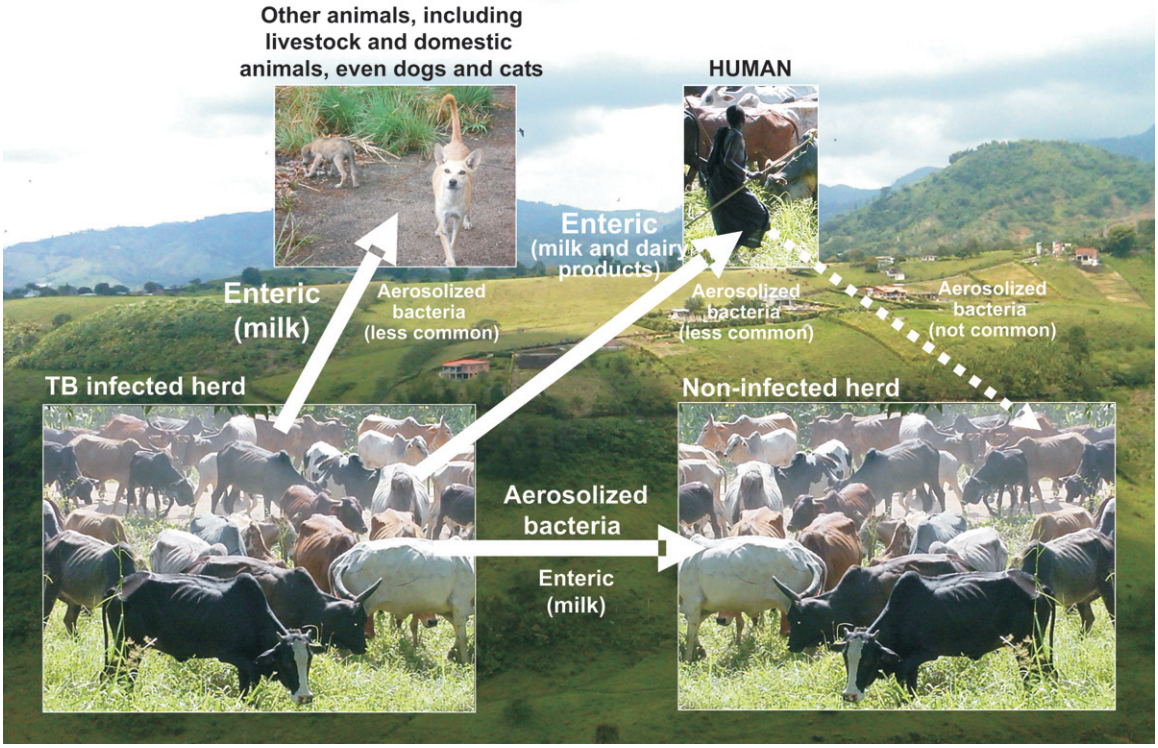

Figure 1 Main ways of transmission of *M. bovis* between animals and human.

Animal Health Information Database interface (Handistatus), during 2004, 13 countries in the America reported bovine TB (Argentina, Bolivia, Brazil, Canada, Chile, Colombia, Costa Rica, Cuba, Dominican Republic, El Salvador, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, USA, Uruguay, and Venezuela) (Table 2). This represents a significant remaining burden of disease in this region, although in such databases there is no precise information on the number of cases of bovine TB reported each year from these countries (Table 2).

In other regions of the world, such as Africa and Asia, a considerable number of countries have reported bovine TB (Table 3). Totalizing, there are in these three regions of the world more than 125 countries that have reported bovine TB prevalence as enzootic or of high prevalence in the last two decades. Adding those countries who have sporadically reported it (17), indicates that in total 142 countries have described cases of bovine TB. However, there are 29 with no data and finally just 26 (less than 20% of the countries) with a test and slaughter policy (Table 3).

At the epidemiological surveillance web system ProMEDMail, during 2011 (1 January–31 December 2011), 18 reports of bovine TB, from Canada, France, New Zealand, UK, and USA were published. In 2010, there were 16 reports, from the same countries. Until 1 May 2012, seven reports have been published, from Poland, UK, and USA.

Moreover, it is also estimated that 70% of the human population live in countries where cattle undergo no control or only limited control for bovine TB, constituting a potential infectious source. Ideally, all cattle that give positive readings to diagnostic tests should be killed or culled, as they may well represent a source of ongoing infection. However, under financial constraints, for example in developing countries, programs to combat bovine TB require a more accurate targeting of cattle that represent the greatest threat of spreading infection. Even more there are countries where no control program exist, are not even part of a zoonosis or foodborne programs and the human TB control programs usually gets attention only if it is *M. tuberculosis* but not infections due to other mycobacteria including *M. bovis*. This situation would be even more important in rural areas where cattle-human contact is high and where consumption of raw milk and dairy products would be considerable. In the context of animal health, we must consider the inability of current assays to discriminate between active and a likely latent infection in cattle, which could make the difference between sacrificing truly contagious animals or only suspected ones. Research and development on latent infection diagnostic techniques in cattle, as has been fully implemented in human TB due to *M. tuberculosis*, should be investigated.

Mycobacterium bovis has a wide range of hosts, but it primarily infects cattle (Figure 1). Cattle (as well other animals with less frequency) can transmit the agent to humans through the consumption of unpasteurized, contaminated dairy products, making bovine TB a zoonotic foodborne disease and a risk for food safety in many countries (Figure 1).

Foodborne *M. bovis* Infection

In developed countries pasteurization of milk as well testing and culling of infected cattle have resulted in steep decreases in the incidence of *M. bovis* TB. *Mycobacterium bovis* caused as much as 25% of the cases of human TB in developed countries in the late nineteenth and early twentieth centuries. Human TB cases in developed countries caused by *M. bovis* usually affected persons who acquired the infection locally before the implementation of control measures, especially from the habit of drinking raw milk. In developing countries where control measures have not been fully implemented it can occur more often and in fact probably occurs, although it is not regularly reported. Despite that reports of *M. bovis* TB in developed countries still are found in the literature and in some epidemiological reports as has been shown. One study during the period 2001–04 described that this zoonotic foodborne disease occurred in New York, USA. Investigators concluded that recent foodborne transmission within the USA had occurred, because there was a lack of evidence of airborne, person-to-person transmission, and because none of the patients <5 years of age (one of whom died because of peritoneal TB) had

a history of international travel for exposure in known bovine TB endemic areas or countries. A significant risk of *M. bovis* infection remains in certain segments of population at endemic countries in the form of: (1) continuing on-farm consumption of unpasteurized cows' milk, (2) retail sales by approved establishments of unpasteurized milk and dairy products, and (3) occupational exposure to infectious aerosols from tuberculous animals and their carcases.

In Europe, Great Britain, particularly in southwest England and Wales, has recently reported that bovine TB has increased over the past two decades. Despite increased controls during a breakdown, many breakdowns recur within a short period of time; nationally approximately 23% recur within 12 months and 38% within 24 months. Recurrent breakdowns can have a damaging effect on the well being of individual farmers and are demanding on government resources for repeated testing and compensation (paid to farmers for slaughtered animals). Even more, a recent report of zoonosis in Great Britain, concluded that 18 of 35 strains isolated from humans had genotypes associated with cattle in the UK and that this was suggestive of domestic acquisition of disease.

Bovine TB can affect humans but today the risks are considered to be very low due to routine testing and slaughtering of cattle and the pasteurization of milk. Although the risk is small, it should not be ignored, particularly in developing countries. However, in developed countries exposure to unpasteurized dairy products imported from countries where *M. bovis* is prevalent is currently recognized as prevalent problem, especially when the world is becamingmore globalized and food importation and trade is routine.

In this context, another issue is the identification of the problem raised. The reporting of human TB in many countries generally does not distinguish between TB cases caused by different *Mycobacterium* species, particularly in developing countries, where more specific diagnostic techniques are not available and in most cases diagnosis only reaches *M. tuberculosis* complex infection. It has also been suggested that owing to a lack of laboratory facilities in many regions, prevalence of human TB due to *M. bovis* in most tropical countries is likewise unknown. *Mycobacterium bovis* infection surveillance in many countries is not regularly done and in other cases is not accurate. Food quality control is not assessed and done in most places, not necessarily for acute foodborne diseases such as zoonotic TB. Even more, the possible presence of *M. tuberculosis* infection in cattle is an issue to be considered while designing monitoring and surveillance systems. The inespecific diagnosis of *M. bovis* in developing countries together with the fact that a considerable proportion of extrapulmonary cases can be caused by *M. bovis*, given its access to the body through foodborne transmission, can lead to the thinking that cases of apparent human extrapulmonary TB, particularly in rural areas where cattle is largely present, can in fact be caused by *M. bovis*. More epidemiological studies are needed to address this question.

Cumulative data from the period 1997 to 2003 show that 31% of the reported human cases caused by *M. bovis* in the EU were found in the UK; that is, one of the EU member states with a higher reported prevalence of bovine TB.

Inspite of this, information on human disease due to *M. bovis* shown in developed and developing countries is scarce. From a review of a number of zoonotic TB studies, published between 1954 and 1970 and carried out in various countries around the world, it was estimated that the proportion of human cases due to *M. bovis* accounted for 3.1% of all forms of TB: 2.1% of pulmonary forms and 9.4% of extrapulmonary forms.

Human disease caused by *M. bovis* has been confirmed in African countries. In an investigation by two Egyptian health centers, the proportions of sputum-positive TB patients infected with *M. bovis*, recorded during three observations, were 0.4%, 6.4%, and 5.4%. In another study in Egypt, 9 of 20 randomly selected patients with TB peritonitis were infected with *M. bovis*, and the remaining with *M. tuberculosis*.

Isolation of *M. bovis* from sputum samples of patients with pulmonary TB has also been reported from Nigeria. Of 102 *M. tuberculosis* complex isolates, 4 (3.9%) were *M. bovis*. Another study in Nigeria reported that 1 of 10 mycobacteria isolated from sputum-positive cultures was *M. bovis*.

In a Zaire study, *M. bovis* was isolated from gastric secretions in 2 of 5 patients with pulmonary TB. In the same study, the prevalence of the disease in local cattle was approximately 8% by tuberculin testing and isolation of *M. bovis*.

In a recent investigation in Tanzania, 7 of 19 lymph node biopsies from suspected extrapulmonary TB patients were infected with *M. tuberculosis* and 4 with *M. bovis*. No mycobacteria were cultured from the remaining 8. Although the number of samples was low, the high proportion (21%) of *M. bovis* isolates is of serious concern.

In Latin America, a conservative estimate would be that 2% of the total pulmonary TB cases and 8% of extrapulmonary TB

cases are caused by *M. bovis*. These cases would therefore account for 7000 new TB cases per year, a rate of nearly 2 per 100 000 inhabitants. From a nationwide study in Argentina during 1982–84, 36 (0.47%) of 7672 mycobacteria cultured from sputum samples were *M. bovis*. However, in another study in Santa Fe province (where most of the dairy cattle industry is concentrated) during 1984–89, *M. bovis* caused 0.7–6.2% of TB cases.

Very limited data on the zoonotic aspects of *M. bovis* are available from Asian countries. However, cases of TB caused by *M. bovis* were not reported in early investigations in India.

Mycobacterium bovis has been classically assumed, dogmatically, that it is less virulent than *M. tuberculosis* in humans and is rarely transmitted from person to person. However, recent literature indicates that *M. bovis* can produce severe disease.

Clinical Presentation of Foodborne TB

The clinical presentation of tuberculosis due to *M. bovis* depends on the route of transmission. In general, zoonotic TB due to *M. bovis* is indistinguishable clinically or pathologically from TB caused by *M. tuberculosis*. Foodborne disease, acquired through contaminated milk or related diary products from infected cattle usually leads to cervical or mesenteric lymphadenopathy and others forms of extrapulmonary disease. Aerogenous infection from cattle or humans leads to pulmonary TB. Pulmonary bovine TB is clinically, radiologically, and pathologically indistinguishable from TB caused by *M. tuberculosis*.

A high index of clinical suspicion is needed in symptomatic patients with a history of possible exposure. At risk groups include animal workers, farmers, meat packers, vets, and zoo keepers.

In immunocompromised subjects, particularly those infected with the human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome, risk of disease is increased. HIV infection can exacerbate the risk following infection from cattle causing more disseminated disease than in those not immunocompromised. The mycobacteria isolated in these cases can turn out to be resistant to rifampin and pyrazinamide.

In general, human TB due to *M. bovis* can certainly be as severe as that due to *M. tuberculosis.* Recent data from San Diego, CA, USA, revealed that persons with *M. bovis* were 2.55 times as likely to die during treatment than those with *M. tuberculosis*.

Diagnosis of *M. bovis*

Diagnosis of *M. bovis* will depend on the availability of diagnostic techniques. Conventional methods for diagnosis and epidemiological studies of bovine TB and other mycobacterial diseases are far from ideal. In the last two decades, molecular biology has provided new approaches which have enabled detailed studies to be made of the molecular characteristics of *M. bovis*. In most developed countries final confirmation of this agent would be made using molecular techniques as PCR and restriction fragment analysis of genomic deoxyribonucleic acid (DNA) from isolates of *M. bovis*.

Human contact tracing includes clinical examination, chest X-ray and Mantoux test or purified protein derivative (PPD). A gamma interferon release assays tests (such as QuantiFERON-TB gold® or T-Spot®) can be utilized in some cases. In developing countries, the intradermal delayed type hypersensitivity (DTH) skin test, using PPD from culture of *M. bovis* (PPD-B) or *M. avium* (PPD-A), is the most frequently used test for diagnosis of TB or detection of *M. bovis* infection in cattle. Many improvements have been made to the original tuberculin test, and molecular approaches to identify and clone antigens may lead to improved specificity and sensitivity of DTH skin tests.

Advances in technology in the past decade have allowed the development of new *in vitro* techniques, such as antibody-based, cell-mediated immunity-based and nucleic acid-based diagnostics, which allow more rapid diagnosis than bacteriological culture. The choice of diagnostic technique should consider both the population being investigated (e.g., apparently healthy animals or a herd with a high prevalence of clinical infection) and aim of the testing (e.g., the screening of healthy animals or confirmation of infection in animals strongly suspected to be infected). Moreover, any evaluation of a diagnostic test must use a carefully selected control population which is representative of the population to be tested in terms of relative proportions of infected and noninfected animals.

Until recently, none of the *M. bovis* typing techniques permitted a satisfactory differentiation of isolates. During the past decade, the genome of pathogenic mycobacteria has been extensively studied, and phylogenetic analyses have shown that all (except *M. avium*) belong to a single genetic species: the *M. tuberculosis* complex.

Finally, as an approach to diagnosis in any case all contacts should be screened, including cattle and humans.

Treatment of *M. bovis*

The treatment of human bovine TB is the same as for the disease due to *M. tuberculosis*, although as *M. bovis* is naturally resistant to pyrazinamide, this agent is usually not recommended. However, susceptibility to other anti-TB drugs is usually similar to that of *M. tuberculosis*. Reported effective treatments include isoniazid, rifampicin, and ethambutol (for 2 months), followed by isoniazid and rifampicin for a further 7 months. Quinolones such as levofloxacin and ofloxacin have been also reported as helpful together with other anti-TB drugs.

The World Health Organization 2003 guidelines on the therapy of bovine TB have no specific recommendations. In practice, patients are treated with the standard course of anti-TB regimens, but pyrazinamide is omitted from the regimen. The American Thoracic Society recommends an initial 2-month regimen of isoniazid, rifampicin, and ethambutol followed by a 7-month continuation phase of isoniazid and rifampicin. For chemoprophylaxis this includes isoniazid and rifampicin for latent TB infection.

Vaccination and Prevention

Vaccination could potentially be used as a practical means of controlling bovine TB in countries in which a wildlife reservoir of the disease is present, and also in those countries which cannot afford conventional control strategies. The development of cattle vaccines would be the best option for long-term

control of TB. Protection of cattle against bovine TB by vaccination could be an important control strategy in countries where there is persistence of *M. bovis* infection in wildlife and in developing countries where it is not economical to implement a 'test and slaughter' control program. Early field trials with Bacille Calmette Guerin (BCG) *M. bovis* vaccine in cattle produced disappointing results, with induction of tuberculin skin-test reactivity following vaccination and low levels of protection. However, other studies using a low dose of BCG vaccine in cattle have produced more encouraging results and field trials.

In general, vaccination of cattle currently is not accepted in many countries because the vaccine could interfere with the skin reaction to the tuberculin test in the field (as happens in humans). Efficacy of *M. bovis* BCG in protecting bovine and other animal species against tuberculous infection has received considerable study. Vaccination of cattle prevents the spread of the disease in populations by reducing the number and size of the lesions, and the load of bacteria (rather than by preventing infection; very similar to what happens in humans, vaccine does not prevent infection but can reduce severe extrapulmonary forms).

A number of new TB vaccines including attenuated *M. bovis* strains, killed mycobacteria, protein, and DNA vaccines are under development and many are being assessed in cattle. Recent results have revealed several promising vaccine candidates and vaccination strategies. In cattle, neonatal vaccination with BCG appeared to be more effective than vaccination of 6-month-old calves and in most situations no other vaccine has been shown to be better than BCG. However, prime-boost strategies involving combinations of BCG with a protein or DNA vaccine, to improve on BCG vaccination alone, have produced very encouraging results.

Effective vaccination strategies would have a major impact in countries that cannot afford expensive test and slaughter-based control strategies. For these reasons there is a concerted international effort to evaluate vaccines for use in cattle populations and to define vaccination strategies which will eliminate the disease from infected herds. DNA, protein and genetically modified vaccines inoculated in a single dose, given as prime-boost or injected concurrently, will elicit significant protection against challenge with *M. bovis* under controlled conditions. However, vaccines and vaccination strategies require evaluation under field conditions in all epidemiological settings. Furthermore, complementary strategies are under development to differentiate immune responses that follow vaccination from those following disease.

In conclusion, recent studies in cattle and wildlife have demonstrated the practicality and effectiveness of vaccinating animals against TB and provide much impetus for future use of vaccines.

Conclusions

Bovine TB is still one of the largely neglected foodborne zoonotic diseases in the world, particularly in developing countries. However its occurrence would be still important in many places. Thus, this zoonosis deserves further research and efforts to establish the real burden of disease in animals as well in humans. Developing strategies of interaction between academia and health care public sectors, including medical and veterinary disciplines, would generate more accurate data. Even more, as human TB due to *M. tuberculosis* is still a public health concern internationally, in developing countries where diagnosis is usually not fully based on molecular and more specific diagnostic techniques, other than microscopy examination for acid-fast bacilli in sputum and other biological samples as well as culture, *M. bovis* would be causing many of *M. tuberculosis*-attributed human disease, particularly in the case of extrapulmonary forms of disease, even more in rural areas where both diseases can overlap and where human–cattle contact as consumption of raw milk and dairy products contaminated with *M. bovis* would be considerable. Finally, zoonosis control programs and human TB control programs, specially in those settings, should consider the importance of *M. bovis* and begin to introduce operational research into their activities as well surveillance to control and prevent disease from this zoonotic agent.

Glossary

Adjuvant An adjuvant is an agent that may stimulate the immune system and increase the response to a vaccine without having any specific antigenic effect on itself.
Enzyme-linked immunosorbent assay An immunoassay that uses an enzyme linked to an antigen or antibody as a marker for the demonstration of a specific protein, generally an antibody or antigen.
Gel diffusion precipitin test Precipitin test made in a layer of agar that permits radial diffusion, in both the horizontal dimensions, of one or both reactants. Double (gel) diffusion in two dimensions (Ouchterlony test) incorporates antigen and antibody solutions placed in separate wells in a sheet of plain agar, permitting radial diffusion of both reactants; this method is widely used to determine antigenic relationships; the bands of precipitate that form where the reactants meet in optimal concentration are of three patterns, referred as reaction of identity, reaction of partial identity (cross-reaction), and reaction of nonidentity.
Mitogen A mitogen is a chemical substance that encourages a cell to commence cell division, triggering mitosis. A mitogen is usually some form of a protein.
Opportunistic pathogen An organism that exists harmlessly as part of the normal body environment and does not become a health threat until the body's immune system fails. The host's resistance may be lowered, for example, by other diseases or drugs.
Polymerase chain reaction A molecular technique for amplifying a single or a few copies of a piece of deoxyribonucleic acid (DNA) by separating the DNA into two strands and incubating it with oligonucleotide primers and DNA polymerase to generate millions of copies of that particular DNA sequence.
Septicemia Pathogenic bacteria in the bloodstream.
Zoonosis Zoonosis, also called zoonotic disease refers to diseases that can be passed from animals, whether wild or domesticated, to humans.

Background

Pasteurella multocida is the type species of the genus *Pasteurella* that was named in honor of Louis Pasteur who first recognized the significance of *P. multocida* in the etiology of fowl cholera (FC) and performed successful vaccination studies with the agent during the 1880s. *Pasteurella multocida* is known to be a widespread veterinary pathogen and also has the potential to cause zoonotic infections in humans. As a primary infectious agent, it plays the principal role in inducing FC in poultry, hemorrhagic septicemia (HS) in cattle and buffaloes, atrophic rhinitis (AR) in swine, and snuffles in rabbits. As a secondary invader, it is associated with pneumonia in swine and ruminants, with respiratory tract diseases in rodents, and with sporadic human infections resulting generally from injuries caused by household pets.

Characteristics of the Organism

Pasteurella multocida is a Gram-negative, nonmotile, nonspore forming, coccoid or rod-shaped facultative anaerobic bacterium. Cells usually measure $0.2–0.4 \times 0.6–2.5\ \mu m$ but after repeated subculturing they tend to be converted into pleomorphic forms. The bacterium is surrounded by a polysaccharide capsule that may be lost during *in vitro* maintenance.

Pasteurella multocida displays considerable phenotypic and genotypic variation. Three subspecies (subsp.) are distinguished by DNA–DNA hybridization and by their carbohydrate fermentation pattern, respectively: *P. multocida* subsp., subsp. *septica*, and subsp. *gallicida* although in recent times subsp. *P. multocida* and *gallicida* have been shown to belong to only one distinct phylogenetic lineage and thus their distinction has become questionable.

Based on the polysaccharide antigens of the capsule, *P. multocida* strains can be classified into five capsular serogroups (A, B, D, E and F) with the application of an indirect hemagglutination assay. This traditional technique is increasingly being replaced with a highly specific multiplex capsular polymerase chain reaction (PCR) assay. Comparing the somatic (cell wall) antigens, the commonly used Heddleston typing system distinguishes 16 *P. multocida* serotypes by recognizing heat stable lipopolysaccharide (LPS) antigens in a gel diffusion precipitin test.

 doi:10.1016/B978-0-12-378612-8.00106-2

Pasteurella multocida strains show considerable diversity in fermentation of different carbohydrates and on this basis 14 biovars can be differentiated at this time.

Promising efforts are currently in progress to develop advanced molecular typing methods for more specific characterization of *P. multocida* isolates. This will be a prerequisite for a better understanding of the epidemiology of *P. multocida* caused diseases.

Epidemiology

Pasteurella multocida is a natural inhabitant of the oropharyngeal and gastrointestinal floras of a wide range of vertebrates, including terrestrial and aquatic mammals and birds. It can survive in the upper part of the respiratory tract of apparently healthy animals, and these carriers are believed to serve as the main spreading sources of the bacteria. Transmission is most common via contaminated saliva, various excretions, or aerosol droplets. Contaminated animal housing equipment may also serve as potential sources of infection. It has been demonstrated that *P. multocida* can survive for a long time in organic materials and up to 1 year in water. Thus the inhalation of aerosolized *P. multocida*-contaminated water droplets may be another possible route of transmission. Moreover, it has been established that *P. multocida* may survive in free-living amoeba representing additional probable *P. multocida* reservoirs in the soil and water ecosystems.

Pasteurella multocida strains are usually restricted to one host species; however, cross infections between different species have also been described.

The importance of zoonotic human infections following companion animal attacks has increased recently. Animal bites create a significant public health problem, the vast majority of them being caused by dogs (85–90%) and less frequently by cats (5–10%). Nevertheless, infections occur more often after cat bites (50% incidence) than dog bites (10–15% incidence) that may be explained by the fact that, among host species, cats have the highest rate of oropharyngeal colonization by *P. multocida*. Although infections associated with cat and dog bite wounds are usually polymicrobial in nature, *P. multocida* is responsible for the highest number of such infections. Severe *P. multocida* infections may also occur in the absence of animal bites or scratches. In the majority of those cases, licking of intact or injured skin by pet animals are the most probable source of entry for the bacterium. Respiratory tract and intra-abdominal infections associated with possible inhalation of the microorganisms have also been reported.

As obvious from the above, human *P. multocida* infections are rare and generally appear to be linked to exposure to animals. There is no evidence that these bacteria pose a threat to the human food chain. Nevertheless, *P. multocida* has the ability to cause serious human infections. Coupled to that, the mitogenic effect of *P. multocida* toxin (PMT), whose gene is found in some human isolates of *P. multocida*, is a cause of concern; such strains are potentially carcinogenic. Therefore, it appears likely that *P. multocida* is a low risk to food safety, but this is a topic that should be kept under surveillance.

Pathogenesis

Pasteurella multocida can produce a broad spectrum of various pathological conditions in a great number of host species. This observation allows us to hypothesize that the pathogenesis of these diseases, beside certain mutual mechanisms, might show specific characteristics. Interestingly, with the exception of AR, our knowledge about the details of the pathogenesis of various diseases caused by *P. multocida* is very limited. There may be a number of reasons for the great variety in disease manifestations such as host adaptation of strains; differences in the production of special virulence factors; and a number of host factors such as ecology, anatomic characteristics, and inborn immunity.

A clear association has been recognized between capsule type and certain hosts and diseases. FC is generally caused by type A and F strains, whereas HS is produced only by types B and E. AR strains belong to type D and A. However, the molecular and cellular basis of these host and disease associations is still waiting clarification.

Pasteurella multocida produces several potential virulence determinants; nonetheless, their contribution to pathogenesis is generally poorly understood. In many cases the virulence of *P. multocida* will possibly be defined by cell-surface expressed components. The most important of these are the polysaccharide capsule and certain typical constituents of the outer membrane of the cell wall such as LPS, a limited number of major proteins, and several minor proteins. During infection, these polysaccharides might help the bacterium to avoid the innate immune mechanisms of the host, such as phagocytosis or complement-mediated killing. By contrast, as antigenic determinants, they stimulate the antibody production of the adaptive immune system. The exact role of the outer membrane proteins during the course of infection is unclear, but they may be the mediators of bacterial interaction with the host environment. They could modulate the cytokine production of innate immune cells of the host. Consequently, alteration in these surface structures may influence the immunogenicity of the strains by increasing antigenic variability and thus helping the bacterium to avoid the defense mechanisms of the host.

AR is a specific manifestation of pasteurellosis and is a typical example of diseases of polymicrobial etiology: *P. multocida* infection needs assistance by *Bordetella bronchiseptica* to establish itself on the intact nasal epithelial surface. Toxin production by *P. multocida* is the key factor in the complex etiology of AR in swine. Toxigenic strains carry the *tox*A gene that encodes a potent exotoxin called PMT. This toxin has the unusual properties of being a very potent mitogen with the capacity to drive proliferation in a number of cell types and in animal models. The *tox*A sequence has a low G–C content (35%) in contrast with the rest of the *P. multocida* genome, suggesting that the gene has a relatively recent origin, and indeed *tox*A is found on an inducible bacteriophage. This observation makes horizontal gene transfer probable and so the spread of the ability of PMT production among various *P. multocida* strains may be predicted.

The toxigenic status of human isolates of *P. multocida* is rarely examined. However, the limited data available would suggest that isolates found in infections linked to companion animals are rarely toxigenic, whereas those linked to exposure

to swine are more likely to be toxigenic. These latter infections mainly affect the respiratory tract, but some cases of wound infections have also been found. However, very little work has been carried out either on the role of PMT in the pathogenesis of human disease, or indeed on the human pathogenesis of nontoxigenic *P. multocida*.

Pasteurella multocida appears to be an opportunistic pathogen in humans; therefore the predisposing conditions decisively determine the prognosis and final outcome of the disease. *P. multocida* infected human wounds typically manifest as local skin or soft tissue infections at the site of the injury. Furthermore, in patients with serious underlying disorder or at advanced age systemic infections can develop that can be fatal.

Pasteurella multocida can cause meningitis via direct inoculation with an animal bite or scratch, by contamination from contiguous infected wounds after trauma or neurosurgery, or by extension from an adjacent infected site by retrograde spread through lymphatic or blood circulation.

Clinical Manifestation and Pathology

FC is an economically important widespread avian disease affecting all types of birds throughout the world. It may occur as peracute to acute septicemia, with high morbidity and mortality, or in chronic forms with localized infections of wattles, nasal sinuses, joints, ovaries, or other tissues. Torticollis may be seen when the meninges, middle ear, or the cranial bones are infected.

HS is a fatal systematic disease of ungulates causing great losses mostly in Asia and Africa, and is characterized by a rapid course; edematous swelling in the throat, pharyngeal, and brisket region; swollen and hemorrhagic lymph nodes; and the presence of subserous petechial hemorrhages on the visceral surfaces throughout the body.

In pigs, beside pneumonia, AR is an important disease resulting considerable economic losses in the affected herds. The major signs are twisting or shortening of the nose due to turbinate atrophy and nasal septum deviation.

As a secondary invader, *P. multocida* frequently plays a major role in the progression to severe form of pleuropneumonia in swine and ruminants. The lesions caused by *P. multocida*, added to those induced by the primary infection, are usually an acute or subacute fibrinous to fibrinopurulent bronchopneumonia, fibrinous pleuritis with adhesion, pericarditis and lobular consolidation.

Wound infections in humans caused by *P. multocida* due to animal bites, scratches, or licks most commonly lead to local cellulitis or abscess formation but may also induce bone and joint infections, respiratory tract infections, intra-abdominal infections, endocarditis, meningitis, and even septicemia. In a typical infection, onset of pain, erythema, and swelling frequently occurs at the site of the lesion within hours of a bite. Pneumonia is the most common manifestation of respiratory tract infections by *P. multocida* accompanied by cough, fever, and pleuritic chest pain. Symptoms of *P. multocida* induced meningitis include headache, pyrexia, neck stiffness, vomiting, and altered level of consciousness.

Diagnosis and Analytical Methods

Early diagnosis is crucial, particularly in immunocompromised patients. Clinical manifestation is diverse and usually nonspecific. Conclusive diagnosis requires isolation and identification of *P. multocida*. Primary isolation from clinical samples is usually performed on enriched agar media supplemented with 5% bovine, horse, or sheep blood among aerobic conditions with the preferable addition of 5% CO_2. In the case of greatly contaminated specimens, the use of one of the several available selective media is highly recommended. Suspected colonies can further be classified with the use of commercially available automated identification systems, like API 20NE system (bioMerieux, Marcy l'Etolie, France), Vitek 2 system (bioMerieux, Marcy l'Etolie, France), and Biolog Microstation ID System (Biolog, Hayward, CA, USA), although it should be emphasized that these devices are not always able to distinguish *P. multocida* from some other closely related *Pasteurella* spp. This problem can be overcome by sequencing of 16S ribosomal ribonucleic acid genes that is increasingly applied as a rapid, accurate, and alternative microbiological technique to phenotypic methods of bacterial identification.

Production of PMT can be detected by its biological activity and immunological characteristics using an appropriate enzyme-linked immunosorbent assay, or the identification of the *tox*A gene by PCR.

Pasteurella multocida strains show high heterogeneity when biochemical characteristics, serotype, pathogenicity, and antibiotic sensitivity are examined. Nevertheless, these parameters do not provide enough details to understand the relationships of the strains. PCR based assays, especially the repetitive extragenic palindromic and enterobacterial repetitive intergenic consensus techniques specific to conserved repetitive sequences have high discriminatory power and provide reproducible results. These methods have proved to be useful tools in epidemiological studies on *P. multocida* isolates originating from various host species.

Control and Preventive Measures

Human infections often occur in the elderly and are difficult to avoid. If animal bites occur, rapid diagnosis is required to enable the immediate and adequate medical care of the injuries.

Accurate information on the susceptibility to antibiotics is essential for successful treatment of bacterial infections. *Pasteurella multocida* is almost always sensitive to penicillin and ampicillin, thus these antibiotics appear to be the most appropriate choices. However, penicillin resistant isolates have also been reported and therefore susceptibility testing must constantly be performed. Third generation cephalosporins have also been used successfully, often in combination with benzylpenicillin and cefotaxime. If there is an obvious history of allergy to β-lactam antibiotics, chloramphenicol may be proposed as an alternative treatment. The optimal duration of antibiotic treatment is not well established and each case has to be evaluated individually. Usually, 2 weeks of treatment is

appropriate for most patients but may need to be extended depending on the clinical response.

In the case of food producing animals, vaccination is the preferable option for preventing *P. multocida* caused diseases as the intensive use of antibiotics significantly increases the hazard of the selection of resistant bacterium variants that may lead to severe public health concerns.

HS: Vaccination is the principal means of prevention. Oil-adjuvanted inactivated whole-cell vaccines have appeared to be the most effective. Success of live vaccine has also been reported.

AR: Combination of *B. bronchiseptica* and *P. multocida* killed vaccine with a satisfactory amount of inactivated PMT content provides good results against the clinical manifestation of the disease and may help the eradication of the toxigenic *P. multocida* from the herd, at least over time.

FC: Adjuvanted polyvalent killed vaccines are widely used and generally provide satisfactory protection. Autogenous bacterins are recommended when polyvalent bacterins are ineffective.

No *P. multocida* vaccine is available for human use.

Plesiomonas shigelloides

RE Levin, University of Massachusetts, Amherst, MA, USA

Glossary

Aeromonas A genus consisting of Gram-negative, polarly flagellated bacterial rods, facultatively anaerobic, bacterial species, members of which produce acid and gas from the fermentation of glucose.

Bacteremia Bacteria in the blood.

Choloangitis An infection of the common bile duct, the tube that carries bile from the liver to the gallbladder and intestines.

Cryptosporidium parvum A protozoan species that causes cryptosporidiosis, a parasitic disease of the mammalian intestinal tract resulting in acute, watery, and nonbloody diarrhea.

Diabetes mellitus A group of metabolic diseases in which a person has high blood sugar, because either the body does not produce enough insulin, or cells do not respond to the insulin that is produced.

Enterotoxin A protein toxin released by a microorganism in the intestine causing diarrhea associated with food poisoning.

Extraintestinal Situated or occurring outside the intestines.

Gastroenteritis Inflammation of the gastrointestinal tract, involving both the stomach and small intestine and resulting in acute diarrhea. Can be due to an infectious virus or bacteria.

Gram-negative Gram-negative bacteria do not retain the dye crystal violet in the Gram stain procedure when alcohol is applied. A red counterstain (safranin) is added after the decolorizing, alcohol step, staining all Gram-negative bacteria red. In contrast, Gram-positive bacteria retain the crystal violet and appear violet under the microscope.

gyrB Deoxyribonucleic acid (DNA) gyrase gene that encodes DNA gyrase which unwinds bacterial double helix DNA allowing DNA replication.

***β*-Hemolytic** The ability of the colonies of certain bacteria to induce complete lysis (hemolysis) of red blood cells when grown on blood agar resulting in clear zones surrounding the colonies.

Holecystitis Inflammation of the gallbladder that occurs most commonly because of an obstruction of the cystic duct by gall stones.

Immunocompromising A state in which the immune system's ability to fight infectious disease is compromised or entirely absent.

Liver cirrhosis A consequence of chronic liver disease characterized by replacement of liver tissue by fibrotic scar tissue leading to loss of liver function. Cirrhosis is most commonly caused by alcoholism, hepatitis B and C, and fatty liver disease.

Meningitis Life threatening inflammation owing to infection of the protective membranes covering the brain and spinal cord, known collectively as the meninges.

Osteomyelitis Bacterial infection of the bone marrow.

Plesiomonas shigelloides A Gram-negative, polarly flagellated rod, facultatively anaerobic, enteropathogenic bacterium, sensitive to the vibriostatic agent O/129, which produce acid but no gas from the fermentation of glucose.

Primary hemochromatosis Hereditary iron overload of the body.

Proteus A genus consisting of Gram-negative, facultatively anaerobic, peritrichously flagellated, bacterial rods.

Pseudomonas A genus consisting of Gram-negative, polarly flagellated rods, obligately aerobic, bacterial species.

Renal insufficiency Kidney failure.

Sepsis A pathological state, resulting from the presence of microorganisms or their toxins in the blood or in other tissue of the body.

Serotyping Distinguishing microbial isolates of the same species on the basis of antibodies produced against antigens such as the cell wall and/or flagella.

Shigella A genus consisting of Gram-negative, nonmotile rods, facultatively anaerobic, and enteropathogenic bacterial species.

Sickle-cell anemia A congenital form of anemia occurring mostly in African-Americans; characterized by abnormal red blood cells having a crescent or sickle shape, resulting in enhanced cell fragility, afflicting approximately 1 in every 500 African-American births and 1 in every 1000–1400 Hispanic-American births.

Splenectopy Surgical excision of the spleen.

Vibrio A genus consisting of Gram-negative, polarly flagellated curved bacterial rods, facultatively anaerobic, sensitive to the vibriostatic agent O/129, and whose species produce acid but no gas from the fermentation of glucose.

Vibrionaceae A bacterial family consisting of Gram-negative bacterial genera, polarly flagellated, and facultatively anaerobic.

 doi:10.1016/B978-0-12-378612-8.00107-4

Introduction

Plesiomonas shigelloides is a Gram-negative polarly flagellated rod native to aquatic animals and environments. The organism has been ranked third as a cause of travelers diarrhea in Asia. Mild to severe self-limiting diarrhea is the most frequent symptom derived primarily from uncooked shellfish although extra-intestinal infections of high mortality are known to occur, particularly among children and immunocompromised individuals. The organism produces a cholera-like (CL) enterotoxin, a thermostable (TS) and a thermolabile (TL) enterotoxin. A large plasmid (>120 mDa) has also been found to facilitate invasion. Methodology has been developed for the direct polymerase chain reaction (PCR) detection of as few as 60 CFU of *P. shigelloides* per gram of shellfish tissue.

Characteristics of the Organism

Plesiomonas shigelloides is a unique Gram-negative polarly flagellated pathogenic bacterium native to aquatic animals and environments. The genus *Plesiomonas* consists of a single homogeneous species. Its metabolism is similar to that of the genus *Vibrio* in that sugars are fermented with acid production but no gas. 5S ribosomal deoxyribonucleic acid (rDNA) sequencing has indicated the organism to be closely related to the genus *Proteus*. Mild to severe diarrhea is the major symptom although extraintestinal infections of high mortality including septicemia and meningitis are known to occur, particularly in immunocompromised individuals. The utilization of inositol with acid production is a unique characteristic of the organism that is exploited with several agar media developed for its selective and differential isolation. The organism is β-hemolytic and produces a CL enterotoxin in addition to a thermostable (TS) and a thermolabile labile (LT) enterotoxin. A large plasmid (>120 mDa) has also been found to facilitate invasion.

Nomenclature and Taxonomy

Plesiomonas shigelloides was first described in 1947 and was indicated to have certain properties in common with *Shigella*. The initial strain possessed the major somatic antigen of *Shigella sonnei* but differed biochemically. This strain, designated C27 and similar isolates were subsequently placed chronologically into the genera *Pseudomonas*, *Aeromonas*, and *Vibrio*). The genus *Plesiomonas* was initially established in 1962 in the family Vibrionaceae based on a number of its unique features and its similarity to the genus *Aeromonas* ('plesio,' neighbor, 'monas,' *Aeromonas*). In common with other members of the family Vibrionaceae, it is polarly flagellated, facultatively anaerobic, and cytochrome oxidase positive. In addition, isolates have in common with members of the genus *Vibrio* sensitivity to the vibriostatic agent O/129. 5S rDNA sequencing has indicated the organism to be closely related to the genus *Proteus*.

Physiological and Biochemical Characteristics

The minimum temperature range for growth is 8–10 °C and maximum is 42–45 °C depending on the specific strain. Most strains do not grow below 8 °C, however, one strain has been reported to grow at 0 °C. Most strains have an optimum growth temperature between 35 and 38 °C. A temperature of 42–44 °C is recommended for isolation to eliminate aeromonads. Although most isolates are able to grow from a pH of 4.0–9.0, strains have been reported to be killed rapidly at a pH of 4.0 and below. Most isolates exhibit growth from 2.0% to 3.0% NaCl. Some strains have been found to grow in 5.0% NaCl. NaCl however is not an absolute requirement for growth.

Identification of *P. shigelloides* is biochemically based on the organism being cytochrome oxidase positive, lysine and ornithine decaboxylase positive, and arginine dihydrolase positive, with production of acid from inositol (Table 1) and the fermentation of sugars without gas production.

Table 1 Metabolic characteristics of *Plesiomonas shigelloides*

Metabolic property	*% of strains positive*
Phenylalanine deaminase	0–4
Arginine dihydrolase	100

estuaries in tropical climates. It is rarely isolated in temperate and cold climates. *Plesiomonas shigelloides* occurs as free-living cells in aquatic systems, including fish, crabs, shrimp, mussels, and oysters. The organism has been isolated from soil and a number of terrestrial animals (amphibians, monkeys, birds, polecats, and reptiles) in addition to domestic animals (sheep, swine, cattle, cats, dogs, and goats). *Plesiomonas shigelloides* has also been reported to occur at a low incidence ($\sim$0.008%) in healthy humans. Uncooked oysters are the major food incriminated in outbreaks in the US.

Toxins and Invasive Factors

Plesiomonas shigelloides produces a CL enterotoxin, a TS and a TL enterotoxin. A large plasmid ($>$120 mDa) has also been found to facilitate invasion.

β-Hemolysis

Although several reports have indicated the absence of β-hemolysin production, an agar overlay system has been found to yield β-hemolysis. More than 90% of isolates have been reported to produce a cell associated β-hemolysin detected with agar overlay and contact hemolysis assays. The observation that surface colonies fail to yield hemolysis is of particular significance, and suggests that either oxygen tension or viscosity may influence β-hemolysin production or its release from cells. Hemolysis has been found to depend on the medium and method used for cultivation of the organism, which may explain the negative results obtained by several authors.

Isolation

Enteric agars were first used for the isolation and identification of *P. shigelliodes* but are not ideal. Growth of most isolates of *P. shigelloides* is obtained on MacConkey, *Salmonella–Shigella*, desoxycholate, Hektoen enteric, and xylose lysine desoxycholate agars, however, some strains may be inhibited. The first selective medium for the specific isolation of *P. shigelloides* was developed in 1977 and designated inositol brilliant green bile salts (IBB) agar (Table 2). Its differential property is based on the fermentation of inositol and selective ability on bile salts. IBB agar has been found to be highly effective for selective isolation of *P. shigelloides* from human feces following enrichment in alkaline peptone water. *Plesiomonas* (PL) agar (Table 1) was developed in 1985 and contains the nonfermented carbohydrates mannitol and arabinose at levels of 0.75% and 0.5% respectively. The fermentable carbohydrate inositol is present at a critically low level of 0.1% along with 0.2% lysine and notably low level of 0.1% bile salts No. 3. The initial pH is adjusted to 7.4 before autoclaving. Contaminating colonies fermenting mannitol and arabinose will be red. Fermentation of the low level of inositol and decarboxylation of lysine will result in a near neutral pH so that typical colonies of *P. shigelloides* are pink. With the plating of aquatic samples, both IBB and PL agars should be used simultaneously at 35 °C for maximum recovery. IBB was found to have a greater recovery rate and PL agar is less inhibitory to injured cells. *Plesiomonas* differential agar (PDA) was developed in 1991 (Table 2) and is a modified *Salmonella–Shigella* agar in which lactose is replaced with inositol. PDA at 44 °C and with a 24 h incubation period has been found to be a suitable medium for isolating *P. shigelloides* from water samples and possibly also clinical samples where the presence of aeromonads poses a problem.

Serology

Serotyping of *P. shigelloides* isolates is based on the detection of O (somatic) and H (flagellar) antigens. The first antigenic typing scheme for *P.* shigelloides established in 1978, was based on 30 O antigenic groups and 11 H antigens. Subsequent studies indicated more than 100 serovars. One of the

most frequently encountered serovars of *P. shigelloides* is 017, which is involved with protection against shigellosis due to *S. sonnei* via a common lipopolysaccharide in the cell walls of both species.

Epidemiology and Outbreaks

A total of 20–50% of persons traveling abroad suffer from diarrhea usually within their first week of travel. Many of these infected individuals report to have consumed seafood or uncooked food in the 2 weeks before the onset of diarrhea. One of the major agents causing travelers diarrhea appears to be *P. shigelloides* which has been ranked third as a cause of travelers diarrhea in various areas of Asia including China and Japan.

A total of 23% of patients suffer from underlying immunocompromising conditions such as diabetes mellitus, renal insufficiency, liver cirrhosis, bowel disease, pregnancy, cancer, primary hemochromatosis (excess deposition of iron throughout the body), splenectopy, or sickle-cell anemia. Most of these predispositional factors suggest that the availability of iron may be a major factor preventing or limiting infections in healthy individuals due to *P. shigelloides*.

The first outbreak of gastroenteritis due to *P. shigelloides* occurred in Japan in 1963 and was due to contaminated cuttlefish salad involving 275 cases of diarrheal infection out of 870 individuals who consumed the salad. Salted mackerel resulted in an outbreak in 1966 in Japan involving 53 cases. Subsequent outbreaks in Japan have involved water-borne diarrhea affecting 978 out of 2141 persons.. Uncooked shellfish is most frequently implicated in cases involving seafood.

Plesiomonas shigelloides is also responsible for a variety of extraintestinal infections, particularly among children and immunocompromised individuals with underlying maladies such as holecystitis and choloangitis, bacteremia and sepsis, arthritis, and polyarthritis, osteomyelitis, neonatal meningitis, and pneumonia. The severity of a generalized *P. shigelloides* infection is reflected by the fact that 1978 to 2010, 8 out of 12 neonatal patients developing bacteremia globally succumbed, even after several of the 8 received appropriate antibiotic treatment.

A suspected factor of predisposition to infection by *P. shigelloides* is coinfection by other intestinal pathogens. Results from monoinfection of BALB/c mice with *P. shigelloides* revealed long-term colonization of the neonatal mouse intestine, along with associated pathological lesions. The effects of coinfection of *P. shigelloides* with *Cryptosporidium parvum* were characterized by bacteremia and heavy colonization of the intestine by *P. shigelloides*. In addition, necrotizing inflammatory changes in the ileum and colon were accompanied by diarrhea and deaths of infected mice. In contrast, the results from monoinfections of neonatal mice with the *Aeromonas* spp. exhibited only short-term colonization of the intestine by these pathogens. However, when mice were coinfected with *Aeromonas hydrophila* and *C. parvum*, growth of the bacterial species was prolonged with no clinical or histopathological changes observed in the mice. A detailed study of *P. shigelloides* associated with gastroeneritis in Ecuador from 2004 to 2008 indicated little evidence that single infection with *P. shigelloides* causes diarrhea but stronger evidence indicated that coinfection with rotavirus causes diarrhea. One study from Germany indicated that from the years 2000 to 2001 *P. shigelloides* was found to cause gastroenteritis 6 times in Ludwigshafen, Germany. Not all of these patients reported a trip to foreign countries or consumption of seafood.

Most isolates of *P. shigelloides* are resistant to ampicillin and mezlocillin. Successful antibiotic therapy of neonates has usually involved the administration of cefotaxime or meropenum.

Application of the PCR

Conventional PCR

PCR assays for confirming the identity of *P. shigelloides* isolates and for the detection and quantitation of the organism in environmental samples have utilized primers that amplify sequences of the 23S rRNA gene, DNA gyrase gene (*gyrB*), and *hugA* gene that encode an outer membrane receptor HugA, required for heme iron utilization (Table 3).

Methodology has been developed for the direct PCR detection of as few as 60 CFU of *P. shigelloides* per gram of clam tissue. Various factors have been found to affect quantitative PCR assays of *P. shigelloides*. Different *Taq* polymerase preparations, varying sets of primers, different DNA stains, and different cell lysing agents have been found to significantly influence the linear relationship between the fluorescent intensities of DNA bands and log of CFU per PCR. Primer dimers formed in the PCR can be eliminated by using different *Taq* polymerase preparations and different sets of primers to run the PCR. In addition, the use of ethidium bromide monoazide has been successful in allowing the PCR to distinguish viable from nonviable cells of *P. shigelloides*. The use of two random primers (Table 2) with random amplified polymorphic DNA (RAPD) has been found effective in distinguishing a number of *P. shigelloides* isolates from diverse sources.

Real-Time PCR

The application of real-time PCR (Rti-PCR) to *P. shigelloides* has primarily employed SYBR green for the reporter molecule. Rti-PCR methodology has allowed the detection of 1×10^3 CFU of *P. shigelloides* per gram of oyster tissue, equivalent to the DNA from 25 CFU per Rti-PCR.

Control and Prevention of *P. shigelloides* Infections

As *P. shigelloides* gastrointestinal infections are frequently the result of the consumption of raw shellfish, and other forms of raw seafood, all seafoods should be adequately cooked to destroy the organism. As much as the organism is associated with fresh and marine aquatic habitats, water consumed directly and also used for food preparation, or rinsing of foods should always be of a potable nature, usually achieved by adequate chlorination. Control of *P. shigelloides* in food

products consists of adequate refrigeration in that most strains are unable to grow at refrigerated temperatures. Adequate refrigeration applies to slaughter, processing, shipping, and storage. As *P. shigelloides* is an intestinal organism, during evisceration of both warm blooded animals and fish species, the intestine should be removed intact so that no intestinal contents are placed in contact with the tissue to be consumed. After handling raw meat, shellfish, or other marine foods, one should thoroughly wash hands with soap or detergent to prevent cross-contamination of other foods, particularly those to be eaten raw such as fruits, vegetables, and salads. Raw meat or marine foods should never be stored in contact or on the same refrigerator shelf as raw fruits and vegetables. Food handlers with active gastrointestinal infections should not be allowed in contact with foods during preparation.

Proteus

Yong Wang, Wayne State University, Detroit, MI, USA
Xiaoling Pan, Michigan State University, East Lansing, MI, USA

Glossary

Dienes typing A method to distinguish *Proteus* strains based on Dienes' phenomenon that *Proteus* strains of the different Dienes types do not merge into each other but leave inhibition lines between strains on the solid medium.
Immunodeterminant A specific structure of an antigen recognized by antibodies or membrane receptors of B cells or T cells; also called antigenic determinant.
Swarming A process whereby bacteria leave colonies and migrate together.
Urease This enzyme hydrolyzes urea into carbon dioxide and ammonia. The urease serving as a pathogenic factor has been observed in many bacteria and fungi. The test of urease activity could diagnose the presence of pathogens.

Background

Proteus spp. are Gram-negative aerobic bacteria. Their size is 0.4–0.8 μm in diameter and 1.0–3.0 μm in length. They are named based on their ability to undergo morphological changes of colonies. With peritrichouse flagella, *Proteus* spp. are motile. Some characteristics of a *Proteus* culture are swarming and an ammonia smell. The *Proteus* habitat is widely distributed in the environment. As an opportunistic human pathogen, *Proteus* is found in the human and animal gastrointestinal tract, skin, and oral mucosa, as well as in feces, soil, water, and plant. *Proteus* causes food spoilage of raw meat, seafood, vegetables, and canned food. The detection of *Proteus* spp. indicates that affected food is not prepared in hygienic surroundings. In autumn, the rate of *Proteus* detection is higher. *Proteus* spp. do not form spores, and they can grow on most culture media and liquefied gelatin. When *Proteus* grows in milk, the milk curds, and then liquefies. *Proteus* strains are able to grow in temperatures ranging from 10 to 43 °C. The optimal temperature for *Proteus* is 25 °C. The swarming occurs between 20 and 37 °C. *Proteus* spp. decompose organic substances. They also oxidatively deaminate amino acids, hydrolyze urea, exhibit proteolytic activity, and produce hemagglutinins and hemolysins.

The genus *Proteus* belongs to the tribe Proteeae of family Enterobacteriaceae and includes five species: *Proteus vulgaris*, *Proteus mirabilis*, *Proteus penneri*, *Proteus myxofaciens*, and *Proteus hauseri*. Besides these, there are three unnamed *Proteus* genomospecies. *Proteus hauseri* and the three unnamed species were characterized as four new genomospecies from a biogroup that was considered as *P. vulgaris*. The three genomospecies left unnamed are due to the lack of phenotypical discrimination standards. *Proteus mirabilis* is the dominant *Proteus* spp. causing human infections. Approximately 25% people carry *P. mirabilis* in the intestine. There is also *P. vulgaris* or *P. penneri* infection in humans, which is mostly nosocomial infection. *Proteus myxofaciens*, isolated from the larvae of gypsy moths, is not considered to be an important species causing human infections.

The tribe Proteeae comprises three genera, *Proteus*, *Providencia*, and *Morganella*. The genus *Morganella* includes only one species, *Morganella morganii*, which was formerly *Proteus morganii*. Based on trehalose fermentation, *M. morganii* is divided into two subspecies, *M. morganii* subsp. *morganii* (trehalose-negative) and *M. morganii* subsp. *sibonii* (trehalose-positive). Another genus in the tribe Proteeae is the genus *Providencia*. All five *Providencia* spp. (*Providencia alcalifaciens*, *Providencia heimbachae*, *Providencia stuartii*, *Providencia rettgeri*, and *Providencia rustigianii*) have the phenylalanine-deaminating activity that *Proteus* spp. possess. Not all *Providencia* strains have urease activity.

Characteristics of the Organisms

The movement across a solid medium surface is not a unique characteristic of *Proteus* spp. The Gram-negative bacteria of *Serratia* spp. and *Vibrio* spp. and the Gram-positive bacteria of *Bacillus* spp. and *Clostridium* spp. also have this swarming phenomenon. During the process of swarming, the *Proteus* colonies display periodic cycles on a solid medium, and the appearance of bacteria cells becomes elongated and flagellated. *Proteus* appears as short rods in broth cultures with the size of approximately 0.6 μm width and 1–2 μm length. After being inoculated to suitable solid media, the cells enlarge to approximately 0.8 μm wide and 2–4 μm long, and then some peripheral cells of colonies gradually elongate to approximately 0.7 μm wide and 20–80 μm long. The morphological change is largely due to the change of flagellates. The shorter flagella become longer, whereas the number of flagella

 doi:10.1016/B978-0-12-378612-8.00108-6

increases. The swarm cell has 50–500 times more flagella than that of original cells. With the facilitation of the abundant longer flagella, *Proteus* spp. more efficiently move outward from colonies. Besides flagella, some extracellular slimes produced by *Proteus* spp., such as cell surface polysaccharides, may also help the movement process by reducing friction. The swarming process includes three stages, which are differentiation, migration of bacterial mass, and consolidation. After the multicellular differentiation, the swarmers migrate away from the colonies. Concentric rings of the cell population form in the peripheral region of the colonies. The swarming continues until the cells spread out on the surface of the medium. Once the swarming stops, the long cells divide into several shorter form normal cells, which is called consolidation. The swarming occurs only in the solid media. When the swarmers are transferred to liquid media, they divide to the septa of shorter swimmers. The flagellar number reduces as well. Furthermore, the swarming is a population behavior. A single *Proteus* cell loses the swarming ability. The swarming of *Proteus* not only requires the mobility and differentiation ability but also coordinating multicellular behaviors. Mutations affecting multicellular coordination prevent the swarming of *Proteus*.

The morphological change of *Proteus* is correlated with the biochemical change. The number of nucleoids increases as the swarmers turn longer. Rather than producing lipopolysaccharides (LPS) with both long and short O-antigenic side chains, the long O-antigenic side chains are dominant type in the swarmers. There are also changes in the protein expression level, such as urease, metalloprotease, hemolysin, and flagellin. Approximately 40–60 genes are involved in the swarming process. There are genes controlling flagellar synthesis, rotation of the flagellar filament, synthesis of cell surface structures (LPS and peptidoglycan), cell division, etc.

The swarming is a disadvantage factor for strain isolation. The inhibition of swarming facilitates *Proteus* strain isolation. Because the swarming relies on the moisture of solid medium surfaces, a dryer medium surface inhibits swarming. The differentiation and swarming of *Proteus* display a glutamine-dependent pattern and can be inhibited by the glutamine analog, γ-glutamyl hydroxamate. Furthermore, the flagella of *Proteus* function as a sensor for the outside environment. Thus, antibodies against flagella also inhibit swarming.

The same *Proteus* strain swarms and coalesces. Different strains repel each other. Therefore, narrow buffer regions are left between swarming *Proteus* strains when two different types of *Proteus* strains are inoculated to a solid medium. This method of *Proteus* strain discrimination is called Dienes typing. The clear line between *Proteus* strains is named the Dienes demarcation line.

Clinical Manifestation, Pathogenesis, and Treatment

Proteus can cause gastroenteritis, urinary tract infections, and wound infections. The ingestion of food contaminated by *Proteus* may contribute to the sporadic and epidemic cases of gastroenteritis, which may cause symptoms such as vomiting, fever, abdominal pain, severe nausea, diarrhea, and dehydration. The incubation period is short, usually 1–3 days. The illness duration is approximately 40 h. Sometimes, blood can be found in patients' vomitus. *Proteus mirabilis* and *P. penneri* are often isolated from diarrheal fecal samples of gastroenteritis patients. The incidence rate of acute intestinal infection of *Proteus* is higher in young children as well as older and immunosuppressed persons, due to their low immunity. *Proteus* is thought to increase the pathogenicity of other microbes. When *Proteus* infection occurs together with other microbes, infant diarrhea is more severe. As a secondary pathogen, *P. vulgaris* has been frequently observed in coinfection with streptococci, staphylococci, *Bacillus coli*, *Bacillus lactis aerogenes*, *Bacillus welchii*, *Bacillus diphtheriae*, etc.

Infection by the genus *Providencia*, another member of the tribe of Proteeae, is rare. *Proteus alcalifaciens*, *P. heimbachae*, *P. rettgeri*, and *P. rustigianii* are usually related to gastroenteritis whereas *P. stuartii* is usually related to urinary infections. The *Providencia*-associated gastroenteritis leads to abdominal pain, vomiting and diarrhea. Some patients may have fever. Most case reports of the *Providencia*-associated gastroenteritis are related to fecal contamination. The common incubation period from the ingestion of contaminated food is 80–90 h. *Proteus alcalifaciens* has been identified as an enteric pathogen. Both *in vitro* cell invasion tests and animal models have proved the pathogenicity of *P. alcalifaciens*.

The third member of the tribe Proteeae is *Morganella* sp. The presence of common food spoiled by *M. morganii* is fish, including mackerel, marlin, mahi-mahi, tuna, and bluefish. Both *Proteus* spp. and *M. morganii* have the histidine dehydrogenase activity to produce histamine. The temperature of 15 °C is a critical point for histamine production of *M. morganii*. When the temperature is lower than 15 °C, the histamine production by *M. morganii* is significantly reduced. In general, *M. morganii* does not produce toxic concentration of histamine below 7 °C. The elevated level of histamine and the factors influencing histamine absorption synergistically lead to symptoms after the ingestion of spoiled food. The symptoms include headache, diarrhea, redness of the face and neck, a feeling of heat, itching, etc. The time elapsed between food intake and symptom onset ranges from minutes to 3 h. Usually, 100 mg dL^{-1} of histamine is the minimum level to cause symptoms, although 20 mg dL^{-1} of histamine may cause symptoms in some individuals. The histamine level in fresh fish is normally 1 mg dL^{-1}, and 50 mg dL^{-1} is the hazardous level. The cases of *M. morganii* outbreaks have been found associated with either raw fish or processed fish consumption. Therefore, cooking is not an effective way to eliminate the toxicity.

In terms of treatment, *Proteus* spp. have varied sensitivity and resistance to antibiotics. Most *Proteus* spp. are sensitive to penicillin, gentamicin, furagin, ciprofloxacin, levofloxacin, and nevigramone, but they are resistant to nitrofurantoin, tetracycline, bacitracin, cecropin, polymyxin, and colistin. The antibiotic resistance of *Proteus* spp. is transferred through plasmids encoding antibiotic-resistant genes. *Proteus* spp. have a high content of phosphate-linked 4-aminoarabinose in their LPS. The less acidic bacterial surface makes them inherently resistant to polycationic antibiotics, such as cecropin and polymyxin. Polymyxin B binds to the negatively charged lipid A portion of LPS. In *P. mirabilis*, L-arabinoso-4-amine substituting the ester-linked phosphate group of lipid A can lead to the resistance to polymyxin B. The first-choice antibiotic

against *P. mirabilis* is ampicillin and the alternative antibiotics are aminoglycoside and cephalosporin. Resistance to fluoroquinolones has been seen in *P. mirabilis* isolates. Most *P. mirabilis* strains are sensitive to ampicillin and cephalosporin, but *P. vulgaris* and *P. hauseri* are not sensitive to them. The first-choice antibiotics to treat *P. vulgaris* and *P. hauseri* are cefotaxime and ceftizoxime, and the alternative antibiotics are cefoxitin and trimethoprim (TMP)-sulfamethoxazole (SMX). In addition, *P. vulgaris* and *P. hauseri* are sensitive to ceftazidime, ceftriaxone, imipenem, ciprofloxacin, netilmicin, sulbactam, meropenem, and levofloxacin. In contrast to other *Proteus* spp., *P. penneri* is resistant to chloramphenicol. Therefore, combinations of antibiotics are more effective treatment against *Proteus*, such as gentamicin with carbenicillin, gentamicin with ampicillin, monomycin with ampicillin, Zosyn (piperacillin and tazobactam), and Unasyn (ampicillin and sulbactam).

Most *M. morganii* strains are resistant to penicillin and cephalosporin and are susceptible to aztreonam, aminoglycoside, and quinolone. *Providencia* is highly resistant to penicillin G, ampicillin, chloramphenicol, colistin, polymyxin B, nitrofurantoin, and nalidixic acid, but it is sensitive to aminoglycoside, quinolone, carbapenem, aztreonam, and modern cephalosporin.

Virulence Factors

Several virulence factors of *Proteus* have been identified. The presence of fimbriae is one of the virulence factors. The *Proteus* spp. adhere to surfaces using fimbriae. The adhesive ability of *Proteus* to intestinal epithelium has been proved. Based on the diameter, *Proteus* fimbriae are classified as the thicker type ($\sim$7 nm) and the thinner ($\sim$4 nm) type. The thicker fimbriae are resistant to mannose and named *Proteus*-like fimbriae. Their acronym is MR/P. The thinner fimbriae are also resistant to mannose and named *Klebsiella*-like fimbriae with the acronym of MR/K. The MR/K type is positive in tannic acid-treated erythrocyte agglutination test whereas the MR/P strain is positive in untreated erythrocyte agglutination test. Owing to the difference in abilities of adherence to epithelial cells, the MR/P and MR/K types exhibit different pathogenicities. For nosocomial infections, the MR/P type of *Proteus* enhances the risk of acute pyelonephritis because the MR/P fimbriae facilitate the strains to colonize in the upper urinary tract. In contrast, the MR/K type has a different tissue-binding pattern, which binds to the tubular basement membranes and glomerular capsules by MR/K hemadhesins. Besides MR/P and MR/K, there are other types of fimbriae, such as *P. mirabilis* fimbriae (PMF), ambient-temperature fimbriae (ATF), *P. mirabilis* P-like fimbriae, etc.

Other surface structures, such as outer membrane proteins and polysaccharides, also play a significant role in the *Proteus* virulence. Outer membrane proteins serve as mitogens for B cells. OmpA protein, one identified outer membrane protein, elevates the level of IgG O-specific antibodies. Immunization of mice with outer membrane proteins shows protective role in pyelonephritis. Another antigenically important surface structure is LPS. The diversity of the O-specific polysaccharides of LPS results in the antigenical heterogeneity of *Proteus*. One feature of the *Proteus* O-specific polysaccharides is the substitution of uronic acids by amino acids. The O-specific polysaccharides of *Proteus* are typical, including hexoses, hexosoamines, and uronic acids, and 6-deoxyamino sugars. The unusual components are lactic acid ethers, (R)-hydroxybutyryl, pyruvic, and phosphate groups. Most of the time, the unusual components are not immunodominant. N-acetyl-D-glucosamine linked to the β-D-GlcA-L-Lys and phosphoethanolamine linked to the β-D-Glc-NAc are immunodominant in the O-specific polysaccharides of *P. mirabilis*. An immunodeterminant of *P. mirabilis* O-specific polysaccharides is the substitution of D-galacturonyl-1,4-D-galactosamine disaccharide by lysine. Furthermore, the flagella and other cell surface components produced during the differentiation and swarming are antigenic and contribute to the *Proteus* virulence.

The *Proteus* enzymes and secretory components are another class of virulence factors. Firstly, the urease of *Proteus* is a virulence factor and contributes to its pathogenicity. The infection ability of the urease-defective mutant is approximately 1000-fold less than that of normal strains. Over 200 Gram-negative bacteria species have urease activity. The urease metabolizes urea into carbon dioxide and ammonia. The alkaline environment is more suitable for *Proteus* to survive in gastric acids. The ammonia produced by *Proteus* may result in gastric and peptic ulcers. Secondly, the proteolytic enzymes expressed by *Proteus* are associated with virulence. The production of proteolytic enzymes to degrade host immunoglobulins is one strategy of protecting *Proteus* from the attack of the host immune system. *Proteus* is capable of IgA protease synthesis. One characteristic of *P. mirabilis* IgA proteases and some *P. vulgaris* IgA proteases is that the protease cleaves IgA heavy chain at a site different from the cleavage site of other microbial IgA proteases. There is also an extracellular proteolytic enzyme produced by *P. mirabilis* cleaving IgA, IgG, and some non-immunoglobulin proteins. Thirdly, the production of extracellular hemolysin is correlated with a higher cytotoxic activity. *Proteus* not only adhere to epithelial cells, but also invade the cells. The penetration ability is correlated with the cell-associated hemolytic activity. The hemolytic activity of *Proteus* is due to the production of cytotoxic hemolysins. Most *P. mirabilis* and *P. vulgaris* strains can degrade erythrocytes. Typically, the hemolytic phenomenon relies on the living cell of *Proteus*. Therefore, the intracellular or cell-associated hemolysis has been found in all strains of *P. vulgaris* and *P. mirabilis* whereas the extracellular or cell-free hemolysis has been observed only in some strains. In contrast, the extracellular hemolysin has been found in all *P. penneri* strains tested, and intracellular hemolysin has been found in some *P. penneri* strains. Lastly, *Proteus* secrets siderophores, an iron chelator, which also contributes the *Proteus* virulence.

Analytical Methods

Proteus strains can be isolated from vomitus and fecal specimens of patients. An isolation method is to grow the sample in dextrose broth fermentation tubes, and then the bacterial cells are streaked on agar or Endo plates. Stool samples can be streaked directly on Endo plates. A pure strain is obtained by successive passage of colonies. Characteristic colonies are

examined by Gram staining, a colorless and round appearance, and motility. Except Gram staining, most common staining methods stain *Proteus*. One staining procedure is summarized briefly as follows. After heat fixing, the bacterial cells are stained by methyl violet for 1 min and Gram's iodine for 1 min. Then, the slide is rinsed with alcohol and water and is stained with 0.1% basic fuchsin for 10 s. The suspected colonies can be further tested by biochemical confirmatory tests. *Proteus* spp. show positive results of hemolytic activity, hydrogen sulfide production, acid production, gas production, gelatin hydrolysis, decomposition of glucose, decomposition of sucrose, and growth in potassium cyanide. Furthermore, *Proteus* is positive in methyl red test and has phenylalanine deaminase activity. None of *Proteus* spp. can ferment lactose, D-adonitol, L-arabinose, D-arabitol, D-mannitol, D-mannose, melibiose, sorbitol, or side marigold alcohol. The species level identification requires both phenotypical characters and genotyping. There are special phenotypical characteristics for some *Proteus* spp. For example, *P. vulgaris* and *P. hauseri* are different from other *Proteus* spp. in indole production. *Proteus vulgaris* uses maltose, salicin, esculin, and amygdalin, but not lactose or mannitol. *Proteus penneri* is salicin-negative, esculin-negative, and chloramphenicol-resistant. The unique character of *P. mirabilis* is that it does not use maltose and has ornithine decarboxylase activity. *Proteus myxofaciens* is negative in the tyrosine clearing test. *Proteus mirabilis* ferments sucrose much slower than others do. Other than classical biochemical tests, the serological test, electrophoresis pattern of multilocus enzymes, and DNA similarity are also used to identify and discriminate *Proteus* strains. The DNA-based genotyping techniques include pulsed-field gel electrophoresis (PFGE), sequencing of 16S rRNA genes, restriction fragment length polymorphisms (RFLP), etc.

Genera *Providencia* and *Morganella* do not have the swarming phenomenon. Furthermore, Genera *Providencia* and *Morganella* can be distinguished from Genera *Proteus* by the negative results in gelatin hydrolysis and acid production from D-Xylose. *Providencia* is different from *Morganella* in acid production from D-Mannose. *Providencia* is negative in acid production from D-Mannose whereas *Morganella* is positive. *Morganella morganii* has urease activity whereas only *P. rettgeri* strains from *Providencia* constantly show urease activity.

Prevention

Proteus may exist on vegetables, meats, poultry, etc. Between approximately 17 and 22 °C, *Proteus* is the dominant spoiler of crustacean meats. *Proteus vulgaris* produces custard-like rot in eggs and sourness in ham. However, *Proteus* still has beneficial effects on food, such as its contribution to cheese flavor. *Proteus* spp. are one of the most common species on the surface of food processing equipment. The biofilm formed by *Proteus* with other bacteria has been found in the aging tank of dairy plants. Effective cleaning and disinfecting processes are required to eliminate accumulated *Proteus* on the equipment surface and prevent biofilm formation. Establishing closed systems can reduce the chance of contamination. During the food storage and distribution process, the temperature and hygiene conditions are critical factors to prevent the growth of *Proteus* spp. For example, fish and crustacean meats could be spoiled by handlers and storage containers. At temperatures between approximately 17 and 22 °C, *Proteus* becomes the dominate spoiler. The carrier rate of *Proteus* is high in raw meat. During a cooking process, sharing chopping boards or containers for raw and cooked food may cause cross-contamination. At the postprocess stage, it is also necessary to reduce the time of placing cooked food above 20 °C. The *P.* vulgaris infections caused by the spoiled overnight food have been reported.

Morganella morganii has been isolated from various seafoods, among which canned mackerel and tuna are the major source. *Morganella morganii* is commonly isolated in the outbreak of histamine fish poisoning. The fish handling and processing procedure is critical to prevent *Morganella* spoilage. To reduce the exposure time to ambient temperature, immediate freezing or chilling in ice upon fish harvest is recommended. To prevent crosscontamination, the fish contacting surfaces should be sanitized regularly. The modified atmosphere packaging, such as 40% carbon dioxide and 60% oxygen, effectively prevents the histamine formation by psychrotolerant *M. morganii*-like bacteria.

BACTERIA

Pseudomonas

Z Hossain, Bangladesh Council of Scientific and Industrial Research (BCSIR), Dhaka, Bangladesh

Glossary

Abscess A localized collection of pus resulting from an infection.
Disinfection The reduction, by means of chemical agents and/or physical methods, of the number of microorganisms in the environment, to a level that does not compromise food safety or suitability.
Endemic A disease that is constantly present to a greater or lesser degree in a human population in a specific geographic location. Enzootic is the comparable term referring to diseases associated with animal populations.
Food safety An assurance that food will not cause harm to the consumer when it is prepared and/or eaten according to its intended use.
Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of food or water.
Incidence The rate or range of occurrence or influence of something, especially of something unwanted.
Infection The invasion and multiplication of microorganisms such as bacteria, viruses, and parasites that are not normally present within the body.
Infectious dose The amount of pathogen (measured in numbers of organisms) required to cause infection in the host.
Inoculation The introduction of a substance into a body in order to induce an immune response.
Intoxication An abnormal state that is essentially poisoning.
Morbidity The incidence of disease; the rate of sickness.
Mortality The number of deaths in a given time or place; the proportion of deaths to population.
Pathogen An organism capable of causing disease.
Percutaneous Through the skin.
Quarantine A strict isolation imposed to prevent the spread of disease.
Surveillance A type of observational study that involves continuous monitoring of disease occurrence within a population.
Virulence The relative capacity of a pathogen to overcome body defenses.

Background

Pseudomonas, first discovered by Gessard in 1882, is a genus of bacteria belonging to the family Pseudomonadaceae. *Pseudomonas* spp. are free-living bacteria commonly found in soil, ground water, plants, and animals, including humans. Although members of the genus *Pseudomonas* are known to be true pathogens of plants, *Pseudomonas aeruginosa* has become increasingly recognized as an emerging opportunistic pathogen of clinical relevance worldwide. *Pseudomonas aeruginosa* is the most common cause of pseudomonal infection, which generally accounts for a necrotizing inflammation (e.g., necrotizing enterocolitis). *Pseudomonas* spp. are generally not considered as foodborne pathogens responsible for typical gastrointestinal (GI) illnesses, and are mainly associated with spoilage of a variety of food, including fruits and vegetables. However, *P. aeruginosa* may spread among particularly immunocompromised individuals by direct contact with or by the ingestion of contaminated foods and water (for further discussion on transmission, see Section Epidemiology), and this organism has been implicated in perirectal infection, pediatric diarrhea, typical gastroenteritis, and necrotizing enterocolitis. Reports suggest that *Pseudomonas* is associated with typhlitis (also termed as neutropenic enterocolitis) in neutropenic patients, who suffer a sudden onset of fever, abdominal distension and worsening abdominal pain as a result of this disease. Pseudomonal infection can trigger a diarrheal disease known as Shanghai fever, which involves high fever, prostration, headache, and diarrhea. Also, this bacterium can potentially cause bacteremia or septicemia by the invasion of GI tissues leading to its lethal entry into the bloodstream. In addition, *Pseudomonas* plays a common role in eliciting the magnitude of food safety as an indicator organism. Food spoilage by this bacterium warns that other harmful bacteria, including those capable of food poisoning could also grow under the same conditions of the food matrices.

Characteristics of the Organism

Nomenclature/Taxonomy and Classification

The word *Pseudomonas* has derived from Greek *Pseudo* (false) and Latin *monas* (single unit). The genus *Pseudomonas* is included in the class Gammaproteobacteria, which constitutes

 doi:10.1016/B978-0-12-378612-8.00109-8

one of the largest groups of bacteria, and have conserved macromolecules, such as 16S ribosomal ribonucleic acid (rRNA) gene sequences. The phylum Pseudomonad once constituted a large number of *Pseudomonas* species, but recent reclassification has identified a few groups that are of great medical interest. Of these, the true or fluorescent *Pseudomonas* comprises *P. aeruginosa*, *Pseudomonas fluorescens*, and *Pseudomonas putida*. Another medically significant group includes *Pseudomonas cepacia*, *Pseudomonas pseudomallei*, and *Pseudomonas mallei*, which are currently categorized as *Burkholderia* spp. implicated in many human and animal infections.

Morphology

Pseudomonas spp. are nonspore forming, Gram-negative rod (bacilli) bacteria measuring 0.5–0.8 μm by 1.5–3.0 μm, and are motile due to possession of single or multiple polar flagella (Figures 1 and 2). Unlike other *Pseudomonas*, *P. mallei* is a nonmotile coccobacillus. Three colony types of *P. aeruginosa* are observed: small, rough colony isolated from nature; large, smooth, colony with flat edges and an elevated appearance from clinical samples; and mucoid colony frequently obtained from respiratory and urinary tract secretions. The smooth and mucoid colonies are thought to be highly associated with colonization and virulence.

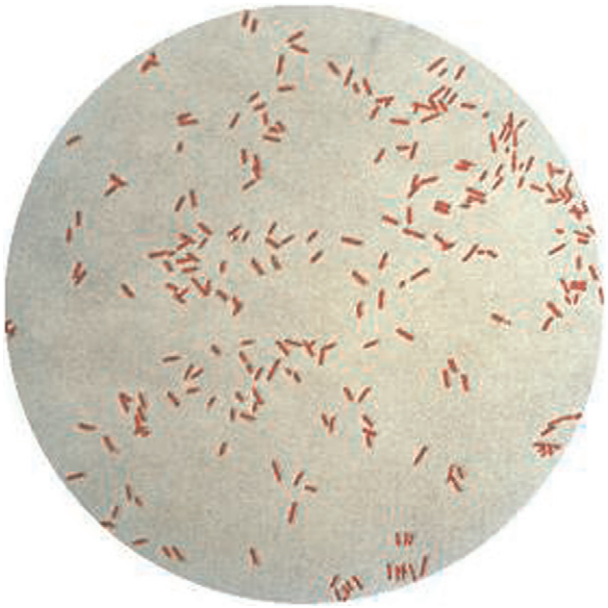

Figure 1 Gram stain of *Pseudomonas aeruginosa* cells. Reproduced from US Centers for Disease Control and Prevention (CDC).

Metabolism

Most *Pseudomonas* spp. are obligate aerobes, and do not depend on fermentation for their metabolism. However, these organisms are able to grow in the absence of oxygen provided that NO_3 is available as a respiratory electron acceptor in the environment. *Pseudomonas* spp. produce acid from glucose or other carbohydrates only in the presence of oxygen. They are usually catalase and oxidase positive, but lactose negative on MacConkey agar. This bacterium is known to have minimal nutritional requirements, and can even grow in distilled water. A simple medium consisting of acetate as a source of carbon and ammonium sulfate as a source of nitrogen is sufficient for pseudomonal growth in the laboratory.

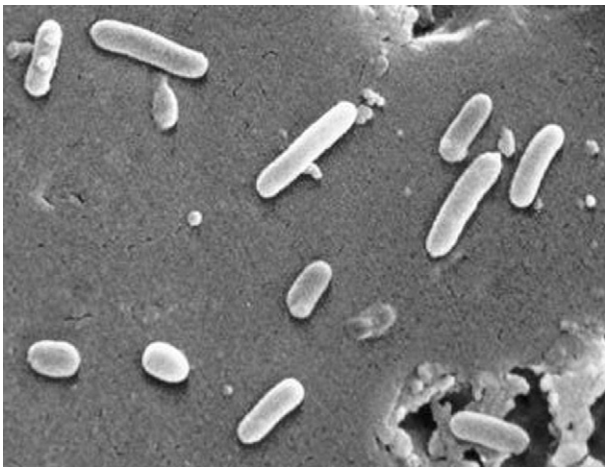

Figure 2 *Pseudomonas aeruginosa* scanning electron micrograph. Reproduced from US Centers for Disease Control and Prevention (CDC).

Survival and Growth Characteristics in Food and Environment

Most *Pseudomonas* spp. can easily thrive in a variety of food materials (e.g., fruits, vegetables, grains, and animal feeds), and may either promote growth of certain foods or subject some food to deterioration. Because of the predilection for growth in moist environments, these bacteria are ubiquitous in soil and water, and found on surfaces in contact with soil or water. *Pseudomonas* is distinguished by the characteristic fruity (grape like) odor of its colonies. *Pseudomonas* species are tolerant to a wide array of physicochemical conditions. *Pseudomonas aeruginosa* not only prefers to grow at 37 °C but is also able to tolerate higher temperatures up to 42 °C.

Biofilm Architecture

Pseudomonas spp. have widely been described in many studies on biofilms. Particularly, *P. aeruginosa* has been used as a paradigm for the study of bacterial biofilm formation. These bacteria have remarkable ability to secrete exopolysaccharides, such as alginate, Psl, and Pel associated with the biofilm formation. It has also been demonstrated that these pathogens perform cell to cell communication by a subtle strategy called quorum sensing via the production of small molecules called acyl homoserine lactones. This mechanism is believed to play a vital role in the biofilm development, and is being investigated further as a therapeutic target for control of chronic infections with *Pseudomonas*. Researchers have already performed a number of studies into the development of an effective quorum sensing blocker in order to limit biofilm-associated infections. Biofilm facilitates the bacterium with

survival through adverse environmental changes. The glycocalyx biofilm formation by *B. pseudomallei* (also *P. pseudomallei*) and transformation into several phenotypic variants protect the bacterium from the hostile environment and aid in its survival. Biofilm in drinking water systems is an important concern worldwide, and can be a reservoir for *P. aeruginosa*. Specific tap assembly units from neonatal wards in Northern Ireland have revealed the presence of slimy *Pseudomonas* aggregates during an investigation following four fatal cases of *P. aeruginosa*-associated bacteremia. Biofilms can be a particular problem in home water treatment devices that utilize carbon filters or membranes. Moreover, the ability of *Pseudomonas* spp. to slow their metabolism allows them to survive within biofilm matrices in the bottled or packaged drinking water for months. The capacity to metabolize a wide variety of nutrients scattered in nature has enhanced the potential of *Pseudomonas* for building such sticky communities in almost every place of the environment (Figures 3 and 4).

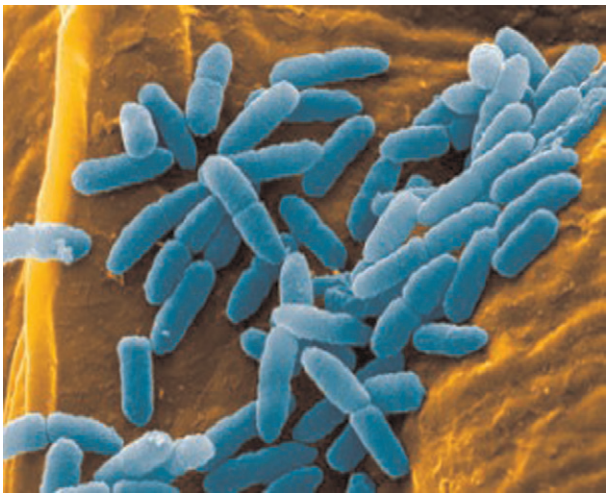

Figure 3 Biofilm matrix of *P. aeruginosa*.

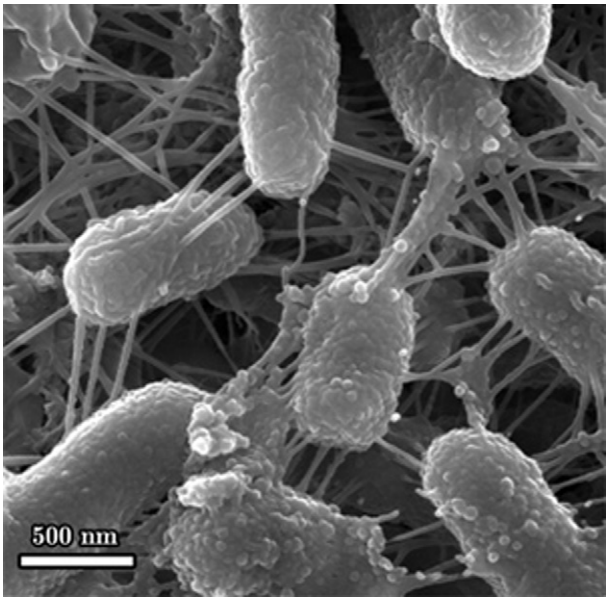

Figure 4 *Pseudomonas putida* biofilm architecture.

Production of Pigments

Another important characteristic of this bacterium, which enables isolation and differentiation of majority of the strains, is the production of certain diffusible pigments. Many *Pseudomonas* species secrete a fluorescent yellow-green siderophore called pyoverdine (fluorescein) under conditions of iron limitation. *Pseudomonas aeruginosa* is capable of producing a blue phenazine pigment pyocyanin, a reddish brown pigment pyorubin, and a brown to black pigment pyomelanin which help differentiate this species from others of the genus. Pyocyanin is produced in large quantities in low iron-containing media and helps with iron metabolism in the bacterium. Infections caused by *P. aeruginosa* are suppurative as a result of secretion of this pigment (derived from 'pyocyaneus' or 'blue pus') at the site of infection. Pyocyanin is also involved in inflammatory response and tissue damage during pathogenesis. *Pseudomonas fluorescens* synthesizes a secondary siderophore quinolobactin, which results from the hydrolysis of the unstable molecule 8-hydroxy-4-methoxy-2-quinoline thiocarboxylic acid (thioquinolobactin) and is yellow, dark green in the presence of iron.

Description of Pseudomonal Toxins

Majority of *Pseudomonas* infections are both invasive and toxinogenic. *Pseudomonas aeruginosa* invades tissues by the production and subsequent release of extracellular enzymes and toxins that break down physical barriers and damage host cells. Two extracellular proteases associated with virulence are elastase and alkaline protease. The bacterium produces three other soluble proteins that have implications in invasion: a pore-forming cytotoxin and two hemolysins. *Pseudomonas* endotoxin lipopolysaccharide (LPS) may contribute to resistance to phagocytosis and the serum bactericidal response. The lipid A moiety of LPS mediates typical pathogenesis of Gram-negative septicemia. *Pseudomonas aeruginosa* also produces two extracellular protein toxins, exoenzyme S and exotoxin A, which are associated with virulence and disease severity. Capsular polysaccharide and type III secretion systems of *P. pseudomallei* have association with intracellular survival. The extracellular polysachharide capsule of *P. mallei* is postulated to be a critical determinant of virulence. Certain *Pseudomonas* spp. are capable of producing a lethal toxin called tetrodotoxin (TTX) harbored by a variety of marine animals (for further discussion on this topic please see Section Tetrodotoxin-Producing *Pseudomonas*).

Genetic Factors of Virulence

Pseudomonas spp. have the ability to exchange genes by conjugation or horizontal gene transfer that may lead to the spread of virulence among strains and species. Expression of certain genes during infections plays an influential role in the pathogenesis and toxicity. *Pseudomonas* is able to regulate the genes to activate and control its virulence. Molecular interactions of homologs of the transcriptional regulators PtxR and PtxS play a key role in the regulation of exotoxin A expression,

which is a primary virulence factor of *P. aeruginosa*. The presence of multiple drug resistance in most *Pseudomonas* sp. is inherent. *R*-factor inheritance and transfer of *R*-plasmids contribute to resistance in mucoid *Pseudomonas*.

Resistance to Different Factors and Survival in the Host

One of the primary clinical concerns relating to *Pseudomonas* is its natural resistance to multiple antimicrobial agents, including penicillin and many related β-lactam antibiotics, as a consequence of the permeability barrier conferred by its characteristic Gram-negative outer membrane. Its widespread resistance to many conventionally used antibiotics is well known and a significant problem in health and agriculture. *Pseudomonas* has developed irrevocable resistance to naturally occurring antibiotics by living in association with bacilli, actinomycetes, and molds in the soil. Horizontal spread of resistance genes among species and strains of *Pseudomonas* poses further challenges in tackling infections with this pathogen. It is also resistant to rich salt and dye concentrations and weak antiseptics. The ability to form biofilms on surfaces also makes this pathogen impermeable to standard therapeutic concentrations of various antibiotics. Alginate production develops the characteristic slimy (mucoid) shield of the bacterium upon colonization on surfaces or substrates, and in the host environment, including the GI system protecting pseudomonads from typical phagocytic killing by mammalian white blood cells (WBCs), such as macrophages. This unique property increases the ability of the pathogen to stick to host cells. The exopolysaccharides are also thought to contribute to the biofilm architecture of *P. aeruginosa*, and to play a critical role in viability of cells in biofilms.

Pseudomonas characteristics are diverse by nature, and have largely contributed to its ecological success as an opportunistic pathogen. Many of these characteristics also provide this bacterium with the scope for its survival and growth under extreme environmental conditions as well as adaptive evolution through atmospheric changes.

Clinical Manifestation in Animals

Glanders and Melioidosis

Pseudomonas mallei (now known as *B. mallei*) is the predominant cause of glanders, which is a contagious and acute or chronic disease, mainly found in horses. This pathogen has also been isolated in other equids like donkeys and mules, and goats, sheep, cats, and dogs. Glanders is difficult to diagnose, and often fatal. Another pseudomonal infection caused by *B. pseudomallei* (formerly *P. pseudomallei*) is known as melioidosis (also called Whitmore disease), which clinically resembles glanders, but the bacterium exists mainly in the contaminated environment unlike *B. mallei*. The occurrence of this disease has been reported in horses, swine, goats, sheep, dogs, and cats. Owing to its wide spectrum of manifestations, i.e., the involvement of most body organs, melioidosis is considered to be one of the 'great imitators.' Infection could be acute, subacute, or chronic (asymptomatic). Both *B. mallei* and *B. pseudomallei* also have ability to afflict humans seriously, and are now considered as potential bioterrorism agents. Owing to their highly pathogenic characteristics, these organisms can be exploited in deliberate-release events.

Incubation

Incubation period for both glanders and melioidosis is unknown, but deemed variable. The average time taken for the onset of the diseases has been reported to be 1–2 weeks after inoculation. Both diseases have been described with potential for reactivation from latent state after decades of incubation.

Signs and Symptoms

The disease is characterized by serial development of ulcerating nodules in the upper respiratory tract, lungs, and skin. The acute form of glanders occurs in affected animals within 2 weeks of incubation period. They usually show symptoms of respiratory discomfort following the onset of septicemia and high fever (up to 106 °F). A thick, mucopurulent nasal discharge is observed in these animals. The severity of the clinical signs accounts for death of the infected animal within a few days, if not treated with appropriate antibiotics. Glanders can potentially affect both nasal mucosa and the lungs of animals. The disease can be recognized by the development of nodules in the nasal septum or the lungs. These nodules further degenerate into ulcers in deep tissues leading to enlarged and edematous lymph nodes. Broken contents of the nodules in the lungs may be released into the bronchioles, and may give rise to upper respiratory tract syndrome.

Melioidosis is clinically presented with local suppurative infections, ulcerative skin, cutaneous abscesses, fulminant bacteremia, or septic shock with multiple abscesses in virtually all organs of the body. Pneumonia has been documented to be the most common syndrome of *B. pseudomallei* infection, particularly in endemic regions. Other syndromes include prostatic abscesses, paralytic encephalomyelitis, or intraabdominal abscess formation, which may require surgery. Mortality rates among those with bacteremia or septic shock are significantly high.

Sequelae/Chronic Effects and Complications

The chronic form of glanders called 'farcy' causes ulceration in the skin and subcutaneous tissues followed by swelling of the affected area. This condition persists and affects surrounding lymphatic vessels, which thicken and consolidate to form 'farcy pipes' or 'farcy buds.' The nodules produce a highly infectious and sticky mucus, which may spread onto other sites of the body. The chronic stage of glanders may also affect liver and spleen, and develop intramuscular abscesses in the arms or legs. The disease sustains for months or years in the infected animals, which may not develop immunity even after recovery.

Chronic symptoms of melioidosis mimic those of tuberculosis. Cutaneous and intramuscular (in the limbs) abscesses are common. Liver and spleen may also be affected by chronic melioidosis. This form of the disease may relapse and recur over the course of years.

Dose of Infections

A significantly low infectious dose (ID_{50}) of *B. pseudomallei* for animals may be sufficient for a successful onset of

characteristic illnesses. The lethal dose (LD_{50}) by inoculation in some susceptible animals has been found to be less than 10 viable organisms. ID_{50} for humans is still unclear, but may vary considerably according to host resistance. Most infections with *B. pseudomallei* have occurred through gross contamination, such as contaminated war wounds and laboratory accidents. Very little is known about the infective dose of *B. mallei* for both humans and animals, but it seems that the parasite is potentially more dangerous than *B. pseudomallei*. Its ID_{50} has not yet been determined in terms of colony-forming units, but has been merely estimated as an inoculum concentration of 0.2 mg by subcutaneous inoculation.

Pseudomonas aeruginosa-Associated Diseases

Infections with *P. aeruginosa* are significant among various animals. It is a clinical problem in mainly neutropenic animals, including mice that are irradiated or treated with chemotherapeutic compounds. This pathogen transits the nasopharyngeal or gut mucosal barrier of these seriously immunodeficient animals, and becomes the cause of systemic bacteremia and sepsis leading to death.

Signs and Symptoms

In mice, clinical presentations of pseudomonal infection include conjunctivitis, nasal discharge, or typical signs of rodent illness, such as stooped posture, anorexia, and ruffle fur. The bacterium is also associated with otitis media, pneumonia, septicemic enteritis, and fulminant death in chinchillas (*Chinchilla lanigera*). *Pseudomonas aeruginosa* is one of the leading causative agents of otitis externa in many animals, including dogs. The disease presents with head shaking or ear scratching, purulent exudates, malodor, swelling of ears followed by inflammation and pain, ulceration, and otitis media. Reports suggest that otitis media is highly associated with preceding otitis externa in dogs. Clinical signs of otitis media include persistent and chronic otitis externa, neurological abnormalities, and ruptured or bulging, hemorrhagic tympanic membranes with exudates in the middle ear. *Pseudomonas* is also known as a secondary pathogen in canine upper respiratory tract infection, and can cause severe bronchopneumonia in dogs that requires immediate clinical attention. *Pseudomonas aeruginosa* is now considered as one of a few unusual pathogens implicated in outbreaks of clinical mastitis in cattle, sheep, and goat. The infection is generally characterized by acute or subacute exacerbations. Some cows may have high mortality following an onset of severe peracute mastitis with toxemia, whereas others may present signs of subclinical infections.

Tetrodotoxin-Producing *Pseudomonas*

Certain species of *Pseudomonas*, such as *P. putida* are capable of producing a potent neurotoxin called tetrodotoxin (TTX) primarily found in marine puffer fish belonging to the family Tetraodontidae. Other than *Pseudomonas*, bacterial species including *Vibrio*, *Bacillus*, *Actinomyces*, *Serratia*, *Aeromonas*, and *Microbacterium* have been reported as TTX producers in marine animals. The first identified bacterial strain producing the toxin was *Vibrio*. TTX was discovered in 1909 by a Japanese scientist Yoshizumi Tahara. This toxin has also been isolated from other marine animals largely different to puffer fish, such as several species of blue-ringed octopuses of the genus *Hapalochlaena*, rough-skinned newt, ribbon worms, parrotfish, frogs of the genus *Atelopus*, xanthid crabs, horseshoe crabs, starfish, and certain angelfish. Puffer fish are now considered as the second most poisonous vertebrates in the world, after the golden poison frog. The toxin is believed to potentially exist in the gonads, liver, intestine, and skin of these fish at levels sufficient to cause rapid and violent death. Bioaccumulation of the toxin is thought to contribute to its high concentrations in the food-chain. Despite potential life-threatening toxicity of the fish, its flesh is widely recognized as a delicacy in Japan, where it is handled and prepared with caution by specially trained and certified puffer chefs. However, cases of TTX poisoning as well as deaths among individuals from puffer fish consumption continue to be reported in this country.

Signs and Symptoms

The onset of clinical sings of intoxication may be visible in minutes to hours of ingestion. Major symptoms develop usually within 24–48 h of incubation. Early common signs of the poisoning are paresthesias (lip, tongue, and face), numbness, and abdominal pain associated with salivation, nausea, vomiting, and diarrhea. Major symptoms involve paralysis of voluntary muscles, including the diaphragm, cardiac dysfunction, loss of sensation, central nervous system dysfunction (e.g., coma) and respiratory failure leading to death. Death usually occurs within 6–24 h, but if the patient survives after 24 h, prognosis improves. There are sporadic cases of TTX poisoning in animals, especially in wild populations. TTX-containing organs or puffer fish can be extremely toxic to most animals when eaten. Common clinical signs of toxicity in dogs include vomiting, wobbliness, drop in the heart rate, and lethargy. Some animals could variably have excess salivation, diarrhea, involuntary contractions or twitching of the muscles, seizures, unusual heart beat, respiratory failure, and death. Consumption of organisms containing TTX is also known to kill dogs, cats, and humans. A dose of approximately 10 mcg kg^{-1} has been estimated to be sufficient for serious toxicity of TTX in humans.

Possible Association with Crohn's Disease

Crohn's disease, also called regional enteritis, is a human inflammatory bowel disease (IBD) or colitis that mainly affects the intestines, but may occur virtually in any part of the GI system from the mouth to the end of the rectum (anus) triggering a variety of symptoms. It is widely hypothesized as an autoimmune disorder characterized by the faulty destruction of healthy body tissues by one's own body immune system. Nevertheless, current understanding of more realistic scenario of the disease pathogenesis proposes its underlying relation to innate immune dysfunction in affected humans.

Clinical Presentations

Crohn's disease is often misdiagnosed as irritable bowel syndrome. Crohn's disease patients suffer chronic inflammation of the GI tract, which results in thickening of the intestinal wall. The disease can be primarily presented with severe abdominal cramps, bloody or mucoid stools, watery diarrhea, nausea and vomiting, constipation, loss of appetite, GI or rectal bleeding, fistulas around the rectal area, and ulceration in the mouth. Crohn's colitis may also cause extra-GI complications, such as fever, fatigue, inflammation and lesion in the eye, skin sores, joint pain and swelling, defective or failed growth and sexual impairment in children, vitamin B_{12} deficiency, and weight loss. Major consequences of the disease, which could pose life-threatening conditions, may include hemorrhage, dilation of the large intestine (toxic megacolon), and even colon rupture. There is no complete cure for the disease, and if it worsens due to inappropriate or lack of medications, patients might be at serious risk of small bowel or colon cancer. Although prolonged medications are crucial in Crohn's disease, its severity in some cases may not fully respond to conventional medical therapy. In such instances, patients may need to undergo surgery for removal of a damaged portion of the intestine or the entire colon, with or without the rectum.

Etiology

Although the true cause of Crohn's disease still remains unclear, various factors are assumed to play an underlying role in the development of this disease. Among these, genetic, immunologic, microbial, and dietary factors may have implications. Infectious agents like *Mycobacterium avium* subspecies *paratuberculosis* (MAP), *Pseudomonas*, adherent-invasive *Escherichia coli*, *Listeria monocytogenes*, *Yersinia pseudotuberculosis*, and measles virus have been proposed as triggers of Crohn's disease, predominantly on the basis of seroreactivity. The association of MAP with the pathogenesis of Crohn's disease has been hypothesized most extensively, but the presence of mycobacterial deoxyribonucleic acid (DNA) in lesions remains controversial. Reduced tolerance to normal GI microbiota has also been argued to be somewhat responsible for Crohn's disease. It is now suggested that *P. fluorescens* has a strong correlation with the disease in humans. Crohn's and similar illnesses have also been reported in animals, such as livestock, cats, and dogs, but their association with *Pseudomonas* spp. has not yet been described. Despite being long known as a psychrotrophic organism, *P. fluorescens* is found as a low-level commensal in the ileal mucosa of humans. Nevertheless, colonization of these bacteria appears to be extensive in the susceptible colonic mucosa in Crohn's disease. The pathogen may become opportunistic in the disordered mucosal environment in genetically vulnerable individuals, and contribute to Crohn's disease mucosal damage through the expression of T cell superantigen, I2 encoded by *PfiT* gene. Studies have revealed that the bacterium is able to adhere to intestinal epithelial cells (IECs), exert cytotoxic effects, and induce proinflammatory response. The presence of specific antibodies against some strains of this pathogen in the serum of patients further indicates its potential role in Crohn's disease pathogenesis. Also, *P. fluorescens*-specific I2 antigen sequence is systematically detected in the ileal mucosa of patients. A positive correlation is found between the level of anti-I2 antibodies and severity of the disease. Certain strains of this species induce secretion of proinflammatory cytokine, interleukin (IL)-8 in human intestinal and colorectal tumor cell lines through a pathway different to that observed in *P. aeruginosa*-activated IL-8 secretion. *Pseudomonas fluorescens* can also alter intestinal epithelial permeability by the rearrangement of *F*-actin microfilaments, and translocate across Caco-2/TC7 cell monolayers via the transcellular pathway. Thus, *P. fluorescens* demonstrates its potential for significant interaction with IECs. Crohn's disease patients with elevated antibody titers against *P. fluorescens* I2 antigen are more susceptible to advancement to perforating or fibrostenotic disease, thereby requiring more surgery.

According to recent theories, Crohn's disease is linked to malfunctioning of innate immune system of the body that recognizes microbe-associated molecular patterns by pattern recognition receptors (PRRs), such as toll-like receptors (TLRs), and subsequent release of cytokines and chemokines. Prolonged exposure to bacterial antigens results in reduced expression of surface TLRs in colonic epithelial cells. Furthermore, polymorphisms in PRRs, including TLRs and nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) NOD2 (also known as caspase recruitment domain (CARD)-containing protein, CARD15) play a role in Crohn's disease susceptibility. Mutations of TLRs and NLRs may also contribute to vulnerability to the disease and progression to fibrostenosis. Therefore, defective sensing of bacterial pathogens or their derivatives is possibly involved in the etiopathogenesis of Crohn's disease. It is, however, ambiguous whether *P. fluorescens* or other bacterial pathogens can mimic or exploit any host cell signaling complex within the GI tract, and induce polymorphisms or mutations in these cytoplasmic receptors. Other fluorescent *Pseudomonas* species may also have implications in the pathology of Crohn's disease. There is evidence of a high prevalence of *Pseudomonas brenneri*, *Pseudomonas migulae*, *Pseudomonas panacis*, and *Pseudomonas proteolytica* in children with Crohn's disease. A former member of pseudomonads, *Stenotrophomonas* (*Pseudomonas*) *maltophilia* broadens the idea of pseudomonal contribution to the occurrence of Crohn's disease. DNA sequences with homology to *P. maltophilia* DNA have been found in inflamed tissues of Crohn's disease patients. In addition, historical review of Crohn's disease suggests that cell wall variants of this bacterium and other *Pseudomonas*-like bacteria may have a relationship with the disease. In fact, there is a coexistence of *Pseudomonas* and other closely related bacteria with the pathophysiology of Crohn's disease. Characteristic inflammation resulting from the disease is considered as a sign of the dysfunctional immune response to the corresponding pathogen. In recent years, *P. fluorescens* has received increased attention as a candidate human pathogen, which plays a putative role in specific magnitudes of Crohn's disease and corresponding immune disorder. Further systematic investigations are needed to elicit a definitive picture confirming its exact implication in the etiology of the disease.

Table 1 Clinical presentations and outcomes of melioidosis in northern Australia

Parameter	*Number of patients*	*Number of deaths*	*Mortality in percentage*
Bacteremic	117	43	37
Pneumonia	66	31	47
Genitourinary infection	23	4	17
Osteomyelitis, septic arthritis	4	1	25
Other diagnoses	24	7	29
Nonbacteremic	135	6	4

Epidemiology

Occurrence of Glanders and Melioidosis

Geographic Distribution, Prevalence, and Incidence

Glanders is a common problem among domestic animals in Central America, South America, Asia, Africa, and the Middle East, but has not occurred in the US since the 1940s. Melioidosis caused by *B. pseudomallei* is endemic in Southeast Asia, and most cases are reported in Malaysia, Singapore, Thailand, Vietnam, Cambodia, Laos, and Myanmar. It is estimated that 5–20% agricultural workers in endemic areas have antibody titers to this pathogen. This bacterium is a major cause of morbidity (an estimated 2000–3000 cases per year) and mortality in northeastern Thailand. Major incidences of this disease are also recorded in northern Australia. Table 1 represents the overall scenario of human melioidosis in this region in accordance with the clinical presentations. During the Vietnam War, melioidosis was referred to as the Vietnamese Time Bomb when American Troops returned from Vietnam, and were diagnosed as carriers of latent infection with likelihood of recurrence. Other regions, where melioidosis is recognized in humans and animals, include Africa, India, China, Taiwan, Brunei, the Middle East, and South Pacific. Incidences have also been reported from Sri Lanka, Bangladesh, and Pakistan. Confirmed periodic cases of the disease have been reported in Iran. Israel has by far had no reports of melioidosis. During the twentieth century, sporadic cases in western countries were documented mainly among returning travelers or military veterans. As cases are being increasingly documented from outside the classic endemic regions for melioidosis, global warming is assumed to play a critical role in further expansion of the endemic boundaries of the disease.

Transmission

Animals, particularly equids are the predominant reservoirs of *B. mallei*. Transmission of glanders in animals commonly takes place via inhalation or direct inoculation with broken or ulcerated skin of carrier animals. Transmission of *B. mallei* between humans is rare, but feasible. It is likely to occur in humans through percutaneous or direct inoculation of nasal mucosa of animals suffering glanders. Therefore, people who are highly vulnerable to the infection are chiefly occupational personnel, such as laboratory workers, butchers, horse handlers, and veterinarians. Infection due to ingestion of food and water contaminated with nasal discharges from these animals is also possible. Chronic glanders or 'farcy' is assumed to occur through direct inoculation of *B. mallei* from affected equines. The organism is considered as a greatly adapted parasite of horses, which cannot continue to survive in nature outside of its host. Modes of transmission of melioidosis in animals are very similar to that of glanders, except ingestion that is paradoxically much less common for the former despite the natural persistence of *B. pseudomallei* in the environment. Transmission is by far believed to occur in humans through percutaneous inoculation being the predominant portal of entry, inhalation, and more rarely sexual transmission. Inhalation of dust from contaminated soil is a likely route of transmission in case of pulmonary infection. Aspiration or drinking of unchlorinated contaminated water may also lead to infection. Two outbreaks of melioidosis in Australia were linked to potable water supplies. Human-to-human as well as zoonotic transmission is rare.

Infections by *P. aeruginosa*

Certain bacterial infections in both humans and animals are being considered as serious problems that question the efficacy of conventional therapeutics and control measures. Some of these problems can be directly attributed to *P. aeruginosa*, which is the causative agent of many opportunistic infections worldwide.

Prevalence and Incidence

This pathogen reportedly occurs in more than 50% of humans, and is routinely detected among many hospital patients. A number of different epidemiological studies have

found the occurrence of *P. aeruginosa* in nosocomial infections that are difficult to treat with most conventional antibiotics due to its extensive antimicrobial resistance. The bacterium is claimed to be the fourth most commonly isolated nosocomial pathogen associated with nearly 10% hospital-acquired infections. These infections primarily include pneumonia, urinary tract infections, surgical wound infections, and septicemia. *Pseudomonas aeruginosa* is the second most common cause of nosocomial pneumonia and the most common cause of intensive care unit pneumonia. It has also been isolated from throat (5%) and stool (3%) of nonhospitalized patients. This ubiquitous pathogen is disseminated in moist hospital environments (e.g., food, disinfectant, sinks, toilets, taps, showers, mops, sewage, respiratory and dialysis equipments, etc.) as well as in nature. In a study conducted on the prevalence of *Pseudomonas* in Indonesian soil samples, 78% of the isolates were *P. aeruginosa*. It is known to be a notorious chronic pathogen associated with long-term infections in individuals with the heritable disease cystic fibrosis (CF). *Pseudomonas aeruginosa* becomes highly resistant to host response and antimicrobials after prolonged colonization of the CF lung. The bacterium is likely to colonize in the lung of approximately 80% of the CF patients. Increasing longevity of young CF patients, particularly children has largely contributed to a dramatic proliferation in the proportion of adult CF patients (from 8% in 1969 to 33% in 1990).

Factors Contributing to Infections

Pseudomonas aeruginosa can rapidly spread in the respiratory and GI tracts of hospitalized patients, particularly those under antibiotic treatment and bedridden for extended periods. Interestingly, young black men have been reported to be more susceptible to pseudomonal endocarditis. *Pseudomonas aeruginosa* reenters the hospital via fruits, plants, and vegetables. Contact with or ingestion of food materials contaminated with this organism may lead to not only general extraintestinal infections but systemic bacteremia or sepsis as well because of its ability to enter the bloodstream through the GI barrier. Visitors as well as patients transferred between facilities can reintroduce the bacterium into a germ-free hospital environment. Spread occurs through hands of healthcare personnel, direct contact with contaminated reservoirs, or ingestion of contaminated foods and water. Certain medical procedures, such as surgery and insertion of catheter or respiratory tube, also predispose the patients to serious infection with this pathogen.

Mortality

Infections with this pathogen have a high mortality rate among the immunocompromised individuals, mostly with syndromes of bacteremia or lower respiratory tract infections. Rates of mortality vary from 15% to 20% of patients (with severe ear infections) to 89% of patients (with left ventricular dysfunction).

Animal Morbidity and Mortality

Pseudomonas aeruginosa is commonly detected in watering systems of animals and humans that include both the drinking water matrix and wash water. It is likely that many animals can transiently harbor this organism. Long-term treatment with antibiotics plays a contributing role in aggressive disturbance of animal gut flora and leads to prolonged colonization of this pathogen. Frequent incidences of mastitis caused by *P. aeruginosa* among cattle, goat, and sheep were reported in past decades. Herd infections have been found to be associated with generous exposure to contaminated wash water, teat cup liners, or intramammary treatments provided by milkers. Infections within the mammary glands may be established due to the use of unhygienic techniques or tools in udder therapy or milking. In the early 1970s, high incidence (80.1%) of *P. aeruginosa* pyocine type 1 in bovine mastitis was recorded in Israel with a high rate of fecal carriage of this organism both in adult cattle and in calves. Pseudomonal mastitis in sheep and goat has also occurred in Israel. More than 15 Israeli dairy sheep and goat herds have been reported for outbreaks with clinical presentations of gangrenous infections. *Pseudomonas aeruginosa*-associated high early mortality rates in chicks have been experienced in chick hatcheries in AL, USA.

Transmission of *P. aeruginosa* between animals is not well documented. Most common mode of entry is exposure to contaminated water. These bacteria can also be transmitted from animals to humans or vice versa via the ground water used for washing by means of ingestion or direct inoculation. Although shedding of mastitic *P. aeruginosa* into raw milk has been poorly documented, it is still likely through infected udder or contaminated milking devices. Animal neutrophils provide the first line of host defense against transmission of this pathogen through wounds or mucosal barrier. Recent emergence of resistance to many therapeutic antibiotics in this bacterium has gained much interest among clinicians and researchers. High prevalence of extended-spectrum β-lactamase-producing *P. aeruginosa* has become an alarming issue in hospitals and laboratories.

Marine Poisoning and Tetrodotoxin

Geographic Distribution, Prevalence, and Incidence

Puffer fish poisoning has been reported to a great extent in many parts of the world, particularly in coastal areas. This poisoning has mostly been associated with the consumption of puffer fish from waters of the Indo-Pacific ocean regions. According to recent evidences, *Pseudomonas* spp. have been considered as putative TTX producers in puffer fish and other TTX-harboring marine animals. The bacteria were isolated from the skin of a puffer fish *Takifugu poecilonotus* in 1987, and production of TTX and its derivatives was subsequently confirmed in the laboratory. During 1974–83, the incidence of puffer fish intoxication was estimated to be approximately 200 cases annually, with almost 50% mortality. Approximately 50 people die of puffer fish poisoning in Japan every year. Cases of death are also found in Hong Kong, Singapore, and Australia. TTX intoxication is also frequently reported from some cities in China. Episodic cases have been documented in the US. Recent cases of morbidity and mortality in Bangladesh due to consumption of puffer fish have also been described. The fishes have been found to be most dangerous if eaten just before or during their reproductive season due to a positive relationship between gonadal activity and toxicity. Other than

Table 2 Levels of TTX poisoning in patients of some Asian countries during 1989–2008

Incident time	*Location*	*Patients involved*	*LOD (ng ml^{-1})*	*TTX concentration in urine (ng ml^{-1})*	*TTX concentration in plasma/serum (ng ml^{-1})*

puffer fish, edible marine gastropod-associated poisoning is also a concern in China and Taiwan. TTX poisoning by horseshoe crab is evident in Thailand. Table 2 summarizes detection of various TTX levels in Asian patients between 1989 and 2008.

Transmission

The main portals of entry of the toxin are ingestion, inhalation, and injection. It can also enter the body through abraded skin.

Crohn's Disease Scenario

Distribution, Prevalence, and Incidence

Pseudomonas fluorescens is widespread in refrigerated food products, soil, and water. Parallel emergence of the pathogen and rise of Crohn's disease has been suggested to be linked to the vast use of refrigerated food in western countries. Surprisingly, it has been isolated from clinical environment, and the I2 antigen specific for this bacterium has been detected in the serum of 54% patients with ileal Crohn's disease. Studies have demonstrated positive test results for *Pseudomonas* spp. in 58% children with Crohn's disease, whereas the percentage has been much less (33%) in non-IBD children. The incidence of Crohn's disease has mounted over the past few decades. Incidences have been estimated to be between 400 000 and 600 000 in North America. Recorded prevalence of Crohn's disease in the US is approximately 7 cases per 100 000 populations, whereas 27–48 cases per 100 000 have been reported in Northern Europe. Crohn's disease incidence in Asia, Africa, and Latin America is postulated to be lower than in Europe. Considerably high incidence and prevalence of Crohn's disease have been reported in Canterbury, New Zealand.

Concerning Factors

Prevalence of Crohn's disease is possible at any age, but the most susceptible age group for the disease is usually 15–35 years. Among all patients diagnosed to be Crohn's disease positive in the USA, nearly 20–30% patients are aged below 20 years. White children seem to be more vulnerable than black children in this country. Similarly, the proportion of whites with IBD has been found to be 97.5% in New Zealand. Family history of incidence and smoking affect the causation of the disease. Although males and females are affected by Crohn's disease almost equally, prevalence is more likely among females in some countries. It is also suggested that Jewish people are more prone to this disease.

Analytical Methods

Typical signs (e.g., nodules, ulcers, scar formation, and debilitated condition) may provide sufficient evidence for a clinical diagnosis of glanders. However, as the symptoms do not develop in the early stage of the disease, the mallein test is a common method of choice for detection of the disease. Complement fixation is another widely used testing technique, but may give rise to a false-positive result. Enzyme-linked immunosorbent assay (ELISA) has been found to be more accurate than complement fixation. Immunofluorescent microscopy on pus or secretions can be a rapid diagnostic tool in endemic areas. Traditional culturing of exudates from lesions could help identify the causative agent. Polymerase chain reaction (PCR) for amplification of 16S and 23S rRNA gene sequences can be used for specific detection and phylogenetic analysis.

Clinical diagnosis of melioidosis is quite similar to that of glanders. A gentamicin-supplemented liquid transport broth called Ashdown's medium is also used for selective growth of *B. pseudomallei*. Repeated indirect hemagglutination test or ELISA renders successful positive results, and is an important technique for testing the seroprevalence among tourists returning from a melioidosis-endemic region. Both *Burkholderia* species can be identified by combining API 20NE or 20E biochemical kit with a simple screening system using Gram stain, typical growth characteristics, and oxidase reaction along with antibiotic susceptibility testing (resistant to polymyxin B and colistin).

Infections with classic *Pseudomonas* spp. in both humans and animals are identified by conventional culture and biochemical methods. Use of cetrimide agar or other commercially available *Pseudomonas* agar media is quite effective in rendering selective confluent growth of colonies with typical

pigment production. On MacConkey agar, *P. aeruginosa* colonies are colorless (nonlactose fermenting) without pigment production, but the colonies appear blue green on ordinary nutrient agar. Culture results are available in 2–3 days. The ability of *P. aeruginosa* to grow at 42 °C may aid in laboratory identification. Hemolytic activity (β-hemolysis) is confirmed by using blood agar (e.g., 5% sheep blood agar). The characteristic grapelike odor of the colonies is also helpful during phenotypic analysis. Biochemical identification includes positive catalase and oxidase reactions and citrate utilization. Blood sample screening and site-specific investigations, such as urine, stool, sputum, pus, cerebrospinal fluid cultures, or drainage from an infected ear or eye are very useful methods. Also, fluorescence is used to detect the bacteria in wound specimens. X-rays and other imaging approaches, including computed tomography (CT) and magnetic resonance imaging (MRI) can be performed to evaluate infections in deep organ tissues. Otitis can be assessed by swab cytology of the otic exudates, where *P. aeruginosa* is found in the presence of neutrophils under high-dry ($\times$400 to $\times$800) or oil-immersion ($\times$ 1000) magnification. Genotypic analysis includes PCR and DNA hybridization. Serotyping and pulse-field gel electrophoresis can be carried out to obtain type-specific information and molecular patterns. Sequence analysis provides further accuracy in species identification as well as antibiotic resistance determination.

TTX poisoning can be assessed in food matrices by mouse bioassay. Production of the toxin and its derivatives can be determined by high-performance liquid chromatography (HPLC), matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometric detection, and ELISA. Quantification of the toxin in the serum, whole blood, or urine may confirm diagnosis of poisoning. Currently, most analytical methods recruit separation by gas chromatography (GC) or HPLC followed by mass spectrometry (GC–MS or LC–MS). Other proposed methods comprise immunoaffinity chromatography, HPLC with postcolumn derivatization and fluorescence detection (HPLC-FLD), and HPLC with ultraviolet (HPLC-UV) detection. Recently, an optical technique making use of surface plasmon resonance immunosensors to detect TTX has been reported to be capable of rapid screening with low reagent consumption. Also, biosensors offer themselves as promising biotools for detection of marine toxins. A novel method called liquid chromatography–electrospray ionization–mass spectrometry (LC-ESI-MS) coupled with a column switching technique is claimed to be helpful in sensitive determination of TTX.

Usual diagnosis methods to detect Crohn's disease encompass barium enema or upper GI series, colonoscopy or sigmoidoscopy, CT scan of the abdomen, endoscopy, MRI, and enteroscopy. Associated microbial infections may be identified by stool and blood culture, serology, WBC count, ileal or colonic mucosal biopsy (pinch biopsy), and 16S PCR.

Control/Preventive Measures

The widespread nature of *Pseudomonas*-associated diseases makes it literally difficult to eradicate many infections caused by the bacteria. Many efforts could further be undermined by the fact that transmission of endemic strains and genetic variants is likely to reoccur. However, appropriate control measures can provide some success in minimizing the number of potential incidences relating to *Pseudomonas* infections.

Possible spread of glanders and melioidosis can be controlled by early detection and elimination of affected animals. Immediate disinfection and quarantine of vulnerable areas may offer great benefits. Airborne and contact precautions must be taken to avoid potential inoculation. CF patients are advised to avoid traveling to high-risk areas. Only melioidosis patients suffering from severe suppurative pneumonia with productive sputum should be isolated. On the contrary, isolation of all infected persons is recommended for glanders. Laboratory personnel should perform handling of specimens and isolation procedure in a biosafety level-3 facility. Respiratory protection is also recommended for manipulating the organisms outside of a biosafety containment capacity. Standard laboratory guidelines must be followed to ensure further safety. Certain antibiotics, including carbapenems, doxycycline, streptomycin, gentamicin, ceftazidime, cefepime, and combinations of sulfazine or sulfamonomethoxine with trimethoprim have been found to be quite effective in the prevention of experimental glanders in endemic areas. Potential vaccine candidates are being investigated. Education in mainly endemic regions to minimize exposure to wet season soils and surface water is also expected to be of significance. Public health surveillance and action procedures may have great impact. Concerns of potential bioterrorism (deliberate release event) using *B. mallei* or *B. pseudomallei* have driven further international alert in recent times.

Infections with *P. aeruginosa* are far more difficult to control as the bacterium is ubiquitous. However, individuals at high risk, particularly immunocompromised patients must be more precautious about any possible incidence caused by this pathogen. This organism can be found on the surface of many raw fruits and vegetables. Hence, patients particularly with neutropenia should not consume these foods because of the risk of subsequent GI colonization and bacteremia. As *P. aeruginosa* is often found in raw milk as a spoilage organism, appropriate heat sterilization of the milk should be applied before consumption considering the potential for pathogenicity of this bacterium. Healthy lifestyle can help prevent many associated diseases. Much of colonization of animals with the bacterium can be prevented by raising them in strict bioexclusion housing. Regular monitoring of water quality is necessary for detection of potential prevalence. Sterilized or chlorinated water must be used for immunodeficient animals, especially those that are neutropenic. Routine application of disinfectants, such as chlorine and chloramine, where appropriate, prevents possible spread of the bacteria from the environment, and may interfere with the biofilm formation. Installation of silver–copper ionization equipment and the use of UV and ozone can help control much of the biofilm growth in various ground and drinking watering systems. Rederivation of animals by embryo transfer or hysterectomy into *P. aeruginosa*-free dams helps achieve healthy (sterilized) progeny. Health professionals should be highly cautious about washing hands with disinfectants before dealing with patients. They should also ensure adequate sterilization of all vulnerable medical devices, and regular monitoring of this action. Aseptic procedures must be followed during surgery and other insertion practices

(e.g., catheterization). Burn patients should be strictly isolated. Potential vaccines to immunize individuals as well as CF patients are under development. Control of extensive or inappropriate prescription and treatment with antibiotics may discourage emergence of new antimicrobial resistance.

Perhaps, harboring of specific bacterial pathogens in marine animals cannot be disturbed, but legislative restrictions on trade and consumption of puffer fish and other TTX-containing gastropods could be enforced. Adequate removal of toxic organs, such as gonad and liver by qualified cooks may provide some protection against possible poisoning. Currently, there is no known antidote available for TTX.

Appropriate therapies support great improvement of the prognosis of Crohn's disease. Cessation of cigarette smoking may reduce the risk of occurrence of the disease and its serious complications. Direct association of *P. fluorescens* and other phylogenetically close bacteria with this disease still needs confirmation for the development of effective measures to control colonization of the microflora in the colon or other parts of the GI system.

Research Needs

Latest advancement in technologies provides global researchers with enormous support in studying comprehensive molecular profiles of infectious bacteria and the etiopathophysiology of various diseases. Th'erefore, it is important to conduct further research into *Pseudomonas* virulence and its spectrum of pathogenesis. Detailed investigations need to be carried out to establish a true relationship between the expression of *P. fluorescens* proteins and the occurrence of Crohn's disease. Another area of great interest would be the underlying functions potentially harbored by this bacterium to predispose the innate immune system to genetic polymorphisms. Understanding the molecular mechanism recruited by this bacterium in the modulation of intestinal epithelial-barrier architecture may provide further insight into the disease. Also, development of an effective compound to inhibit biofilm formation on indwelling medical devices and in wounds remains a challenge.

Salmonella Non-Typhi

S Ethelberg and K Mølbak, Statens Serum Institut, Copenhagen, Denmark
MH Josefsen, Technical University of Denmark, Søborg, Denmark

Glossary

All-in/all-out A production system whereby animals are moved into and out of facilities in distinct groups. By preventing the commingling of groups, spread of disease is limited. Production facilities should be cleaned and disinfected thoroughly between groups of animals.
Flagella A tail- or hair-like projection that protrudes from the cell body of certain bacteria and functions in locomotion.
Organoleptic The sensory properties of a particular food: the taste, color, odor, and feel.
Outbreak The occurrence, in a community, of an illness with a frequency that is clearly in excess of normal expectancy. For foodborne illness, it is usually defined as the occurrence of two or more cases of a similar foodborne illness resulting from the ingestion of the same food.
Phage A bacteriophage is a virus that infects bacteria. Phage typing is a typing method that is based on the reaction of bacterial isolates toward experimental infection with a series of specific bacteriophages.
Preharvest Measures to improve food safety applied before slaughter or harvest, that is, usually at the farm level.
Postharvest Measures to improve food safety applied at or after slaughter or harvest, that is, during the processing and preparation of the food.
Type III secretion system Type III is a protein appendage found in several Gram-negative bacteria. It consists of a needle-like structure used by the bacteria as a probe to detect the presence of eukaryotic organisms and secrete proteins that help the bacteria infect them. The proteins are secreted directly from the bacterial cell into the eukaryotic cell, also known as 'the host' cell.

Background

Bacteria of the genus *Salmonella* are widespread and important causes of foodborne infections. Serotypes Typhi (*S.* Typhi), *S.* Paratyphi, and *S.* Sendai are highly adapted to humans. The nontyphoid *Salmonella* serotypes are widely distributed in nature, including the gastrointestinal tract of mammals, reptiles, birds, and insects. Most clinical infections of humans are transmitted from healthy carrier animals to humans through food. Nontyphoid *Salmonella* was among the earliest of the so-called emerging pathogens with an important impact on the public health and economy in industrialized countries.

Historical Aspects and Current Perspectives

In 1885, the bacteriologist Theobald Smith, who worked in the US Department of Agriculture, isolated *S.* Choleraesuis from porcine intestine, and the genus *Salmonella* was named after Salmon, his laboratory chief. The first report of a laboratory confirmed outbreak of foodborne salmonellosis was described by Gärtner: 58 persons in 25 different families who had eaten beef developed acute gastroenteritis, one died. Gärtner isolated the 'Gärtner-bacillus' from the infected cow from which the meat came, and from organs of the fatal case. In the following years, several outbreaks of salmonellosis affecting man or animals were reported, and the old concept of 'meat poisoning' was linked with the etiological agent *Salmonella*.

Although *S.* Typhi became an enormous problem in the US in the early industrial era, the disease burden associated with nontyphoid *Salmonella* was low before World War II. Improvements in sanitation nearly eliminated *S.* Typhi as a cause of indigenous infections in the US. However, decades later, the incidence of nontyphoid salmonella infections started to increase, as seen from Figure 1. A similar picture was seen in many other developed countries. In the 1980s and 1990s, two *Salmonella* serotypes in particular, *S.* Enteritidis and *S.* Typhimurium, became major causes of foodborne illness in Western countries as well as in countries that currently are adopting industrialized food production. By contrast, in most developing countries a more diverse range of *Salmonella* serotypes are found in humans.

In many countries, food safety programs have recently resulted in declines in the number of reported salmonella infections. However, salmonella continues to be the most frequent cause of bacterial foodborne disease outbreaks. In addition, new vehicles are recognized as causes of infections in man and the problems are aggravated by an increase in the number of salmonella infections caused by multidrug-resistant strains. Finally, outbreak investigations, trace back investigations, and efforts to improve food safety are becoming increasingly challenging due to the globalization of the food supply; a trend that will continue in the coming years.

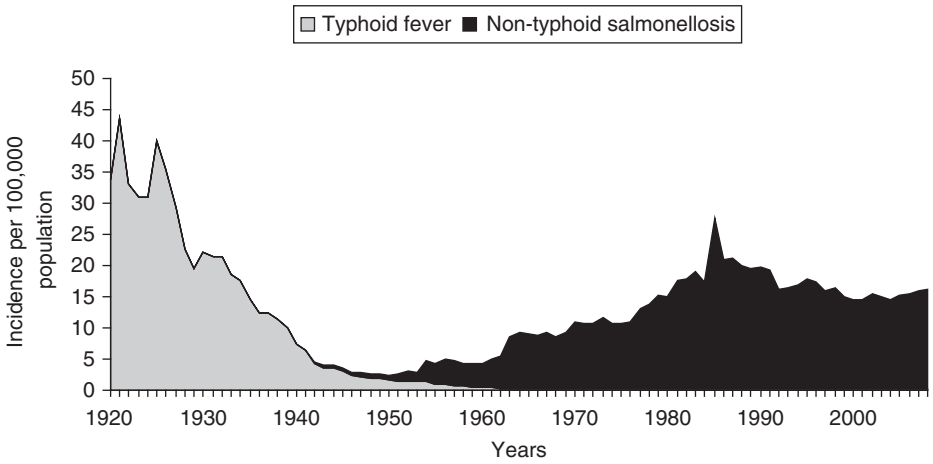

Figure 1 The number of registered infections per 100 000 population caused by *S.* Typhi (gray shading) and nontyphoid salmonella (dark shading) in the US from 1920 to 2008. Data from the CDC kindly provided by Rob Tauxe.

Characteristics

Nomenclature/Taxonomy and Classification

The zoonotic salmonella differs from most other pathogens by the existence of a very large number of different named salmonella types of which *S.* Enteritidis and *S.* Typhimurium are the two most frequently occurring. The classification into these types is based on serological reactions by different surface proteins. An extensive serotyping scheme was developed by Fritz Kauffmann and David White in the 1930s and 40s and is currently maintained by the World Health Organization (WHO) collaborating center for salmonella serotyping at the Institute Pasteur. According to this so-called White–Kauffmann–Le Minor scheme, serotypes are distinguished and named according to reactions to sera against two different groups of antigens: the cell surface lipopolysaccharide (LPS) proteins (for historical reasons called 'O' antigens) and flagellar proteins ('H' antigens). The 'H' antigen (the flagella) derives from German '*hauch*' (breath), first used to describe the swarming of highly motile organisms. 'O' derives from German '*ohne*' (without), first applied to nonswarming (i.e., nonflagellated) bacteria, but now used as a generic term for the LPS somatic antigens of enteric bacteria including *Salmonella*. The Vi antigen was thought to be responsible for virulence. Salmonella strains will typically express either of two sets of genes encoding the flagellar antigens, and two distinct H-antigen 'phases' are therefore said to exist and both need to be expressed in order for the serotyping to be performed. For a small number of serotypes, biochemical reactions or reactions against capsule proteins (Vi antigens) are also included. According to the established notation, the antigenic formula is written with numbers and letters, with antigenic groups separated by colons. Thus, for instance, *S.* Typhimurium has the formula 1,4,5,12:i:1,2 because it carries an LPS protein reacting against the *1,4,5*, and *12* antisera and the *i* phase I H antigen and the *1,2*, phase II H antigen. Today, more than 2570 different serotypes are recognized. Although serotype names were originally inspired by symptoms or by the names of their discoverers, serotypes are now typically named after the geographic location in which they were first characterized (for instance, *S.* Heidelberg, *S.* London, and *S.* Napoli).

According to current bacteriological taxonomy, *Salmonella* constitutes a genus within the Enterobactericeae family. The genus has two species, *Salmonella enterica* and *Salmonella bongori*. More than 99% of serotypes belong to *S. enterica* which is further subdivided into six subspecies: *enterica*, *salamae*, *arizonae*, *diarizonae*, *houtenae*, and *indica*. The salmonella serotypes associated with disease in humans are typically found within *S. enterica* subsp. *enterica*, which contain most of the known serotypes. Formally, the taxonomically correct name of, for instance, the salmonella type that is commonly referred to as *S.* Typhimurium would thus be: *S. enterica* subsp. *enterica* serovar Typhimurium. In general, *S. enterica* subsp. *enterica* are associated with warm-blooded animals, whereas the five remaining subspecies of *S. enterica* are predominantly found in cold-blooded animals (in particular reptiles) and the environment.

Morphology, Metabolism, and Growth

Salmonella enterica is a Gram-negative rod-shaped enterobacterium. The size of the rods ranges from 0.7–1.5 μm to 2.2–5.0 μm; *Salmonella* produces colonies of approximately 2–4 mm in diameter. They have peritrichous flagella, although they are sometimes nonmotile. They are facultative anaerobic chemoorganotrophs. They are oxidase negative and catalase positive. They are generally: able to reduce nitrate to nitrite, able to grow on citrate as sole carbon source, capable of producing acid and gas from glucose, able to produce hydrogen sulfide on triple sugar iron and decarboxylate lysine and ornithine, and able to hydrolyze indole and urea.

Salmonellae are adapted to life in the animal gut and their optimal growth temperature is 37 °C. Some serotypes may be found in a number of different hosts whereas others have adapted to specific hosts. Serotypes may be said to be 'host adapted' if they are prevalent in one particular host, and also able to colonize and perhaps cause disease in other hosts. An example of this would be *S.* Dublin which infects cattle, but rarely humans; however, when doing so causes systemic

infections at a very high rate (resulting in case fatality rates of 20–30%). *S*. Kentucky, common in poultry but less common in humans, is another example of a host-adapted serotype. Some serotypes are host specific, i.e., are able to grow in one host only. A special example hereof is *S*. Typhi and *S*. Paratyphi that are found in humans only, where they cause enteric fever (and are thus not zoonotic salmonella types). In general, the mechanisms underlying host adaptability are poorly understood.

Salmonella may survive for long periods outside of the body and may persist for long periods in, for instance, food production environments. *Salmonella* has rarely given rise to outbreaks via drinking water, but may survive and multiply in foods, and storage of foods at room temperature for prolonged periods before consumption has been found to be a risk factor for outbreaks to occur on multiple occasions. *Salmonella* will not normally grow at refrigerator temperatures; the temperature range of growth is 7–45 °C. *Salmonella* normally survives freezing. Optimum pH for growth is 6.5–7.5, but salmonellae can proliferate in the range of pH 4.5–9.5. Growth of *Salmonella* has not been reported in foods with an a_w of less than 0.93. Nonetheless, bacteria may survive very well in dry foods.

Genetic Factors of Virulence

Salmonella generally infects via the fecal–oral route, survives passage through the stomach acid, and causes lesions in the lower end of the small and upper end of the large intestine. These lesions and the following disease manifestations follow colonization of host cells associated with the gut epithelium. Nontyphoid salmonella strains generally cause self-limiting, transient enterocolitis with watery diarrhea. On rare occasions, they may also cause system infections. In contrast, other strains primarily cause systemic infection and bacteremia, including several of the host-adapted strains, such as *S*. Typhi in humans. Much knowledge has been gained about bacterial virulence factors and pathogenicity through *in vitro* and cell culture studies and through studies of *S*. Typhimurium in mice. The latter model resembles that of systemic infections more than that of general diarrhea, whereas a cattle intestinal loop model has been used for the study of the diarrheal pathogenesis. It is fair to say, however, that the mechanisms behind the induction of enterocolitis are still poorly understood.

Salmonella Typhimurium is a well-adapted pathogen which contains a large number of different virulence genes, many of which are organized in chromosomal pathogenicity islands. Salmonella can enter cells via several routes. Through phagocytosis they are taken up by macrophages where they persist in a special vacuole, called the salmonella-containing vacuole. Factors that are part of a type III secretion system encoded by the salmonella pathogenicity island 2 are required for this. Another mechanism which is probably of more relevance for the induction of diarrheal disease is bacterial-mediated endocytosis. Through fimbriae and other surface molecules, the bacteria attach to epithelial cells. Here they induce endocytosis by use of a separate type III secretion system. This is encoded by the so-called salmonella pathogenicity island 1 and consists of a needle-complex that introduces effector proteins into the cell membrane and cytosol of the host cell. This, in turn, induces cytoskeleton rearrangements and membrane ruffling and eventually uptake of the bacterium. Following invasion, the bacterium induces diarrhea through interplay of a number of virulence factors. Disruption of the normal epithelial control of the passage of ions and immune cells in addition to the generation of localized inflammatory responses following complex signaling with different types of host cells have been suggested to be important elements in this process.

Clinical Manifestations

Exposure of humans to nontyphoid salmonella from contaminated foods or from environmental sources occurs frequently and may lead to clinical or subclinical infection. The serotype, number of organisms ingested, vehicle of infection, microbial environment of the gut, and several other host-associated factors are important in determining the outcome of exposure.

Incubation Time

Within 6–48 h after ingestion of contaminated food, diarrhea occurs. Most patients develop symptoms 24–48 h after exposure, but with ingestion of a high dose the incubation period may be as short as a few hours. In other situations, patients may initially be subclinically colonized, and symptoms develop more than a week after exposure.

Symptoms

Nontyphoid salmonella infection often presents as an acute gastrointestinal illness, indistinguishable from that due to many other gastrointestinal pathogens. In addition to diarrhea, other common symptoms include abdominal pain or cramps, fever, chills, nausea, vomiting, pain in the joints, headache, myalgia, general malaise, and weight loss. Diarrhea varies in volume and frequency, and may be blood-containing. Between 3 and 7% of immunocompetent persons infected with *S*. Typhimurium or Enteritidis have positive blood cultures. The risk of blood stream infection is higher for less common serotypes like Dublin, Choleraesuis, Oranienburg, and Virchow. The proportion of blood isolates is higher in patients of extreme ages, and particularly in the elderly.

Immunosuppression and chronic underlying illness, including inflammatory bowel disease, organ transplantation, malignancy, and malnutrition, are risk factors for severe gastroenteritis, as well as blood stream infection. Subsets of patients develop a primary septicemia without prominent gastrointestinal symptoms.

Duration

In uncomplicated cases, fever usually resolves within 48–72 h, and the average time to recovery from gastroenteritis is 1–2

weeks. However, many patients (up to 25%) report changes in bowel habits up to 6 months after the acute phase.

Carrier Duration

The mean duration of carriage of nontyphoid salmonella is 4–5 weeks after resolution of the gastroenteritis. This duration varies with age of the patient and the serotype. For some less common serotypes, such as *S.* Panama, *S.* Muenchen, and *S.* Newport, more than 20% are still positive after 20 weeks, whereas 90% of *S.* Typhimurium patients are negative at 9 weeks postinfection. A higher proportion of infants than adults have prolonged shedding, but the delayed clearance in neonates and infants does not result in permanent carriage. Treatment with antimicrobials may lead to longer excretion. A chronic carrier state is defined as the persistence of salmonella in stool or urine for periods greater than a year. It is estimated that between 0.2% and 0.6% of patients with nontyphoid salmonella infections develop chronic carriage, which is less than for *S.* Typhi.

Dose

Salmonella infections are acquired by the fecal–oral route, although the swallowing of contaminated aerosols may cause infections in rare situations. Data on the number of salmonella organisms required to cause disease come from volunteer studies and investigation of outbreaks in which the numbers of bacteria in the food vehicles have been determined. Volunteer studies are not generalizable because of the limited number of subjects included, because the physical and chemical properties of the vehicle may not represent relevant food vehicles, and because laboratory passage strains may be less virulent than those found in food animals. Furthermore, higher doses of salmonella may be required to cause disease in healthy volunteers than in populations of high risk. There is evidence of a correlation between dose and disease severity for several common serotypes, including *S.* Typhimurium, *S.* Enteritidis, *S.* Infantis, *S.* Newport, and *S.* Thompson.

Under certain circumstances, very small inoculae have been sufficient to cause the disease. In an outbreak of *S.* Typhimurium infection caused by contaminated chocolate, less than or equal to 10 *S.* Typhimurium bacteria per 100 g of chocolate was found. The authors concluded that the infectious dose was fewer than 10 organisms. In an outbreak caused by paprika and paprika-powdered potato chips contaminated by a variety of serotypes (*S.* Saintpaul, *S.* Rubislaw, and *S.* Javiana), the infective dose was estimated at 4–45 organisms, with an attack rate of only 1 in 10 000 exposed persons. Another example was a massive outbreak of *S.* Enteritidis linked to commercially distributed ice cream made from a liquid premix that had been transported in tanker trucks used previously to haul liquid raw eggs. The highest level of product contamination documented in this outbreak was only six organisms per half-cup (65 g) serving of ice cream. In these three outbreaks, the estimated concentration of *Salmonella* is likely to have been similar to that of the product at the time of consumption. These studies confirm that low-level contamination of food by salmonella, and thus extremely small infectious doses, can cause disease in humans. Ingested salmonella must pass the acid barrier of the stomach, which is a first line of defense against enteric infections. Most strains of *S. enterica* survive poorly at normal gastric pH (less than 1.5), but survive well at pH more than or equal to 4.0, and may have an adaptive acid-tolerance response that may promote survival at low pH. If the salmonellae are suspended in a lipid vehicle, the kill from the acid barrier is reduced, and consequently the infectious dose is reduced. Examples of such vehicles include ice cream, several other types of desserts, some sauces, chocolate, cheese, and peanut butter.

Therapy with antimicrobial drugs has been shown to be a risk factor for salmonella infections. Recent administration of antimicrobials may provide a relative advantage for the Gram-negative flora, a so-called competitive effect. In addition, if the salmonella is resistant to the drug, it has a selective advantage compared with other bacteria in the gut. Chronic illness, including immunosuppressive disease, malignant disease, and diabetes may also decrease the number of bacteria needed to cause infection. A lower dose of bacteria may cause illness in neonates, infants, and seniors than children and young adults.

Sequelae, Chronic Effects, and Complications

Nontyphoidal salmonella gastroenteritis is often described as a mild disease without any complications; without spread to the bloodstream, most infections are self-limiting. However, carefully conducted epidemiological studies suggest that complications are experienced by a significant proportion of patients. Persistence of bowel symptoms is common and is responsible for considerable morbidity and health-care costs. More severe complications are less common. Among 3328 Danish patients, extraintestinal disease was present in 4% and complications in 7%, including 27 unnecessary appendectomies. Complications include endocarditis or arterial infections, intestinal perforation and abdominal, soft tissue, and urogenital infections. Between 2% and 15% of episodes of *Salmonella* gastroenteritis are followed by reactive arthritis, Reiter's syndrome, or erythema nodosa (all correlated with HLA-B27 antigen). Arthritis occurs at an average of 10 days after the onset of diarrhea. Acute phase mortality (case-fatality) has been estimated to be 1.3% in the US, 1.4% in Spain, and 1.2% in Denmark. Case-fatality is higher after septicemia than gastroenteritis only, and is higher in the very old than in individuals below 60 years of age. In addition, infants may have a higher case-fatality. In a registry-based study, 1-year mortality risk was 3.1%, 2.9 times higher than a matched sample of the Danish population, suggesting that the mortality after salmonella infections may be underestimated.

Epidemiology

Surveillance Systems, Sources of Knowledge

Based on symptoms, salmonella infections cannot be distinguished from gastroenteritis caused by several other infectious agents (e.g., *Campylobacter* spp.) and surveillance, therefore, has to rely on laboratory confirmed infections.

Many countries have surveillance systems by which information on diagnosed patients is reported to the national surveillance center from all or a subset of primary diagnostic laboratories. Many countries also have systems by which strains are referred to central or reference laboratories for confirmation and serotyping, and in some cases also additional phenotypic or molecular typing. A number of countries also examine veterinary or food specimens for salmonella in a structured manner, and a substantial added value may be achieved when data from the human surveillance systems are analyzed together with such data from the food chain.

International data on salmonellosis are collected and collated by a number of different institutions or networks, of which some prominent examples are given below. In Europe, the European Centre for Disease Prevention and Control (ECDC) has collected national surveillance data from the EU member states beginning from 2007. The predecessor for salmonella, the EU-supported network 'Enternet,' collected data from European and other countries from 1994 to 2006. In the US, Centers for Disease Control and Prevention (CDC) collects surveillance data from the individual states. In addition, surveillance data are actively collected from a large number of state diagnostic laboratories through the national surveillance network FoodNet. Another important surveillance network is PulseNet US, a typing network coordinated by the CDC in which a subset of salmonella patient isolates from the entire country is subjected to molecular typing using the PFGE or, more recently, the MLVA method, and compared centrally. The aim of this network is to find outbreaks in a timely manner and the network has been extended beyond the US to other countries and regions. By comparing and linking 'fingerprints' of *Salmonella*, subtyping networks are able to discover general outbreaks even when they include single or only few cases in each geographic location. National and international outbreaks have been frequently detected by this approach. International surveillance networks also exist, one example being the Global Foodborne Infections Network (formerly known as the Global-Salm-Surv), a WHO-supported network that collects surveillance data globally and works to improve laboratory detection and typing methods in a number of countries.

The above mentioned systems have improved surveillance of salmonella infections and a paralleled development has been seen in several countries at both national and local levels in recent years. Public health departments are increasingly cooperating and using data from surveillance systems and also alerted by food control authorities, clinicians, and the public professionals. Sharing of information has the potential to detect foodborne outbreaks that would have gone unnoticed in the past and to identify the food source and remove it from the market as soon as possible and, thereby, prevent outbreaks from becoming larger than if no action were taken.

Trends

Table 1 shows the 10 most frequent serotypes in recent years in selected countries. In all countries, either *S*. Enteritidis or *S*. Typhimurium or both are the most prevalent. In the US, the same five serotypes have been found at the top of the list for several years, whereas in many European countries, the serotypes following *S*. Enteritidis and *S*. Typhimurium will vary from year to year. Typically, however, 10 or 20 different serotypes will account for 9 out of 10 infections each year with the remaining 10% of the infections being due to a large number of rarely seen serotypes. Also notable from the table are the relative differences in the number of registered infections, this point is covered in the next section below.

In most of the industrialized world, the number of infections with nontyphoid *Salmonella* types clearly went up in the 1980s and 1990s. From being a relatively unknown organism in the general population, owing to the fairly low level of infections in the 1960s and 1970s, the rising number of infections and the frequently publicized outbreaks helped salmonella to gain notoriety, and consumers began to be aware of the risks of handling food (particularly poultry and eggs) in their homes. During the recent decade, the number of infections has been stable or has followed a downward trend in some countries. Several reasons may be identified behind the overall emergence of *Salmonella* infections, however, most are associated with modern-society, industrialized food production. A number of factors characteristic for the changes in food production systems that have taken place in the past 3–4 decades have facilitated the transmission of salmonella (Table 2). Large-scale production of animals and crops and breeding pyramids of specially bred, genetically similar food animals are vulnerable to salmonella infections. Intensified farming may make animals more prone to infections and trade with live animals can, if they become infected, efficiently distribute the infections from one country to another. New types of foods, for instance the increased use of ready-to-eat foods, and new production systems may sometimes also be liable to contamination. Also, it may take some time before producers or consumers become aware that certain foods are risk products.

In most industrialized countries, *S*. Enteritidis and *S*. Typhimurium are the two most frequently occurring serotypes. In Europe, they together constitute more than 80% of all serotypes. *S*. Enteritidis is the most frequent serotype generally responsible for approximately two-thirds of the infections in Europe (Figure 2). In the US, *S*. Typhimurium is generally more frequent than *S*. Enteritidis and their collective share is approximately 35–40% of all infections.

Because of the high number of infections with these two serotypes, they need to be categorized into smaller groups, necessitating the use of identification methods that go beyond serotype. Phage typing, a phenotypic typing method based on the reaction of *Salmonella* strains toward experimental infection with a series of specific bacteriophages, is a method that has been used widely, and phage-typing systems have been developed for *S*. Enteritidis, *S*. Typhimurium, and few other common serotypes. The antibiogram of strains, though not *per se* a typing system, has also been used widely to categorize serotypes into finer subgroups. Using such methods, it has been possible to obtain a better understanding of the spread of drug-resistant subtypes, and in some instances trends in the number of infections have been found to be constituted by the rise and fall of specific subtypes. Such subtypes, sometimes termed 'success-clones,' have had the genetic make-up that allowed them to establish themselves in important food-production animal reservoirs from where they have, for various reasons, spread from one to several countries.

Table 2 Examples of factors that have had a major contribution for the emergence of nontyphoid salmonellosis in industrialized countries in the past 3–4 decades

Level of food chain	*Factor*	*Effect*
Consumer level	Less familiarity with preparation of new risk foods	Increased incidence of salmonellosis, in particular following emergence of new risk foods
	Increasing number of elderly or immunosuppressed consumers	
Retailers and restaurants	Occasional break down in safety barriers, cross-contamination in large kitchens, use of exotic fruits and vegetables	Outbreaks, sometimes large
Food production/ processing	Large-scale production of minimally processed and ready-to-eat products	Amplification of contamination, widespread dissemination of contaminated products
	Globalized trade	
Animal production systems	Trading of live infected animals for food production or pets (e.g., reptiles)	Spread of infection (and new 'success-clones') from one country or continent to another
	Increased use of genetically similar animals in breeding pyramids	Infection of large number of animals if infection occurs at top of pyramid
	Large-scale production systems	
	Long-distance transport of animals	Transport-induced stress enhances shedding and spread of salmonella
Feed and antimicrobial drugs for food animals	Compound feed, international trade with feed	Changes in intestinal ecology, dissemination of serotypes
	Antimicrobial growth promoters and antimicrobial treatment	Changes in intestinal ecology, selection of resistant bacteria that are passed on to humans

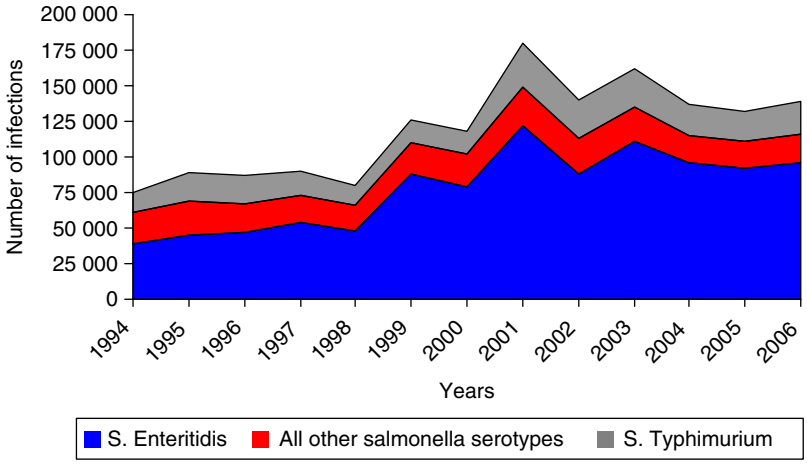

Figure 2 Number of human infections with *S.* Enteritidis, *S.* Typhimurium and remaining serotypes 1994–2006 as registered in the Enternet network database from all European countries supplying data to the network (n = 1 555 464).

One example is the *S.* Typhimurium phage type DT104 which in its original form carried a genetic cassette conferring resistance to five different antimicrobials ('penta-resistance'): ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. This was among the genetic factors that not only helped made it 'successful,' but has also served as a means of identifying the strain where phage typing has not been used. *S.* Typhimurium DT104 was largely nonexistent before 1980, but then appeared in the UK where it gradually spread in the 1980s from cattle to other food production animals and from thereon in the 1990s, spread to continental Europe and North America and other parts of the world. DT104 is common in a broad range of food animals, such as poultry, pigs, and sheep, and in many countries is, or has been, the most common subtype of *S.* Typhimurium isolated from humans. In later years, however, this type has been declining again in several countries.

During primarily the 1980s and 1990s, *S.* Enteritidis successfully infected chickens used for egg production and have since given rise to millions of human infections, transmitted via the consumption of eggs. A number of necessary or contributory factors have been found to lie behind this very severe food safety problem. Genetically, *S.* Enteritidis has the unique capacity of being able to infect the ovaries of chickens without causing symptoms. Thereby the bacterium may enter the egg internally and thus both spread to the offspring and transmit to consumers. It has been argued that *S.* Enteritidis has filled an ecological niche that became vacant following the control of the host-specific serotypes *S.* Gallinarum and *S.* Pullorum, both of which gave symptomatic infections. In the kitchens, before this problem arose, eggs were safe to eat raw and a number of common dishes and desserts contained raw eggs. Consumers were, therefore, caught unguarded and needed to adapt to the new situation. Salmonella may multiply within the egg or in the prepared dish before consumption, thus sometimes growing to high numbers, and increasing the potential for causing disease. Also at the level of production systems, major changes have been introduced. Small-scale egg production has been substituted for large often battery chicken production systems. These rely on genetically clonal animals that are all offspring of the same few ancestor birds, which have been bred for high performance and are supplied by commercial companies. When, as it happened, infected chickens are delivered into the top of such breeding pyramids, a very large number of birds will quickly become infected. This way the infection was able to spread very efficiently.

Many phage types of *S.* Enteritidis have been recognized as forming part of the problem, some being more prominent in certain geographical regions. *S.* Enteritidis phage type 4 was particularly predominant in Europe and North America where it spread in the 1980s and 1990s. Figure 3 shows the situation in the UK, where this type was particularly important and caused what was in reality a 20-year long outbreak. The decline that started in the late 1990s was concomitant with the introduction of vaccination of egg-laying hens against serovar Enteritidis. Other factors such as improved biosecurity in egg-laying flocks, a build-up of immunity in other animals, and the rise in the number of livestock infections with host-adapted serovars of *Salmonella* have also played a part in this decline.

The Surveillance Pyramid and Differences Between Countries

National and international salmonella surveillance data will never truly reflect reality and, therefore, should be interpreted with great care. This relates to the fact that salmonellosis is a transient and comparably mild disease and so will always be under-diagnosed. However, only diagnosed cases show up in the statistics. Salmonellosis is normally a self-limiting disease and most patients will choose not to see a doctor. For those who do, the doctor may often choose not to request a stool sample examination, and even when examination is performed, only a subset of the true patients will be correctly diagnosed and reported to the national registration systems. Salmonella surveillance systems will therefore only capture a fraction of the true cases and will tend to capture the more severe manifestations. Population studies performed in the Netherlands, the UK, and US indicate that the true number of symptomatic cases in the community is from 3.8 to 38 times as high as the surveillance data would indicate, and other studies have shown even higher conversion factors.

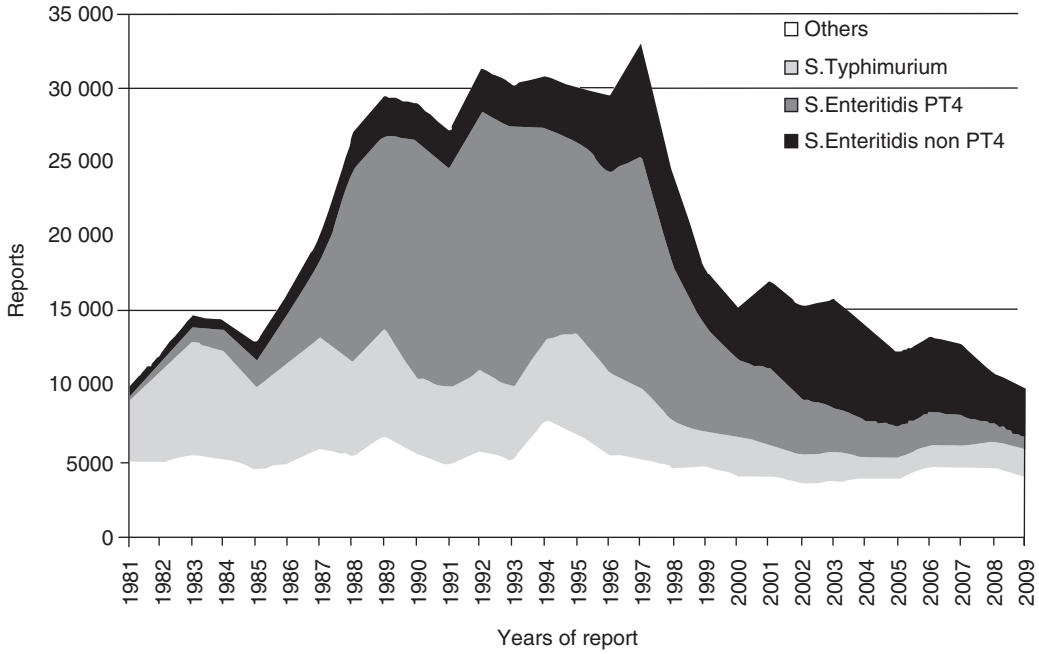

Figure 3 Incidence of reported infections by most frequent types of Salmonella, England, and Wales, 1991–2009. Data from the national surveillance systems in England and Wales. Courtesy of Chris Lane, HPA, London.

For the same reasons it is generally also not possible to directly compare rates of salmonellosis between countries. This is evident from Table 1. Local practice, the priority given to foodborne illnesses, and financial factors will influence heavily on how many samples are analyzed for salmonella. Also, laboratory methods may vary and serotyping may not be complete. Furthermore, strains and information may not always be routinely collected centrally, or may be collected from a subset of laboratories only. Therefore, a low number of cases in a given country or region may sometimes be little more than a reflection of a suboptimal diagnostic or surveillance system. This is true not only for human cases, but also for surveillance data covering the food chain.

To make comparisons between countries, surveys or special studies have to be performed. An example from the veterinary perspective is the so-called baseline studies that have been conducted jointly in the EU member states recently. As part of these, the levels of salmonellosis in pigs, egg layers, and broilers have each been assessed through a uniform scheme of sampling and testing. Recent attempts to compare the level of human infections have involved comparison of burden-of-illness studies, sero-epidemiological studies, and evidence from infected travelers. For instance, studies of returning infected travelers from Sweden, which have a very low level of endemic salmonellosis, have been used to address the degree of underreporting in national statistics and the risk of infection in different countries, which in Europe largely was found to follow a north–south gradient.

Developing Countries

Infectious diarrhea is a massive problem in many developing countries and carries a high mortality, particularly among young children. Although salmonellosis in developing countries is often well characterized and subject to various forms
of control programs, the situation is quite different in the developing world. Owing to poor sanitation, *S*. Typhi and *S*. Paratyphi continues to constitute significant health problems in many countries. However, although not well documented, nontyphoid salmonella infections also appear as a considerable health problem in developing countries in so far as they are frequently the etiological agent in infectious diarrhea. In addition, they will often cause blood stream infections in immunocompromised persons, and may therefore seriously complicate the clinical picture of malaria or HIV-infected individuals. One estimate holds that 10% of HIV-positive adults in Sub-Saharan Africa will develop nontyphoid salmonella bacteremias each year, resulting in considerable mortality. The problem in developing countries is often complicated by high levels of antimicrobial drug resistance in a variety of salmonella serotypes that causes invasive infections in children.

Age, Gender, and Seasonality

Figure 4 shows the incidence year by age and gender of the total number of notified laboratory confirmed nontyphoid salmonella infections in Denmark. The incidence of *Salmonella* is substantially higher in infants and young children, a result of both increased susceptibility and a diagnostic bias, because relatively more samples from children will be examined for salmonella. The incidence rate also increases slightly in young adults in their twenties, but then remains fairly constant. A similar picture is seen in many other industrialized countries, sometimes with a slight additional increase among elderly persons. In the US, the overall yearly reported incidence ranged from 19 to 13 per 100 000 population from

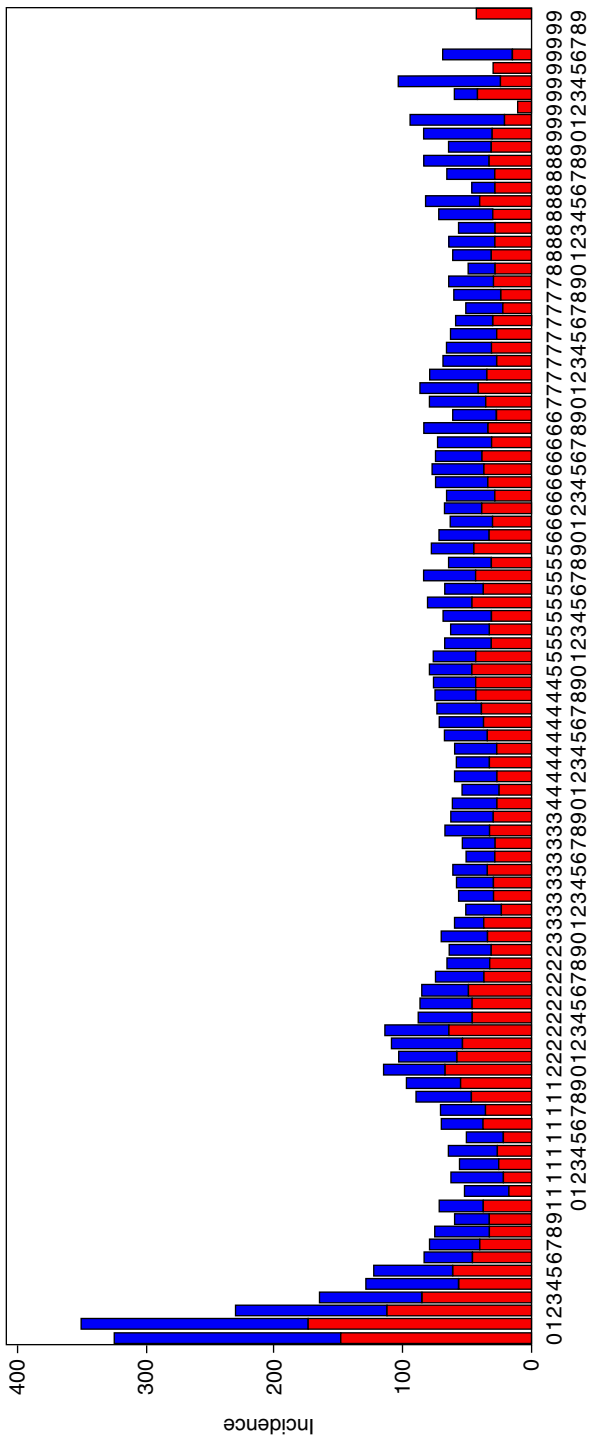

Figure 4 Age- and gender-specific incidence of human laboratory confirmed salmonella episodes in Denmark 2005–2009 (n = 11 063). Cases are shown per 100 000 Danish residents by gender and at each year of age. Reproduced from Statens Serum Institut, Denmark.

1987 to 1997, whereas the incidence in infants was as high as 122 per 100 000. Slight differences between genders are also frequently seen, typically with a higher incidence in boys than in girls, but among adults a higher incidence in women than men. The reason behind this may involve health-seeking behavior, physician's behavior, age- and gender-specific exposures, transmission patterns as well as hormonal and immunological factors.

In temperate climates, salmonella infections exhibit a marked seasonal pattern, typically with a several times higher incidence of domestically acquired infections in the warmer months compared with the colder. Depending on their reservoirs, some serotypes may however deviate from this pattern.

Geographic Distribution of Certain Serotypes

A few serotypes are geographically restricted. A good example is *S.* Weltewreden, which is widespread throughout South Asia and South East Asia, but rarely occurs in Europe except as imported infections. Other examples are *S.* Eastbourne in West Africa or *S.* Concord in Ethiopia. Some serotypes are typical for geographical location they take their name from; *S.* Napoli is frequently found in Italy and *S.* Mississippi in limited areas of the Eastern and South Eastern USA. *S.* Javiana is common in young children in Eastern US. Infections with such serotypes may be caused by direct or indirect contact with a particular animal reservoir or be associated with a local and limited production of food items. Knowledge about geographical restriction may, similar to knowledge about predominance of certain serotypes in certain animal reservoirs, be very helpful when trying to find sources of human infections.

Isolation, Identification, and Enumeration

Conventional Detection of *Salmonella enterica*

Culture-based detection and isolation procedures for salmonella principally consist of four steps: nonselective preenrichment, selective enrichment, isolation, and confirmation. However, minor differences in the use of media, incubation time, and temperature can be found in various standard methods.

Food, animal feed, and environmental samples usually contain low numbers of potentially stressed salmonella bacteria and therefore preenrichment in nonselective media is needed to aid the recovery of sublethally injured salmonella. Even though salmonellae are viable and able to cause disease under the right conditions, the organisms can easily be killed if they are grown under selective pressure, such as high temperature or in the presence of chemical additives. Buffered peptone water and lactose broth are two of the most widely used media for preenrichment.

The second step is enrichment in selective media. This increases the number of salmonella to a level where detection on selective agar plates is possible, whereas at the same time inhibiting growth of accompanying microflora by selective agents in the media. The most commonly used media for selective enrichment are Rappaport-Vassiliades soy broth, selenite cysteine broth, and tetrathionate broth. Modified semisolid Rappaport-Vassiliades is another selective media particularly useful for detecting salmonella in feces and environmental samples.

Isolated colonies are obtained by streaking out the selective enrichment broths on the surface of selective solid media. Growth of accompanying bacteria is repressed by the addition of inhibitory compounds and salmonellae are differentiated from other bacteria by, for instance, the production of H_2S or acid from sugars. Most standard methods recommend employing two media exerting different selective pressures. Commonly employed media include brilliant green, xylose lysine Tergitol-4, bismuth sulfite, Hektoen enteric, and xylose lysine deoxycholate agars. Recently, novel chromogenic agars have been compared favorably with these common agars, being more sensitive and specific.

Finally, presumptive *Salmonella* colonies are subcultured on nonselective plates in order to get well-isolated colonies that can be used for further characterization by biochemical and serological analysis. Several biochemical reactions are tested, i.e., triple sugar iron, mannitol, urea, ornithin decarboxylase, and lysine decarboxylase. A serological verification by determining the antigenic composition is performed. The O and H antigens are determined by agglutination testing using polyvalent antisera. Miniaturized tests such as API 20 E (bioMérieux) and BBL™ Enterotube™ II (BD Diagnostics) have been developed for confirmation and they present an efficient and labor-saving alternative. Identification of isolated colonies by polymerase chain reaction (PCR) is a reliable, cost-efficient, and labor-saving option, becoming widely applied in microbiological laboratories. Several well-validated PCR assays are described for this purpose, some of them providing additional discrimination between strains or information on antibiotic resistance depending on the target gene(s) of choice.

Human gastroenteritis caused by salmonella is diagnosed by culturing of fecal samples. Normally, isolation is accomplished by direct plating on selective agar plates from fecal samples containing high numbers of target bacteria. An enrichment step in selenite broth has been reported to increase the sensitivity of the direct culture, but this has to be weighed against an additional time for diagnosis of 24 h. Confirmation of presumptive salmonella is performed as described earlier.

Conventional methods for detection of *Salmonella* are time consuming and labor intensive. Furthermore, these methods may suffer from poor specificity due to, for instance, difficulties in recovering sublethally injured cells, problems in the identification of atypical colonies, a high degree of false-positive results, and lack of detection of viable but nonculturable bacteria. However, among the advantages of conventional culture methods are that they are universally accepted, have a history of good reliable performance, and produce an isolate that can be characterized further.

Detection of *Salmonella enterica* by Alternative Methods

Polymerase Chain Reaction

PCR offers many advantages compared to conventional culture-based detection methods regarding sensitivity, specificity,

speed, and possibility of automatization. Numerous PCR assays for the detection of salmonella in a variety of sample matrixes have been described in the literature. The majority of them deal with detection in food, reflecting the epidemiology of this human pathogen. The PCR-based detection methods in food commonly employ a preenrichment step combined with subsequent PCR detection. The preenrichment times reported vary from 6 to 24 h, depending on the artificial inoculation level of *Salmonella* in the experimental design of the studies. The studies taking into consideration the limit of detection of 1 colony-forming unit (CFU) per 25 g in food samples report a minimum of preenrichment of 8 – 10 h. The majority of these PCR assays amplify part of the *invA* gene, encoding a protein involved in the invasion of epithelial cells, however, it has been shown that *invA* is lacking in some strains.

The methodology, i.e., enrichment media, time and temperature, sample preparation, PCR primers, probes, and thermal profile, varies according to the food matrix in question, and with the abundance of methods and lack of standardization it can seem overwhelming to identify a suitable method. A description of some of the more recent validated methods for detection in relevant food matrices and a review of molecular methods for detection and discrimination of foodborne salmonella may be found in the literature list at the end of the article.

The major advantage of PCR-based detection of a foodborne pathogen like *Salmonella* is the reduction in time of analysis. A negative sample is usually diagnosed within 24 h with PCR, compared to 3–4 days using culture-based detection. Furthermore, a higher degree of automation of PCR-based detection is achievable, making high-throughput analysis possible.

Multiplex PCR assays simultaneously detecting a range of relevant pathogenic bacteria are likewise described in the literature. Such methods would constitute highly effective screening tools for determining the microbiological safety of certain food commodities; however, implementation of the majority of these assays is hampered by a lack of validation.

PCR detection methods have been described for human clinical samples as well. A number of them are designed to target specific serotypes and have little use as diagnostic screening tools, but more broad methods for *S. enterica* have compared favorably with conventional culture-based methods in several studies.

Other Methods

Methods combining immunomagnetic separation (IMS) with detection steps like enzyme immunoassays (EIAs) or PCR assays have been developed. The salmonella cells are separated from their matrix by IMS of magnetic beads coated with salmonella-specific antibodies, and subsequently detected by PCR or EIA. This primary concentration of target cells should theoretically result in an improved limit of detection, however, the findings are not convincing.

Loop-mediated isothermal amplification (LAMP) methods for detection of *Salmonella* in food matrices and clinical samples are being increasingly developed, and are reported to be more sensitive than equivalent PCR methods. Because there are no instrument needs with this type of assay, the application possibilities are far greater, and LAMP has the potential to be applied as a simple screening assay in the field or at the point of care by clinicians.

DNA microarrays for detection and characterization of pathogens such as salmonella are being developed more frequently. The microarray oligonucleotides are designed to recognize a variety of *Salmonella* genes involved in virulence, antibiotic resistance, or serovar-specificity, and information on presence and expression can be obtained. DNA microarrays targeting and partly characterizing multiple pathogens including salmonella have been described in the literature as a diagnostic tool for rapid and simultaneous identification of pathogens involved in clinical diarrhea.

Enumeration

Assessment of the illness a pathogen can cause in a given population is a key factor in food safety. Because the severity of salmonellosis is associated with the degree of contamination (dose–response relationship), these risk assessments are based on information on the number of salmonella.

Culture-based enumeration of salmonella relies either on the most-probable-number (MPN) technique if low numbers are expected, or on direct isolation on selective solid media if high numbers (more than 100 CFU g^{-1} or ml) are believed to be present. Although the MPN technique is quite laborious, results obtained from direct isolation can be influenced by the amount of background flora and the physical state of the salmonella cells.

PCR-based enumeration of salmonella would, on several levels, be a welcome alternative to culture-based enumeration. However, the sensitivity of PCR still makes detection, without prior enrichment or an improved sample preparation step to concentrate target cells, impossible in the case of low-level contamination.

Food Sources of Infection and Preventive measures

Routes of Transmission of *Salmonella enterica* to Humans

Nontyphoid salmonella infections are generally acquired via food, though in the developing world contaminated drinking water can also be a route of infection. Person-to-person transmission is normally rare because of the relatively high infectious dose of the organism, but infections may be transmitted through direct animal contact. Transmission from reptiles held as pets is well documented, particularly in the US. However, foodborne infections are by far the most common, and salmonellosis has traditionally first and foremost been transmitted as zoonotic infection via consumption of products from infected animals, in particular eggs, poultry meat, pork, and beef. Increasingly however, other types of foods are also seen as sources of infection, including fresh produce.

Principles of Control

Animal food production systems can be viewed as a chain of successive steps, each of which holds the potential for introduction of salmonella infection or contamination. Efficient control of salmonella is, therefore, only reached when all steps in this chain are monitored and targeted by quality programs.

Animal feed may be infected and, therefore, needs to be controlled. Animals may become infected at the farm via contact with wild animals, insects, the environment, farmers or veterinarians, or the introduction of infected animals in the flocks or herds. At slaughter, meat from noninfected animals may become cross-contaminated via infected animals that introduce salmonella into the slaughterhouse environment. Contaminated meat products may give rise to a large number of infections if processed in a way that allow for growth of salmonella or if processed into ready-to-eat products without sufficient reduction of counts or inhibition of growth. At retail, breach of the cold-chain or improper handling of products may pose a hazard.

Finally, contaminated products in kitchens in the homes or in commercial establishments may give rise to illness if not handled properly, as for instance through lack of separation of raw meat and salad ingredients, improper storage, or through improper cooking procedures. On this basis, education of consumers and food handlers in respecting safe food-preparation measures forms a part of the overall attempts to control salmonella. Important elements include cooking poultry, meat, and eggs thoroughly, keeping food at safe temperature, separating raw and cooked food, using safe water and safe raw materials, and careful personal and kitchen hygiene.

Countries to varying degree have legislation and food control and inspection systems that cover the later steps in the food chain, ensuring that hygienic standards are in place and that quality assurance systems, hazard analysis and critical control points (HACCP) programs, and own-check programs are followed. However, at farms and slaughterhouses, *Salmonella* is more difficult to control and much research has been focused on controlling or limiting the introduction of *Salmonella* at these points in the chain. As a general principle, it is better to control the problem early in the food chain, thus arguing for prioritizing preharvest rather than postharvest control programs. Obviously, sampling and testing at different steps in the chain are also important in order to monitor the effect of the control programs. An integrated process, where data are shared and steps agreed among different stakeholders in the food chain is very much advisable, though this may be challenging to establish because of the required cooperation between different types of sectors, both commercial (farmers, slaughterhouses, and retailers) and public (different ministries and levels of administration). There are historic examples of successful salmonella control. In Sweden, a large *S.* Typhimurium outbreak occurred in 1953, killing 90 people. This led to a national action plan against salmonella, decades before this infection reached the agenda of other countries. As a result, Sweden has been officially free of *S.* Enteritidis and *S.* Typhimurium for more than 20 years. Sweden and Finland were able to maintain their 'salmonella-free' status when they entered the EU. To what extent experiences from the Nordic countries can be adapted by other countries with different and larger production systems remains a debatable issue.

Major Transmission Reservoirs and Their Control

Eggs: As also discussed above, eggs are a very important source of human salmonella infections. *Salmonella* may reside both on the inside – *S.* Enteritidis only – and outside of the egg, the latter being the more frequent. Even when contamination is a rare event it may lead to a disproportionately high number of human infections, because eggs are so frequently consumed and because raw eggs – as opposed to raw meats – are an ingredient in many dishes (mayonnaises, cold sauces, cakes, and ice creams, to name a few) and may cause infection even when partially heat treated (eggs fried on one side only or lightly scrambled eggs).

Infections occur frequently.: An EU baseline study of large laying hen holdings was conducted in 2005 and found 30% of flocks to be infected. The percentage of positive flocks in different countries varied widely, going from 0 to 80%. Infection may be introduced into the chicken houses by a number of means, and both biosecurity and cleaning in conjunction with an all-in/all-out strategy is of major importance. By far, the most important way of introducing infections, however, is introduction of infected animals. Because of the breeding pyramid production system, a small number of infected grandparent-hens will result in a large number of infected layers two generations down the line. However, targeting control measures at the top of the breeding pyramid may potentially have a major effect as have been shown in Scandinavia. In Denmark, both layers and broilers were heavily infected in the 1990s which prompted the introduction of a national top-down eradication strategy based on testing and elimination of infected birds at the top of the breeding pyramid. Today, layers and broilers are in essence salmonella free.

Postharvest strategies have also proven efficient, most notably heat decontamination of the shell and pasteurization of either the egg white, yolk, or whole eggs. The latter is done through a process of placing the eggs in water baths for several hours, which may reduce the salmonella counts within the egg by up to 7-log without changing the organoleptic properties of the egg.

Poultry: Studies from a number of countries in Europe and from North America document that broiler flocks frequently test positive for *Salmonella*, and figures ranging from 0 to 60% of flocks being infected have been reported depending on the geographic area. Commercial flocks of turkeys, geese, and ducks typically have an even higher infection rate than do broilers. Broilers may be infected with several serotypes in addition to *S.* Enteritidis and may be a source of human infection with serotypes such as *S.* Infantis, *S.* Hadar, *S.* Virchow, and *S.* Typhimurium.

The measures applying to preharvest control of salmonella in layers also applies to broilers, and controlling the infection at the top of the breeding pyramid is generally advisable. Vaccination using a live attenuated vaccine is used in some countries both for broilers and layers with good results. Vaccination does not eliminate *Salmonella* in flocks, but will increase the animals' resistance to infection and colonization and thereby serve to markedly reduce the levels of *Salmonella* in the flocks. Vaccination has been shown to have highest effectiveness if it is accompanied by hygienic measures as well. Postharvest control is important for broilers, and care should be taken to control each of the steps in the slaughter process. Several systems aiming to reduce or eliminate salmonella in the slaughtered birds or the chicken meat have been developed.

Pork: Pork meat and pork products are also an important source of human infections. An EU member state baseline study of salmonella in slaughter pigs conducted in 2007 found that 1 in 10 slaughter pigs were positive, with country prevalences ranging from 0 to 29%. The most frequently isolated serotypes were *S*. Typhimurium and *S*. Derby. An EU risk evaluation has subsequently estimated that pigs are the source of 10–20% of all human cases in the EU.

Denmark is among the few countries that have an integrated food-chain control program with focus on preharvest reduction. All herds and pigs are registered and meat juice is sampled and tested by serology at slaughter. Thereby, herds are divided into three levels of infection. Farmers with severely contaminated herds receive guidance helping them to reduce the problem, and are at the same time paid less per slaughtered pig. Also, pigs from such herds are slaughtered in a particular hygienic manner and the use of the meat is restricted.

Beef: Cattle is also a source of human infections, though probably less often. Cattle may be infected with several serotypes, but the host-adopted serotype *S*. Dublin is frequently found in cattle. This serotype does not normally cause infections in humans; although this may happen, in particular, in immunosuppressed individuals, and will then lead to bacteremia at a high rate. Both pre and postharvest measures are important for reduction of *Salmonella* infections. Movement and purchase of animals is an important route of introduction of infections and therefore also important points of control.

Unpasteurized milk is a well-documented source of human infections. Outbreaks have been described where inadequately pasteurized milk or postpasteurization contaminated milk or cheeses were found to be the source. Postprocess contamination may also occur in a range of other products, including infant food and other dry processed food products.

Other sources of infection: Fruits and vegetables have become an increasingly important source of salmonella infections. In the US, fruits and vegetables have given rise to more outbreaks than meat products in recent years. Fruits and vegetables may be contaminated in the field (by animals or by contaminated irrigation water), at harvest, processing, packing, and distribution. It appears that water used for rinsing or spraying may often be a point of contamination. Rinsing conditions should be set up so that they prevent cross-contamination and the water used should be clean. Examples of fruits and vegetables that have given rise to outbreaks recently include melons, tomatoes, lettuce of several different sorts, and sprouts. In 2008, a nationwide outbreak of *S*. Saintpaul in the US was traced back to jalapeño and serrano peppers produced in Mexico. Washing the products in the kitchens may not always eliminate the problem; thus alfalfa sprouts, which have been the source of a number of outbreaks, may be infected internally because contaminated seeds may 'incorporate' the bacteria when sprouting.

Decontamination of food by ionizing radiation has been suggested as an effective postharvest measure to improve the safety of food products. In the current European legislation, irradiation can be applied to spices and herbs. Radiation treatment at doses of 2–7 kGy – depending on condition of irradiation and the food – can effectively eliminate potentially pathogenic nonsporeforming bacteria including salmonella. If measures at the farm fail, radiation decontamination can also be applied to poultry and red meat, egg products, and fishery products. It is a unique feature of radiation decontamination that it can also be performed when the food is in a frozen state. Radiation can also be applied to seeds such as sprout seeds with only little effect on germination. However, for various reasons, radiation has currently only limited use as a postharvest measure.

Many other nonanimal foods may be the source of salmonella infections. For example, almonds have produced large outbreaks, spices may be contaminated, and several outbreaks have been caused by chocolates, which serve as efficient vehicles of infection in part because, as discussed above, the fat content of the chocolate protects the bacteria when passing through the acidic environment of the stomach. It is often difficult to attribute cases to these less usual sources of infections and also difficult to solve outbreaks caused by such sources. Owing to improved control of traditional animal sources of infection and increased global trade with exotic food products, it is expected that foods of nonanimal origin and 'unusual' vehicles will become relatively more important sources of salmonella infections in the future.

Salmonella Typhi and *Salmonella* Paratyphi

SP Luby, Stanford University, Stanford, CA, USA

Glossary

Carrier Person infected with a pathogen who is not ill, but who is capable of transmitting the pathogen to others.
Molecular clock analysis Technique that compares the rates of random mutation among conserved housekeeping genes between related strains of microbes to estimate the time they last shared a common ancestor.
Peyer's patch Lymphoid follicles in the distal small intestine important for gastrointestinal immune surveillance and response.
Pseudogene Nucleic acid sequences that were functional in ancestral organisms, but have become modified and no longer function.
***Salmonella* pathogenicity islands** Nucleic acid sequences in *Salmonella enterica* that code for functions critical to invasion, infection, and survival in the host.
***Salmonella* serovar** A subgrouping of *Salmonella enterica* distinguished by serological testing of surface and flagellar antigens.
Type III secretion system A bacterial process that detects host eukaryotic cells and injects bioactive proteins into them.
Typhoid Vi A polysaccharide coat that surrounds most *Salmonella* Typhi and contributes to virulence.

Background

In 1881, Karl Joseph Eberth, a pathologist at the University of Zurich, used a microscope to examine sections of spleen and mesenteric lymph nodes of a patient who died of typhoid fever and published the first description of the morphological characteristics of the responsible bacteria. The bacterium was initially referred to as Eberth's *Bacillus*. The primary causative agent of typhoid fever is now referred to as *Salmonella enterica* serotype Typhi. It is more commonly referred to as *Salmonella* Typhi, but if this shorthand is used Typhi should not be italicized, because it is not a species designation. Typhi denotes a serovar of the species *S. enterica*. *Salmonella enterica* is a remarkably diverse species. Three additional serovars of *S. enterica* that also cause typhoid fever are Paratyphi A, B, and C. *Salmonella* Typhi and Paratyphi A, B, and C are collectively referred to as the typhoidal *Salmonellas*.

Characteristics

Salmonella enterica are rod-shaped, facultative anaerobic Gram-negative bacteria. Most *S. enterica* infect birds and domestic animals and zoonoses are an important pathway for human infection, but *Salmonella* Typhi and Paratyphi A have a much more restricted host range. Although it is often stated that *Salmonella* Typhi only infect humans, it can also infect other primates closely related to humans, though it is not known how frequently this occurs in nature, nor whether such infections contribute to the propagation and survival of the organism. *Salmonella* Paratyphi B and C infect other animals.

Salmonella Paratyphi A, B, and C are quite different organisms. Although *Salmonella* Paratyphi A is in a different serogroup than *Salmonella* Typhi, because of a minor difference in lipopolysaccharide sugars, they are genetically very closely related. The restricted host range of *Salmonella* Typhi apparently results from the inactivation of over 200 pseudogenes (5% of its genome). Over half of the pseudogenes are inactivated by a single frame shift or stop codon. *Salmonella* Paratyphi A also has numerous inactivated pseudogenes comprising 4% of its genome. The *Salmonella* Paratyphi A pseudogenes are less diverse than those in *Salmonella* Typhi suggesting that *Salmonella* Paratyphi A is a younger clone. *Salmonella* Paratyphi B is a remarkably diverse serovar; only some of these strains cause enteric fever. Other strains of *Salmonella* Paratyphi B, previously identified as *S. enterica* serotype Java now referred to as biotype Java, commonly infect poultry and do not typically cause typhoid fever. The *Salmonella* Paratyphi C genome is more closely related to other *S. enterica* serovars than it is to *Salmonella* Typhi.

Human infection with most *S. enterica* produces an exudative intestinal inflammation that causes diarrhea, which increases the shedding of the pathogen and so it's opportunity for ongoing transmission and survival. By contrast, in human typhoidal *Salmonella* infection, diarrhea is uncommon, occurring in only 30% of cases severe enough to be hospitalized and in $< 10\%$ of outpatients with milder illness. The typhoidal *Salmonellas* are invasive, cause systematic infection, and 1–4% of all *Salmonella* Typhi and Paratyphi A infections result in

long-term colonization of the hepatobiliary tract, especially the gallbladder. Typhoid/paratyphoid carriers can excrete the organism for decades, which provides opportunities for ongoing transmission of these host-restricted pathogens. Indeed, the evolutionary survival benefit of invasion and systematic infection for *Salmonella* Typhi and Paratyphi A likely results from the increased opportunity for hepatobiliary colonization and chronic carriage.

Like other *S. enterica*, when the typhoidal *Salmonellas* are inoculated at favorable temperatures into a nutrient-rich environment, such as cut fruit or dairy products, they reproduce exponentially.

Clinical Manifestations

Human challenge studies suggest that 10 000 *Salmonella* Typhi bacteria induce infection among 40% of human volunteers, though there is likely a wide range of infectious doses depending on the level of immunity of the person exposed, and characteristics of the food matrix where the bacteria is embedded that might protect it from stomach acids. The incubation period from exposure until onset of symptoms depends on the dose and is most commonly 7–14 days, but can be as short as 3 days and as long as 60 days. Up to 20% of infections have an incubation period >3 weeks. Typhoid fever presents with a range of severity. Among patients managed without hospitalization, high-grade fever is the cardinal symptom and no other single sign or symptom occurs among >25% of cases. Among patients with a more severe illness requiring hospitalization, most have anorexia and headache and 25–40% have vomiting, hepatomegaly, and abdominal pain. Such patients often present with a characteristic apathetic affect.

Untreated typhoid fever typically has a 4-week clinical course that can be shortened considerably with appropriate early antimicrobial therapy. Typhoid fever relapses in 5–10% of patients treated with antimicrobials. Relapse has also been observed in the absence of antimicrobial therapy.

Gastrointestinal bleeding resulting from erosion of the Peyer's patch into an intestinal vessel occurs in 10–20% of cases of typhoid fever, but blood loss is usually minor and not life threatening, detectable only through testing for fecal occult blood. Intestinal perforation, most commonly at the site of an infected Peyer's patch, occurs in 1–3% of cases. Intestinal perforation is a life-threatening complication with a case fatality rate between 10% and 45% that accounts for at least 25% of deaths from acute typhoid fever. Fluid rehydration, emergency surgery, and appropriate parenteral antibiotics can be life saving. Neuropsychiatric syndromes associated with typhoid fever include typhoid encephalopathy, meningitis, encephalomyelitis, Guillain–Barré syndrome, and cranial or peripheral neuritis.

The reported case fatality of typhoid fever varies widely. In the preantibiotic era, reported case fatality ranged from 7.5% to 19% in population-based assessments and was as high as 30–50% among hospitalized cases. More recently, case-fatality varies by location though apparently remains higher among hospitalized cases with more severe disease than among patients with more mild diseases who are treated as outpatients. However, there are very few community-based estimates of case fatality rate, and on review of available literature the estimate of global burden of typhoid assumed an average global case fatality of 1% (Crump *et al.*, 2004).

Infections with strains of *Salmonella* Typhi that are multiply drug resistant tend to cause more severe illness, are more likely to require hospitalization, and are associated with a higher case fatality ratio. Typhoid fever due to infection with *Salmonella* Paratyphi A, B, or C has a clinical presentation similar to *Salmonella* Typhi, though they tend to have a somewhat shorter incubation period and a milder clinical course.

Several studies have demonstrated an increased risk of hepatobiliary cancers among typhoid carriers. An assessment of a Scottish population-based registry compared the rate of cancers among persons who were confirmed typhoid or paratyphoid carriers to the general population of Scotland and to people who were acutely affected during a typhoid outbreak 30 years previously (Caygill *et al.*, 1994). There was no excess risk of cancer mortality among persons who had acute typhoid and who did not become typhoid carriers. By contrast, the chronic carriers (two-thirds of who carried *Salmonella* Paratyphoid serovars) had a risk of carcinoma of the gallbladder that was 167 times higher than the general population and a risk of carcinoma of the pancreas that was 8.1 times higher. The lifetime risk of gallbladder carcinoma among chronic typhoid/paratyphoid carriers was at least 6%. Patients with gallstones are at increased risk of becoming chronic typhoid carriers and are also at increased risk of gallbladder cancer. Thus, one explanation for these findings is that typhoid carriage is simply a marker of gallstone disease that does not contribute additional risk beyond the risk of gallstones. However, more recent case–control studies conducted in India, where typhoid carriage is common, have identified a higher prevalence of typhoid carriage among patients with gallbladder cancer compared with patients who have gallstones but no cancer. Although the precise molecular basis for the increased risk of carcinoma has not been identified, a clear association of gastric cancer with chronic infection of *Helicobacter pylori* confirms that chronic bacterial infection can give rise to gastrointestinal cancers. Taken together these data provide strong evidence that chronic carriage of typhoidal *Salmonellas* increases the risk of hepatobiliary cancer, especially of the gallbladder.

Pathogenesis

When nontyphoidal *Salmonellas* or other pathogens invade the gastrointestinal tract, they cause inflammatory diarrhea where the site of local invasion is characterized by neutrophilic infiltration. By contrast, typhoidal *Salmonella* intestinal invasion produces a less pronounced inflammatory response where mononuclear cells predominate and with few neutrophils. Apparently, typhoidal *Salmonellas* express toxins that downregulate the normal inflammatory host response in the intestinal mucosa. After epithelial penetration, the invading microorganisms move to the intestinal lymphoid follicles and into the reticuloendothelial system.

Macrophages engulf typhoidal *Salmonella*, but the typhoidal *Salmonellas* have an unusual ability to survive and

reproduce within macrophages. This process has been studied extensively in the mouse model of *Salmonella* Typhimurium. *Salmonella* Typhimurium is genetically closely related to *Salmonella* Typhi and Paratyphi A. *Salmonella* Typhimurium causes a typhoid syndrome in mice, but not in humans. *Salmonella* Typhimurium induces the host cell to elaborate an intracellular membrane that surrounds the bacteria and permits them to survive and replicate. This unique structure, the *Salmonella*-containing vacuole, develops an extended tubular network termed *Salmonella*-induced filaments. Within the *Salmonella*-containing vacuole, typhoidal *Salmonellas* have such high-level resistance to antimicrobial peptides, nitric oxide, and oxidative killing that even when lysosomes are fused with the *Salmonella*-containing vacuole, typhoidal *Salmonella* survive. Because they survive and multiply within mononuclear phagocytic cells, typhoidal *Salmonellas* are eventually released into the bloodstream and circulate throughout the body. The most common sites of secondary infection include the liver, spleen, bone marrow, gallbladder, and Peyer's patches of the terminal ileum.

Virulence Factors

The genetic and molecular basis of the virulence of the typhoidal *Salmonellas* is incompletely understood, but is an area of active research especially using the mouse model of *Salmonella* Typhimurium infection. *Salmonella* Typhi has several large insertions in its genome, apparently acquired by horizontal gene transfer, termed *Salmonella* pathogenicity islands that encode genes important for survival within the host. *Salmonella* pathogenicity island 1 includes genes that are important for cellular invasion of nonphagocytic cells. This invasion is mediated by a Type III secretion system that produces toxin-like virulence factors that induce a reorganization of the host cell actin cytoskeleton, prompting endocytosis of the bacteria.

Salmonella pathogenicity island 2 includes genes that are important for survival within macrophages. These genes encode a second Type III secretion system that injects over 20 effector proteins across the phagosomal membrane that subvert host functions to modify the intracellular environment. Over 900 *S. enterica* Typhimurium genes are differentially regulated in responses to the phagosomal environment. These genes encode resistance to antimicrobial peptides, nitric oxide, and oxidative killing and other incompletely characterized functions. Mutant strains of *Salmonella* Typhimurium defective in macrophage replication are not virulent in mice.

Salmonella pathogenicity island 7 is the largest genomic element present in *Salmonella* Typhi but absent in *Salmonella* Typhimurium. It contains the genes for the Vi capsule, and is present in both *Salmonella* Typhi and Paratyphi C. Clinical studies demonstrate that Vi-negative strains are less infectious and less virulent. Recognition of bacterial lipopolysaccharide by the host immune system induces a strong inflammatory response. Mouse studies suggest that the Vi capsule is able to mask *Salmonella* Typhi lipopolysaccharide from the host immune system. The presence of a very similar *Salmonella* pathogenicity island 7 in the distantly related *Salmonella* Typhi, Paratyphi C, Dublin, and *Citrobacter freundii* genome, and its absence from other serovars of *S. enterica* suggests that this gene sequence was a mobile element that was separately inserted into these diverse organisms.

Epidemiology

A formal evaluation of the global burden of typhoid fever for the year 2000 estimated that *Salmonella* Typhi infection resulted in 22 million illnesses and 220 000 deaths and *Salmonella* paratyphoid caused 5.4 million illnesses (Crump *et al.*, 2004). These estimates extrapolated incidence from 22 published studies that collected data between 1954 and 2000, which included population-based estimates of typhoid fever incidence (**Figure 1**). This estimate relies on several assumptions. It assumes that the incidence of typhoid fever is similar in places where it has not been studied compared with the places where studies were conducted. It assumes that blood cultures will identify 50% of persons who are infected with *Salmonella* Typhi. It assumes that 1% of persons who develop a clinical illness from *Salmonella* Typhi will progress to death. It assumes that the combined incidence of *Salmonella* Paratyphi A, B, and C is one-quarter the incidence of *Salmonella* Typhi. It does not account for any contribution of the typhoidal *Salmonellas* on hepatobiliary cancer mortality. There are quite limited data to support each of these assumptions, but unless better data become available, the range of estimates of the burden of typhoid fever will remain broad.

Typhoid fever occurs most commonly within communities where available water is routinely contaminated with human feces and the population density is high. The highest incidence rates of typhoid fever have been reported from urban slums in Asian megacities. Several lines of evidence suggest that the incidence of typhoid is lower in rural areas compared with urban areas. Published studies of the highest incidence of typhoid fever are consistently from urban sites. Hospital case series suggest that typhoidal *Salmonellas* are less common causes of febrile illness in rural African settings compared with urban settings in Asia (Mweu and English, 2008). Among population-based studies in rural Africa that routinely collected blood cultures from febrile children, studies measuring the incidence of *Streptococcus pneumoniae* and *Haemophilus influenza* type B noted a much lower incidence of febrile illness associated with typhoid fever than has been reported from Asian megacities. One study within Kolkata, India, noted that even within a densely populated urban slum, the areas of highest population density were at increased risk of typhoid fever (Sur *et al.*, 2009). It is an open question how much of the apparently lower incidence of typhoid fever in Africa may be due to lower population density and how much may result from differences in bacterial ecology in sub-Saharan Africa compared with South Asia.

Unlike other *S. enterica* serotypes, *Salmonella* Typhi and Paratyphi A do not live in the gastrointestinal tracts of domestic animals, so contamination of human food products by gut contents during domestic animal slaughtering is not a pathway for transmission to humans. Rather, each human infection with *Salmonella* Typhi or *Salmonella* Paratyphi A originated from a strain whose reservoir was almost certainly

Figure 1 Geographic distribution of population-based studies of typhoid fever incidence. ■ High incidence (>100 episodes/100 000 per year). ■ Medium incidence (10–100 episodes/100 000 per year). □ Low incidence (<10 episodes/100 000 per year). □ Region with high development index countries. ○ Site of contributing disease incidence study. Reproduced with permission from Crump JA, Ram PK, Gupta SK, *et al.* (2008) Analysis of data gaps pertaining to *Salmonella enterica* serotype Typhi infections in low and medium human development index countries, 1984–2005. *Epidemiology and Infection* 136(4): 436–448.

another person. Typhoidal *Salmonellas* move from the feces of an infected person to the mouth of an uninfected person. In the urban slums of Asian megacities, where the incidence of typhoid fever is highest, drinking water is routinely contaminated with human feces. When water is available through a piped network, it tends to be distributed in water distribution systems that have numerous breaks which permit cross-contamination with sewage. The water in these systems typically runs intermittently. When the water is not running, the pipes are at negative pressure relative to the surrounding environment, drawing in sewage contamination through these breaks in the pipes. In settings of high typhoid incidence, case–control studies consistently implicate drinking untreated water as a risk factor for typhoid fever.

Case–control studies also consistently implicate food as a source of typhoid fever. In low-income countries, the most likely pathway is that water contaminated with typhoidal *Salmonellas* is used to process food. Many foods provide a sufficiently nutritious environment for exponential growth of typhoidal *Salmonellas*, so that a sufficiently large dose of organisms are ingested to produce human infection. Dairy products are among the most commonly implicated foods. Because neither *Salmonella* Typhi nor *Salmonella* Paratyphi A are resident in the guts of cattle or goats, the contamination of dairy products almost certainly results from mixing contaminated water with dairy products during processing. Other foods implicated in typhoid fever include cut fruits, raw vegetables, and food sold by street vendors. Sewerage is commonly used to irrigate crops near large cities, and many of these crops may be eaten raw. In communities where typhoid fever is common, the water that is used in markets to rinse produce and cut fresh fruit is typically contaminated at least occasionally with strains of typhoidal *Salmonella*.

Nonvaccinated visitors from high-income countries generally have quite limited immunity against typhoidal *Salmonella*. Seventy percent of typhoid fever in the US is associated with foreign travel. Sporadic outbreaks of typhoid fever in high-income countries occur when a person who is either acutely infected with typhoid from recent travel or is a typhoid carrier contaminates food during preparation. An outbreak of 80 cases of typhoid fever in San Antonio, TX, USA, in 1981 occurred among patrons of a Mexican takeout restaurant who consumed barbacoa, a mixture of muscle, lips, ears, tongue, and eyes handpicked from steamed bovine head skulls by employees. One of these employees continually excreted *Salmonella* Typhi until undergoing cholecystectomy. An outbreak of 43 cases of confirmed typhoid fever occurred among guests and staff at a New York hotel in 1993 who consumed fresh orange juice that was prepared by an asymptomatic food worker who was subsequently identified as a typhoid carrier. An outbreak of 24 cases of typhoid stretching over 7 years in Terrassa, Spain, occurred among patrons of a family-run delicatessen where an elderly grandmother who was an unrecognized asymptomatic carrier of *Salmonella* Typhi helped to prepare the cannelloni once a week. Other food vehicles that have been implicated in these outbreaks include milk and other dairy products, potato salad, cooked beef, chicken salad, tossed salad, guacamole, fish, and cake. Shellfish that are exposed to human sewage have also been implicated in typhoid outbreaks.

In settings where typhoid is common, exposure to the organism is widespread, but some people are at increased risk of

illness with typhoidal *Salmonella*. Children, who have a less completely developed adaptive immune response compared with their older siblings and adults, are at increased risk of developing illness on exposure. Taking antibiotics alters gut flora and in animal studies reduces the infectious dose of *Salmonella* 100 000 fold (Bohnhoff and Miller, 1962). Case–control studies of risk factors for *Salmonella* Typhi that have included an assessment of prior antibiotic use have noted an increased risk of typhoid fever among persons who took antimicrobials in 2 weeks before onset of symptoms. As antimicrobials are available without a prescription in most low-income countries, this may be an important factor contributing to human infection and ongoing transmission of the typhoidal *Salmonellas*.

There is consistent evidence of person-to-person transmission especially for *Salmonella* Typhi. Persons with typhoid fever frequently shed the bacteria. Several case–control studies implicate having a family member or close associate with typhoid fever as a risk factor for developing typhoid fever. Case–control studies also suggest that regular handwashing with soap protects against typhoid fever. Handwashing with soap removes organisms from hands and so can interrupt transmission. In a cluster-randomized vaccine trial of Vi typhoid vaccine in Kolkata, 39% of the residents who lived in a cluster where vaccine was offered, did not receive the vaccine (Sur *et al.*, 2009). Nevertheless, these nonvaccinated persons who lived in the neighborhood cluster where 61% of their neighbors had received the vaccine, were 44% less likely to contract typhoid compared with persons living in clusters that did not receive the typhoid vaccine. This demonstrates that *Salmonella* Typhi was transmitted not just through food or water that was contaminated far outside the community, but from more local exposure.

Salmonella Typhi and Paratyphi A are organisms specifically adapted to humans, and so are dependent on humans for their propagation and survival. Molecular clock analysis suggests that *Salmonella* Typhi emerged approximately 50 000 years ago (Kidgell *et al.*, 2002), which is during Paleolithic times when human population densities were low and humans were living as hunter gatherers in relatively small extended family groups. Carriage provides a long-term reservoir for typhoidal *Salmonellas*, widespread geographical dispersion, and ongoing survival despite only occasional opportunities for transmission to new individuals and new communities. Mary Mallon, known as Typhoid Mary, was the most widely recognized typhoid carrier. She worked as a cook for several families in and around New York City in the early twentieth century. Investigators linked her to 47 typhoid cases and 3 deaths over 15 years, and suspected many more. She was forcibly isolated to protect the public health. In endemic areas today it is unclear how much transmission results from the shedding of chronic carriers and how much results from shedding associated with acute infection. However, because carriers can excrete the organisms for years, chronic carriers are certainly contributing to environmental contamination with the typhoidal *Salmonellas*.

When chloramphenicol was first introduced in 1948 all strains of *Salmonella* Typhi were universally sensitive, though drug resistance was identified within 2 years of its introduction. By 1972, chloramphenicol resistance was widespread with outbreaks in both Latin America and Asia. Chloramphenicol resistance was mediated by a plasmid that also carried resistance to sulfonamides, tetracycline, and streptomycin, though initially strains remained sensitive to ampicillin and cotrimoxazole. In the late 1980s and into the 1990s, *Salmonella* Typhi that was multiply drug-resistant to the three first-line antimicrobials – chloramphenicol, ampicillin, and cotrimoxazole – emerged in Asia, Africa, and Latin America. The drug resistance was again encoded on a single plasmid and the outbreaks were characteristically clonal. With the switch to ciprofloxacin and other fluoroquinolones as first-line drugs for the treatment of typhoid fever, the incidence of multiply drug-resistant typhoid has declined. Strains of *Salmonella* Typhi and Paratyphi A with decreased susceptibility to ciprofloxacin are being identified with increasing frequency. The ciprofloxacin resistance results from one of several single point chromosomal mutations of the DNA gyrase enzyme and is independent of the multiply drug-resistant plasmid. As noted above, patients infected with drug-resistant strains of typhoidal *Salmonella* are at increased risk of death. The history of antimicrobial resistance suggests that in the coming years the typhoidal *Salmonellas* will acquire more drug resistance and be associated with worse survival.

The epidemiology of *Salmonella* Paratyphi A, is generally similar to the epidemiology of *Salmonella* Typhi. Some studies suggest that *Salmonella* Paratyphi A infection is more common among persons who are somewhat older. There is also some suggestion that a higher dose of *Salmonella* Paratyphi A is required to cause illness compared with *Salmonella* Typhi. In some settings in South Asia, the incidence of *Salmonella* Paratyphi A is clearly increasing. In previous studies, *Salmonella* Paratyphi A was associated with as few as 5–10% of the number of typhoid fever cases, but in some settings more recently accounts for 50% of the cases. Human infection with *Salmonella* Paratyphi B and C is reported less commonly than infection with either *Salmonella* Typhi or *Salmonella* Paratyphi A.

Analytical Methods

There are many approaches to the diagnosis of typhoid fever, but none are optimal. In communities where typhoid fever is common, local clinicians often make the diagnosis based on clinical signs and symptoms. Unfortunately, this low-cost approach does not reliably differentiate typhoid fever from other common causes of fever including dengue and malaria.

The most definitive approach to diagnose typhoid is direct culture of *Salmonella* Typhi/Paratyphi A, B, or C in bone marrow, blood, or stool. Bone marrow culture is the most sensitive, because the organism is present at 10 times the concentration identified in blood and there may be less antimicrobial penetration into the bone marrow. However, bone marrow culture is uncomfortable and uncommonly performed in settings where typhoid fever is most common. A positive blood culture for *Salmonella* Typhi or Paratyphi A, B, or C provides a definitive diagnosis. In high-incidence settings, *Salmonella* Typhi is generally the most common pathogen identified in blood cultures. However, single blood cultures are only approximately 50% sensitive, a sensitivity that is reduced by the common practice of pretreatment with antimicrobials. The typhoidal *Salmonellas*

can also be cultured from stool during acute illness, but stool culture is <30% sensitive during the first 2 weeks of illness. Because culture-based diagnosis is expensive, does not reliably exclude infection, and provides results only after several days delay, in settings where typhoidal *Salmonella* is common, clinicians treat most patients with suspected typhoid fever without a definitive diagnosis.

The Widal test, an antibody-based test that has been used for over 100 years, is the most commonly used laboratory test to aid in the diagnosis of typhoid fever. The Widal test is inexpensive and available throughout typhoid-endemic areas, but is fairly insensitive, especially early in illness when a clinician is deciding whether or not to treat with antimicrobials. The Widal test is also nonspecific, especially in settings where typhoid and other *Salmonella* infections are common. Different laboratories also use different reagents and different cutoffs, further complicating interpretation of Widal test results.

Several other antibody-based tests have been developed, but none have sufficient sensitivity and specificity especially early in illness to be widely used. Some laboratories have developed polymerase chain reaction (PCR)-based diagnostics for typhoidal *Salmonella* DNA and report somewhat higher sensitivities than with culture. Different groups are currently using different primers and so the approach is not yet standardized. In addition, the cost and infrastructure required to perform PCR using currently available platforms means that it is unaffordable to low-income families at high risk of disease.

Salmonella Typhi is isolated from feces or food similar to any other *S. enterica*. A 25-g sample of feces or food is cultured in a nonselective buffered peptone broth, and then selectively enriched with a broth containing selenite. After incubation, selective enrichment broth is spread on selective agar plates for identification. Representative colonies are selected for biochemical testing and tested for agglutination against flagellar and cell surface antigens.

Control/Prevention Measures

Preventing human fecal contamination of community water supplies would dramatically reduce the burden of typhoid and paratyphoid fever. This is a difficult long-term task, but it is not impossible. Cities around the globe, beginning in the USA during the early twentieth century but more recently in Singapore and other select Asian cities, have sufficiently improved their water and sanitary infrastructure so that typhoid fever no longer presents a substantial public health problem. Upgrades to municipal water supplies so that they no longer provide a regular vehicle for enteropathogen transmission, have consistently required that the population served earn sufficient income to support the construction and ongoing maintenance of the water treatment and distribution infrastructure. This strategy is effective for middle-income countries, but has not been successfully implemented in low-income countries where the burden of typhoid fever is highest.

Improving water quality is particularly difficult when water supply is limited. When there is insufficient supply to provide piped water 24 h a day, then every day there are opportunities for contaminants to seep back into water distribution systems that are inevitably somewhat permeable to the environment. The prospect of achieving 24-h water availability is worsening because of growing demand for water and reduced supply. Currently there are only two cities in all of India that provide water 24 h a day to all of their residents. This situation is likely to worsen because of the exhaustion of fossilized groundwater sources that have been exploited to provide water to cities but require centuries or millennia to recharge; with global warming eliminating mountain ice packs as steady sources of water throughout the summer and population growth increasing water demand, countries are diverting rivers to population centers under their political authority, leaving cities in the original downstream communities increasingly water short. Thus, while efforts for a safer, steadier water supply in those communities at highest risk for typhoid fever should continue, such solutions will not come quickly. As the risk of typhoidal *Salmonella* strains that are resistant to all antibiotics is a growing public health threat, interim measures should be undertaken.

One focused context to reduce transmission risk would be improving the safety of the water that is used in food processing. Markets in settings where typhoid fever is common frequently use water to rinse and process produce. Providing water that is free of human feces to these facilities, or at least to the largest of these facilities, could substantially reduce typhoid transmission. Dairy products are consistently implicated in typhoid fever transmission, so the provision of water that is free of human feces to producers of dairy products could also be an efficient point of intervention. In countries where typhoid fever is common, there are often many small producers of dairy products. It would be more efficient to first improve the water supplying the largest producers. Sewage irrigation of crops, especially those that are consumed raw, is an efficient vehicle of enteropathogen transmission. The economic incentives to use sewage as a source of water and fertilizer and grow crops close to the large city markets are large enough so that simple recommendations and regulations are unlikely to overcome the strong financial incentives. One approach to consider would be for local authorities to restrict crops grown with sewage to those that are less likely to transmit enteropathogens, presumably those crops that are cooked before consumption and/or have a smooth surface.

Whatever attempts at interventions are undertaken, surveillance of human illness from *Salmonella* typhoid/paratyphoid would allow an ongoing assessment of the effectiveness of interventions. Specifically monitoring foodstuffs and water supplies for contamination with *Salmonella* Typhi and Paratyphi A, B, and C would be inefficient because these organisms are only one of many enteric pathogens that are prudent to restrict from the food and water supply.

Three licensed vaccines effectively prevent typhoid fever. Older whole killed vaccines were effective in reducing typhoid fever but had such frequent disabling side effects, including local pain and fever that was severe enough to require missing a day of school or work in 15% of vaccine recipients that they are no longer used. Ty21a is a live vaccine derived from a mutated *Salmonella* Typhi strain with lower pathogenicity. In clinical trials, Ty21a vaccine was approximately 60% effective in preventing typhoid fever, and is used as a vaccine for travelers from wealthy countries who are visiting typhoid-endemic areas. Vaccine trials suggest that Ty21a may provide

partial protection against *Salmonella* Paratyphi B. Because Ty21a vaccine is expensive by the standards of vaccines purchased by low-income countries and because it requires a cold chain and three doses, Ty21a has never been adopted as an ongoing government-sponsored public health intervention in a typhoid-endemic country.

Typhoid Vi vaccine is a genetically recombinant Vi capsular polysaccharide. It was developed by the US National Institutes of Health and is free intellectual property under no patent protection. In individually randomized controlled trials, Vi vaccine is 60% protective to individuals in preventing typhoid fever but, as noted above, when administered throughout communities Vi vaccine was also 44% protective to unvaccinated persons living in communities where 60% of their neighbors were vaccinated. There are several manufacturers of Vi vaccine in typhoid-endemic countries including China, Vietnam, and India. Within these settings the vaccine cost is less than $0.60 per dose. Vi vaccine has been used by local authorities as part of public health prevention programs in Vietnam, in typhoid-endemic areas of China, and in Delhi state in India. Program assessments in Vietnam and China suggest marked reduction in typhoid from these interventions.

Limitations of the Vi vaccine include that it is not effective neither against *Salmonella* Paratyphi A or B nor against *Salmonella* Typhi strains that lack the Vi antigen. Vi-negative *Salmonella* Typhi strains have been occasionally identified among patients with typhoid fever in Pakistan and India, though their global prevalence is unknown. It is theoretically possible that Vi vaccines may create sufficient evolutionary pressure so that *Salmonella* Paratyphi A and B or Vi-negative stains of *Salmonella* Typhi may fill the ecological niche of Vi-positive *Salmonella* Typhi strains, but to date there is little empiric evidence to support this hypothesis. The Vi vaccine is not immunogenic among children under the age of 2 years and, because the immunity is not T cell based, it requires revaccination at 2-year intervals. Despite these limitations, the Vi vaccine has been demonstrably effective in reducing the burden of *Salmonella* Typhi in endemic areas. The World Health Organization has endorsed the use of vaccines against typhoid fever in areas with endemic typhoid. Ongoing surveillance should assess the impact of intervention programs on disease and on any differences in circulating strains.

There are several new vaccines in development that may eventually provide even more effective approaches to prevention. A Vi vaccine that is conjugated to *Pseudomonas aureginosa* exotoxin A is immunogenic in young children and provides prolonged immunogenicity beyond 5 years. This raises the possibility of integrating typhoid vaccination into childhood vaccine programs in endemic areas and reducing or eliminating the need for periodic revaccination.

Another important approach to preventing typhoid transmission is promoting handwashing. Traditional approaches to handwashing promotion emphasized didactic health education instructing people that washing hands prevented diarrhea. More recent approaches frame handwashing promotion as a behavior change task that requires habit adoption. Newer approaches recognize the need for basic handwashing infrastructure and often employ messages encouraging handwashing using approaches that have been effective for private soap manufacturers.

Identifying and treating the 1–4% of people infected with typhoidal *Salmonella* who become chronic carriers reduces the reservoir of infection and the ongoing contamination of the environment. However, there are multiple barriers to implementing carrier identification and treatment in settings where typhoid fever is most common. In these low-income communities, typhoid fever is usually treated without confirmatory testing and so the diagnosis is both uncertain and often missed. Twenty-five percent of typhoid carriers have no clinical history of typhoid fever, and local health authorities have other higher priorities. Moreover, when the sole motivation of identifying these carriers is treating them to prevent disease in others, there is less incentive for the asymptomatic carrier to bear the inconvenience of multiple stool cultures for diagnosis and additional drug treatment. However, because carriers of typhoidal *Salmonella* are at markedly increased risk for hepatobiliary cancers, treating carriers would protect their health as well as the health of the community. Two to four weeks of high-dose antimicrobial therapy can eliminate carriage in patients without gallstones, but in the presence of gallstones surgical cholecystectomy is generally required. In New York State, in the early 20th century before the advent of antimicrobial therapy, the number of typhoid carriers progressively decreased with the spread of water treatment and sanitary infrastructure. In typhoid-endemic settings, identification and treatment of carriers is not the highest priority for typhoid control, but eradication of *Salmonella* Typhi and Paratyphi A, which is theoretically possible because of their restricted host range and the potential effectiveness of newer generation vaccines, would require reducing the reservoir sufficiently to interrupt transmission.

Research Needs

Productive areas for future research include development of a diagnostic test that is sensitive and specific early enough in illness to guide treatment and inexpensive enough to be affordable in regions where typhoid is common. The inevitable progression of antimicrobial resistance will require a robust pipeline of new antimicrobial drugs to avoid returning to the high case fatality rates that characterized typhoid fever in the preantibiotic era. Because definitive improvement in water and sanitation infrastructure in areas where typhoid is common are likely to require several decades to achieve, strategies that can reduce typhoid burden even in the setting of compromised water and sanitary infrastructure should be piloted and evaluated. For example, improving water quality in markets that sell fresh produce may be a focused cost-effective intervention that can reduce the burden of typhoid fever and other serious foodborne pathogens. Further development of typhoid fever vaccines, including those that are effective in infants, those that protect against typhoid carriage, those that provide longer term protection, and those that are effective against *Salmonella* Paratyphoid A and B would be particularly helpful. Detailed epidemiological transmission studies paired with infectious disease modeling may help to identify optimal strategies for eradicating these dangerous human pathogens.

BACTERIA

Shigella

MZ Zaghloul, Ain Shams University, Cairo, Egypt

Glossary

Antibiotic A drug that destroys bacteria.
Antibody A substance produced by the immune system to fight invading organisms such as viruses.
Arthritis A disease that causes inflammation and pain in the joints.
Bloody diarrhea Diarrhea with blood in stool.
Gastroenteritis Inflammation of the stomach and intestine, with vomiting.
Hemolytic anemia Anemia due to decreased life span of erythrocytes. It is caused by excessive destruction (as in chemical poisoning, infection, or sickle-cell anemia) of red blood cells.
Proctitis A chronic inflammatory disease of the rectum which causes bloody diarrhea.
Seizure Convulsions; sudden involuntary movements of the muscles.

Family: Enterobacteriaceae

Genus: *Shigella*

Shigellosis is an acute bacterial infection of the intestinal lining caused by a group of bacteria called *Shigella*. It occurs worldwide, and tends to occur whenever war, natural calamities (e.g., earthquakes and floods), or unhygienic living conditions result in overcrowding and poor sanitation. The reported incidence of *Shigella* infections was 1780, 3.8 per 100 000 population, in 2010. It is more common in summer than in winter, especially among travelers in developing countries, day care centers, nursing homes, refugee workers, and residents of camps. Outbreaks of shigellosis are associated with poor sanitation, contaminated food and water, and overcrowding. Children aged 2–4 years are most likely to get the condition.

Shigella is a genus of gammaproteobacteria in the family Enterobacteriaceae. The genus was named more than 100 years ago after the Japanese microbiologist Kiyoshi Shiga who discovered the causative organism, *Shigella dysenteriae* type 1, of the 1896 large Japanese epidemic of dysentery.

Shigella are Gram-negative, rod-shaped, nonsporeforming, nonlactose fermenting (with the exception of *Shigella sonnei*), nonmotile because of the absence of flagellar H and capsular K antigens, urease-negative, and have translucent white or pale yellow colonies on MacConkey agar. Indole reactions are sometimes positive and sometimes negative, with the exception of *S. sonnei* which is always negative. *Shigella* not only makes adenosine-5′-triphosphate (ATP, an energy molecule) by aerobic respiration in the presence of oxygen but is also capable of switching to fermentation (facultative anaerobe). It can ferment carbohydrates with only acid production (no gas production). *Shigella* are closely related to *Escherichia coli* and *Salmonella* and share common antigens with one another and other enteric bacteria. Humans are the only host of *Shigella*, but they have also been isolated from higher primates such as monkeys and chimpanzees.

Shigella species are classified into four serogroups based on only the O antigen:

- Serogroup A: *S. dysenteriae* (13 serotypes).
- Serogroup B: *Shigella flexneri* serotypes 1 through 5 (12 including 'subtypes') *S. flexneri* (6 and 6A serotypes).
- Serogroup C: *Shigella boydii* (20 serotypes).
- Serogroup D: *S. sonnei* (1 serotype).

Groups A–C are physiologically similar, *S. sonnei* (group D) can be differentiated by biochemical assays. Three *Shigella* groups are the major disease-causing species: *S. flexneri* is the most frequently isolated species worldwide and responsible for 60% of the cases in developing countries; *S. sonnei* causes 77% of the cases in developed countries, whereas it causes only 15% of the cases in developing countries; and *S. dysenteriae* is usually the cause of epidemics of dysentery, particularly among refugee camps, whereas *S. boydii* is responsible for sporadic cases in India.

Causes of Shigellosis

Shigellosis is spread when the bacteria in feces or on soiled fingers is ingested. Poor hand-washing habits and eating contaminated food and drink may cause the condition.

- Food may become contaminated by infected food handlers who do not wash their hands with soap after using the bathroom.
- Vegetables can be contaminated if they are harvested from a field that has sewage in it.
- Shellfish and oysters can be contaminated with sewage or contaminated water.

- Flies can breed in infected feces and contaminate food.
- Drinking or ingesting contaminated water can occur while taking a bath or swimming. Water may become contaminated through a fecal source such as illegally discharged sewage or improperly sited latrines or if persons excreting *Shigella* take a bath, swim, or wash their soiled laundry in it.
- Shigellosis can also be spread through sexual intercourse, especially through anal and oral sex.

Shigellosis is often found in child care centers, nursing homes, refugee camps, and other places where conditions are crowded and sanitation is poor.

The infectivity dose is extremely low. As few as 10 *S. dysenteriae* bacilli can cause the disease, whereas 100–200 bacilli are needed for *S. sonnei* or *S. flexneri* infection. The reasons for this low-dose response are not completely clear; one possible explanation is that virulent shigellae can withstand the low pH of gastric juice.

Associated foods:

- Raw oysters and shellfish harvested from contaminated water.
- Vegetables harvested from fields contaminated with sewage.
- Salads including chicken, fruit, lettuce, macaroni, pasta, potato, shrimp, tuna, turkey, and vegetable.
- Water contaminated with sewage.

Populations that are at high risk for shigellosis include the following:

- Children under 5 years of age and their caregivers in child care centers.
- Persons in custodial institutions.
- People living in crowded conditions with poor sanitary facilities and inadequate clean water supply (e.g., refugee camps and shelters for displaced people).
- International travelers.
- Homosexual men.
- People with human immunodeficiency virus (HIV) infection.

Prevalence of Shigellosis

The global burden of shigellosis has been estimated at 165 million cases per year, of which 163 million are in developing countries. More than one million deaths occur in developing countries yearly due to *Shigella* infection. In developing countries, *S. flexneri* predominates. Epidemics of *S. dysenteriae* type 1 have occurred in Africa and Central America with case fatality rates of 5–15%. By one estimate, *Shigella* infections are responsible for 300 000 illnesses and 600 deaths per year in the USA. By another estimate, each year 450 000 Americans are infected with *Shigella*, causing 6200 hospitalizations and 70 deaths.

In general, *Shigella* is one of the most communicable and severe forms of the bacterial induced diarrheas. No group of individuals is immune to shigellosis, but certain individuals are at increased risk. Small children acquire *Shigella* at the highest rate, and persons infected with HIV experience shigellosis much more commonly than experienced by other individuals.

The following statistics relate to the incidence of shigellosis:

- 3.70 cases of shigellosis per 100 000 population in Canada, 2000.
- 2.5 new cases of shigellosis per 100 000 population were notified in Australia, 2002.
- 496 new cases of shigellosis were notified in Australia, 2002.

Symptoms and Signs

Dysentery is a severe diarrhea containing blood and mucus in the feces. Dysentery results from viral, bacterial, or protozoan infections or parasitic infestations. Amebic dysentery (amebiasis) is caused by an ameba called *Entamoeba histolytica*. Bacillary dysentery is a type of dysentery and a severe form of shigellosis caused by *S. sonnei*, *S. flexneri*, and *S. dysenteriae* characterized by blood in stool, which is the result of invasion of the mucosa by the pathogen. The most common symptoms of shigellosis are watery diarrhea, sudden fever, nausea, vomiting, abdominal pain, flatulence, tenesmus, lassitude, and prostration, 1–7 days (average 3 days) after ingestion of contaminated food or drink. The stool may contain blood, mucus, or pus. The condition may be asymptomatic in some cases or severe, especially in children. In very severe cases of shigellosis a person may have seizures, stiff neck, headache, extreme tiredness, and confusion as central nervous system symptoms, especially with *S. dysenteriae*. Shigellosis can also lead to dehydration and in rare cases other complications like kidney failure can occur. Symptoms usually last for several days, but can also last for weeks. The more severe cases of shigellosis can lead to sequelae such as reactive arthritis in 3% of cases, especially after *S. flexneri* infection.

Postinfection Excretion

Shigella can be passed into the person's stool for approximately 4 weeks even after the obvious symptoms of illness have resolved, although antibiotic treatment can reduce the excretion of *Shigella* bacteria in the stool.

Asymptomatic Carriers

Asymptomatic carriers have been incriminated in the maintenance and spread of the disease in the community. Asymptomatic carriers may shed the organism for months, although chronic carriage (>1 year) is rare. Secondary attack rates in households are high, up to 40%.

Shigella Toxins and Immune Evasion

Several virulence factors have been associated with *Shigella* spp., the most common being the ability to colonize and invade the intestinal cells. This phenomenon is mediated partially by the invasion-associated locus (*ial*), which is carried on a plasmid of 120–140 MDa, and the invasion plasmid

antigen H (*ipaH*) gene, which is present in multiple copies in both the plasmids and chromosomes of these organisms.

Another virulence factor related to *Shigella* spp. is its capacity to produce an enterotoxin called Shiga toxin (Stx) which is produced by *S. dysenteriae*. This protein enterotoxin is released by the microorganism in the intestine. The Stx acts on the vascular endothelium of the blood vessels. It is made up of an A-subunit (toxic) and a B-subunit. The B-subunit of the toxin binds to a component of the cell membrane known as Gb3 (glycolipid globotriaosylceramide) and the complex is engulfed by the target cell. When the protein is inside the cell, the A-subunit interacts with the ribosomes to inactivate them. The A-subunit of the Stx is an *N*-glycosidase that modifies the ribonucleic acid component of the ribosome to inactivate it and so brings protein synthesis to a halt, leading to death of the cell. The vascular endothelium has to continually renew itself, so this killing of cells leads to a breakdown of the lining and hemorrhage. The first response is commonly a bloody diarrhea because Stx is usually taken in with contaminated food or water. *Shigella* species have a large virulence plasmid that carries the genes necessary for invasion and colonization of the epithelial cell layer of the human gut, resulting in dysentery (bloody diarrhea). *Shigella* moves from cell-to-cell by using proteins (IcsA, a *Shigella* protein essential to intracellular movement and spread) that trigger actin polymerization in the host cell in a 'rocket' propulsion fashion. In fact, in order to evade the host's immune system, *Shigella* species avoid being presented by major histocompatibility complex (MHC) class II molecules by escaping from the endosome/phagosome after being engulfed, before it fuses with a lysosome containing enzymes that digest the bacteria and prevent it from causing harm.

Shiga-like toxin 1 and 2 (SLT-1 and 2 or Stx-1 and 2): the Stxs produced by some *E. coli* strains. Stx-1 differs from Stx by only one amino acid. Stx-2 shares 56% sequence homology with Stx-1. Both Stx-1 and 2 are encoded by a bacteriophage inserted into the chromosome. Stx-1 increases inflammatory cytokine production by human macrophages, which in turn leads to a burst of interleukin (IL)-8. This could be relevant in recruiting neutrophils to the lamina propria of the intestine in hemorrhagic colitis and accounts for elevated levels of IL-8 in serum of patients with diarrhea-associated hemolytic uremic syndrome (HUS).

Intestinal Adherence Factor

Intestinal adherence factor favors colonization *in vivo* and in animal models. This is a 97 kDa outer-membrane protein encoded by each gene on chromosomes. This codes for intimin protein, and an anti-intimin response is observed in children with HUS.

Pathology

The rectosigmoid lesions of shigellosis are characterized by proximal extension of erythema, edema, loss of vascular pattern, focal hemorrhage, and purulent exudate. Biopsy specimens from affected areas are edematous, with congestion of the capillary, focal hemorrhage, crypt hyperplasia, goblet cell depletion, mononuclear and polymorphonuclear (PMN) cell infiltration, shedding of epithelial cells and erythrocytes, and microulceration.

Initially the organisms are ingested by membranous (M) cells that are associated with lymphoid microfollicles in the colon. After transcytosis through the M cell, the bacteria are deposited into the subepithelial space where they are phagocytosed by macrophages. The macrophage phagosome is subsequently degraded, and the intracellular shigellae cause release of IL-1 that evokes an influx of PMN leukocytes. Eventually the infected macrophages undergo apoptosis (programmed cell death), and the bacteriae are released onto the basolateral surface of adjacent colonic enterocytes. In addition, PMN transmigration through the epithelium disrupts tight junctions, allowing shigellae to migrate into the subepithelial space. The bacteriae infect enterocytes by induced endocytosis, and the endocytic vacuoles are subsequently degraded. The intercellular shigellae attach to actin in the enterocyte junctional complex and then multiply and spread to contiguous enterocytes by induced actin polymerization. Ultimately, the infected enterocytes die, and the resulting necrosis of the epithelium, in conjunction with the continuing inflammatory response, constitutes the lesions of shigellosis.

Transmigration of infiltrating PMNs through the tight junctions of local epithelial cells and into the intestinal lumen allows the reverse migration of shigellae from the lumen into the subepithelial spaces. These organisms then infect the columnar epithelial cells by inducing endocytic uptake at the basolateral surface. Immediately after infection of enterocytes, intracellular shigellae lyse endocytic vacuoles and attach to the actin cytoskeleton in the area of the junctional complex. As these organisms multiply within the enterocyte cytoplasm, occasional daughter cells induce polar nucleation of filamentous actin, resulting in a 'tail' that propels the shigellae into protrusions impinging on contiguous enterocytes. Plasma membranes enveloping the organisms are again lysed, and the organisms are deposited within the contiguous host cell, resulting in intercellular bacterial spread.

The Host's Immune Response to *S. flexneri*

Innate Immunity

The most important consequence of the host's innate immune response appears to be the cytokine-induced migration of PMN cells. The transcription factor NF-κB (nuclear factor kappa-light-chain-enhancer of activated B cells) is activated in *Shigella*-infected epithelial cells in a lipopolysaccharide-dependent mechanism, leading to the production and secretion of IL-8 by the infected cells. IL-8 is a potent chemoattractant for PMN cells as is the IL-1 released from apoptotic macrophages. *Shigella* is unable to escape from the phagocytic vacuole of PMN cells and is killed inside the phagosome. Recent research has implicated the human neutrophil elastase as a key host defense protein of the neutrophil capable of degrading *Shigella* virulence proteins within 10 min of *Shigella* infecting the neutrophil. PMN cells ultimately play a crucial role in controlling the *Shigella* infection, confining

extracellular bacteria to the mucosa and preventing deeper tissue invasion and systemic spread.

Another host defense mechanism directed against *Shigella* has recently been discovered. The glycoprotein, lactoferrin, present in mucosal secretions, breast milk, and phagocytic cells can impair the ability of *S. flexneri* to invade HeLa cells, exposing IpaB–IpaC complexes to protease degradation by disrupting the bacterial surface.

Cellular Immunity

Studies have shown increased T-cell activation in shigellosis patients and T-cell clones have been isolated, which proliferate in response to *S. flexneri* antigen. The cytokines induced by *Shigella* antigens in vaccine studies are suggestive of T helper (Th)1 and Th2 lymphocyte responses. Additionally, the increased susceptibility of acquired immunodeficiency syndrome patients, deficient in cluster of differentiation (CD)4^+ T-cells, to shigellosis could suggest that cell-mediated immunity can play a protective role in shigellosis.

Humoral Immunity

The humoral immune response is a major component of protective immunity to shigellosis with both systemic and mucosal responses activated against the LPS and some virulence plasmid-encoded proteins including the Ipa proteins. It appears that both the systemic and mucosal arms of the humoral response are activated as serum immunoglobulin (Ig)G, IgM, and secretory IgA (sIgA) have all been implicated in the generation of serotype-specific immunity against *S. flexneri*.

Secretory component of the sIgA binds to the mucosal coating of the epithelial cells of the intestine, forming an antibody shield over the cells. sIgA can also coat the outer membrane of *Shigella*, preventing their attachment to the mucosal surfaces, mediate antibody-dependant cell-mediated cytotoxicity, and interfere with bacterial utilization of growth factors. Also, IgA plays an important role in immunity to reinfection. Despite shigellosis generally being a localized mucosal infection, serum antibodies IgG and IgM are detected in human infections directed against the LPS and virulence plasmid antigens IgG and possibly IgM directed against the LPS have been shown to play a protective role in immunity to *Shigella* in mice studies. Serum antibodies directed against the LPS of *S. flexneri* generate serotype-specific immunity by stimulating complement to kill bacteria or mediate antibody-dependant cellular cytotoxicity in the mucosal area.

Complications from *Shigella* Infections

Complications from shigellosis can include dehydration; seizures, especially in children; bleeding per rectum; and invasion of the blood stream by the bacteria. Young children and the elderly are at the highest risk of death. The following is a list of various specific complications caused by *Shigella*.

- Proctitis and rectal prolapse: Due to inflammation of the lining of the rectum or rectal prolapse.
- Reactive arthritis (Reiter's syndrome): Approximately 3% of persons who are infected with *S. flexneri* may subsequently develop pain in the joints, irritation of the eyes, and urethritis. This condition is called Reiter's syndrome. On an average, symptoms appear 18 days after infection.

  It can last for months or years and can lead to chronic arthritis which is difficult to treat. Reiter's syndrome is a late complication of *S. flexneri* infection, especially in persons with a certain genetic predisposition, namely human leukocyte antigen (HLA)-B27. HLA-B27 is a class I surface antigen in the MHC on chromosome 6 and presents microbial antigens to T-cells.
- Toxic megacolon: In this rare complication, the colon is paralyzed and unable to pass bowel movements or gas. Symptoms of toxic megacolon include abdominal pain and swelling, fever, weakness, and disorientation. If this complication goes untreated and the colon ruptures, the patient's condition can be life threatening.
- HUS: *Shigella* rarely results in HUS, which is more commonly a complication of Stx-producing *E. coli* infections. HUS can lead to kidney failure.

Mortality/Morbidity

Although shigellosis-related mortality is rare in developed countries except among travelers, *S. dysenteriae* infection is associated with substantial morbidity and mortality rates in developing countries.

- The overall mortality rate in developed countries is less than 1%.
- In the Far East and Middle East, the mortality rates for *S. dysenteriae* infections may be as high as 20–25%, mostly among children.

Diagnosis

Clinical

Patients presenting with watery diarrhea and fever should be suspected of having shigellosis. The diarrheal stage of the infection cannot be distinguished clinically from other bacterial, viral, and protozoan infections. Dehydration with fast heart rate, low blood pressure, and abdominal tenderness are important signs. Microscopic examination of stool smears from patients with bacillary dysentery is characterized by sheets of PMN. Sigmoidoscopic examination of a shigellosis patient reveals a diffusely erythematous mucosal surface with small ulcers.

Laboratory Studies

Hematology

The total white blood cells (WBC) count reveals no consistent findings. A shift to the left (increased number of band cells) in the differential WBC count in a patient with diarrhea suggests bacillary dysentery. Leukopenia or leukemoid reactions are occasionally detected.

In HUS, anemia and thrombocytopenia occur.

Stool Culture

Watery, bloody, and mucoid stools are highly indicative of shigellosis, but the differential diagnosis should include

enteroinvasive *E. coli*, *Salmonella enteritidis*, *Yersinia enterocolitica*, *Campylobacter* spp., and *E. histolytica*.

Rectal swab or fecal specimens of the patients suspected of having shigellosis were collected in sterile screw-capped containers and immediately subjected to the following microbiological examination:

- Wet preparation by saline and eosin to exclude *E. histolytica*, *Giardia lamblia*, and other cysts or ova of parasite.
- Basic fuchsin smears to exclude *Campylobacter* spp.
- Methylene blue preparation to detect pus cells.
- Gram-stained film and motility to exclude *Vibrio*.
- Initial streaking of the blood-tinged plugs of mucus in stool specimens on the following as a primary isolation media with aerobic incubation:
  - MacConkey agar, Hektoen enteric agar, and *Salmonella–Shigella* agar: These media contain bile salts to inhibit the growth of other Gram-negative bacteria and pH indicators to differentiate lactose fermenters (coliforms) from nonlactose fermenters such as shigellae.
  - Xylose lysine deoxycholate agar is a selective growth medium used in the isolation of *Salmonella* and *Shigella* species from clinical samples and from food. It has a pH of approximately 7.4, and the indicator is phenol red. *Shigella* colonies are red because it cannot ferment sugar.
  - A liquid enrichment medium (selenite broth) may also be inoculated with the stool specimen, incubated at 37 °C and subcultured onto the selective/differential media after a short growth period. Nonlactose-fermenting colonies are streaked and stabbed into tubed slants of Kligler's iron agar or triple sugar iron agar. In these differential media, *Shigella* species produce an alkaline slant and an acid butt with no bubbles of gas in the agar. Also, nonlactose-fermenting colonies could be identified biochemically by analytical profile index (API) 10S (bioMérieux, Stoke on Trent, UK) and slide agglutination tests with antisera for serogroup and serotype confirm the identification.

Enzyme Immunoassay

An enzyme immunoassay for Stx is used to detect *S. dysenteriae* type 1 in the stool. Also, enzyme-linked immunosorbent assay using antiserum or monoclonal antibody recognizing Ipa proteins can be used to screen stools for enteroinvasive pathogens.

Rapid Techniques

Additional diagnostic tools such as gene probes and polymerase chain reaction (PCR) analysis of stool for specific genes such as *ipaH*, *virF*, or *virA* can detect cases not diagnosed by culture but are usually available in research laboratories. Also, real-time PCR was used to detect *Shigella* deoxyribonucleic acid from rectal swab specimens. Several typing methods such as serotyping, drug resistance pattern, plasmid analysis, ribotyping, and pulsed-field gel electrophoresis have been frequently used for subtyping of *Shigella*.

Food Analysis

Isolation of shigellae from foods remains a challenge. A molecular-based method (PCR) that targets a multicopy virulence gene has been developed and implemented by Food and Drug Administration. Isolation and identification of *Shigella* from foods by culture needs several days (rather than hours, as is the case with stool) depending on the food matrix and storage conditions, for example, temperature. *Shigella* species can be outgrown by the resident bacterial populations found in foods, which may reflect the usual low numbers of the organism present in foods. Another factor that reduces the chance of isolating *Shigella* from foods may be the physiological state of the pathogen at the time of analysis. Environmental conditions could affect its ability to either grow or survive in any food matrix.

Alternative Diagnoses List for Shigellosis

For diagnosis of Shigellosis the following lists of conditions have been mentioned as possible alternative diagnoses to consider during the diagnostic process for shigellosis:

- *Salmonella*
- *Campylobacter*
- Stx-producing *E. coli* (e.g., *E coli* 0157:H7)
- Amebic dysentery
- Inflammatory bowel disease
- Viral gastroenteritis
- Food poisoning
- *Y. enterocolitica*
- Cholera
- *Clostridium difficile* colitis
- Cryptosporidiosis

Treatment of *Shigella* Infections

The most commonly used antibiotics for shigellosis treatment are ampicillin (2 g day^{-1} for 5 days), trimethoprim (8 mg kg^{-1} day^{-1}), and sulfamethoxazole (40 mg kg^{-1} day^{-1}). These antibiotics will eradicate sensitive organisms quickly from the intestine, but resistance to these agents is increasing. Effective antibiotic treatment reduces the average duration of illness from approximately 5–7 days to approximately 3 days and also reduce the period of *Shigella* excretion after symptoms subside. Unfortunately, some *Shigella* bacteriae have become resistant to antibiotics and using antibiotics to treat shigellosis can actually make the germs more resistant in future. Ciprofloxacin (1 g day^{-1} for 3 days) is effective against multiple drug-resistant strains, especially in patients more than 17 years of age, to avoid the risk of cartilage damage. Persons with mild infections will usually recover quickly without antibiotic treatment. The oral rehydration treatment developed by the World Health Organization has proven effective and safe in the treatment of acute diarrhea, provided the patient is not vomiting or in shock from severe dehydration. Antidiarrheal agents such as loperamide (Imodium) or diphenoxylate with atropine (Lomotil) should be avoided. The best way to determine which antibiotic is effective is to obtain a stool culture and antibiotic sensitivity tests. Candidate shigellosis vaccines currently in advanced development include both polysaccharide conjugate and live attenuated

vaccines and mostly focus on the most frequently isolated *S. flexneri* 2a and *S. sonnei*, as well as on *S. dysenteriae* 1, because of the severity of cases. Other candidate *Shigella* vaccines such as formalin-inactivated *S. sonnei* vaccine (SsWC) was developed as an oral, killed, whole-cell vaccine at the Johns Hopkins University in Baltimore, USA and recently tested in a Phase I trial on a small number of volunteers. Similarly, Antex (USA) is developing a *Shigella*-inactivated whole-cell vaccine as well as an oral travelers' diarrhea vaccine (ActivaxTM) containing antigens from *Campylobacter*, *Shigella*, and enterotoxigenic *E. coli* (ETEC) These candidate vaccines will shortly undergo clinical testing. In China, a recombinant, live, oral, bivalent vaccine, produced by the Lanzhou Institute of Vaccines and Biological Products, is available for adults. The vaccine has approximately 60% efficacy for both *S. flexneri* and *S. sonnei*.

Preventing a *Shigella* Infection

A safe water supply important for the control of shigellosis is probably the single most important factor in areas with substandard sanitation facilities. Chlorination is another factor important in decreasing the incidence of all enteric bacterial infections. Of critical importance to the establishment of a safe water supply are the general level of sanitation in the area and establishment of an effective sewage disposal system. Frequent hand washing with soap and water after going to the bathroom and before eating is the key to prevent the spread of *Shigella* from an infected person to other person because individuals can carry *Shigella* without noticing symptoms, and *Shigella* bacteria can remain active for weeks after illness.

Basic food safety precautions and disinfection of drinking water prevents shigellosis from food and water. However, people with shigellosis should not prepare food or drinks for others until they have been shown no longer carrying the *Shigella* bacterium or if they do not have diarrhea for at least 2 days. Only treated or boiled water should be consumed while traveling, one should eat fruits peeled by oneself after washing them thoroughly, and hot food should be eaten after disinfecting the surface where food is prepared.

If a child in diapers has shigellosis, after changing the diaper the changing area should be wiped down with disinfectant such as diluted household bleach and the diapers should be put in a closed-lid garbage can, and then hands should be washed with soap and warm water. People who have shigellosis should not prepare food or pour water for others until they have been shown no longer carrying the *Shigella* bacterium. One should swim in pools maintaining a chlorine level of 0.5 ppm, and swimming beaches should have enough bathrooms near the swimming area to keep the water from becoming contaminated.

The most effective methods for controlling shigellosis are provision of safe and abundant water and effective feces disposal.

Outbreaks

Outbreaks commonly occur under conditions of crowding and poor sanitation, such as in correctional facilities, institutions for children, day care centers, mental hospitals, crowded camps, and aboard ships. If an outbreak of shigellosis (i.e., two or more cases) is suspected in a child care facility, the Epidemiology and Response Division should be notified immediately. Outbreaks of shigellosis in this situation would ordinarily be controlled by exclusion and treatment of symptomatic children and staff.

Examples of foodborne outbreaks:

1. Military campaign Operation Desert Shield, 1990: Diarrheal disease during military operation can obviously reduce the effectiveness of troops. In Operation Desert Shield, enteric pathogens were isolated from 214 US soldiers and out of those 113 cases were diagnosed with *Shigella*; *S. sonnei* was the prevalent of the four shigellae isolated. Shigellosis accounted for more time lost from military duties and was responsible for more severe morbidity than the morbidity caused by enterotoxigenic *E. coli*, the most common enteric pathogen isolated from USA troops in Saudi Arabia. The suspected source was contaminated fresh vegetable, notably lettuce. Twelve heads of lettuce were examined and enteric pathogens were isolated from all.
2. Local outbreak – moose soup in Alaska, 1991: In September 1991, the Alaska Division of Public Health was contacted about a possible gastroenteritis outbreak. In Galena, 25 people who had gathered at a local community event in which homemade foods were consumed contracted shigellosis. The implicated food was homemade moose soup. One of the five women who prepared the soup reported that she had gastroenteritis before or at the time of preparing the soup. *Shigella sonnei* was isolated from one hospitalized patient.
3. Doubletree Hotel *Shigella* Outbreak, Colorado, 2003: In September 2003, the Colorado Department of Public Health and Environment began to get reports of *Shigella* infections. Their investigation led them to the Doubletree Hotel in Westminster, CO, USA which was a common link for the infected parties. Two large groups of hotel guests were identified, a wedding party and a World War II veterans' reunion, with attendees from a number of different states. Members of both groups as well as a random sample of hotel guests were contacted and interviewed. Ten individuals were diagnosed with culture-confirmed cases of *S. sonnei* infections after eating honeydew melon served at the breakfast buffet. Three food handlers and a kitchen chef were tested positive for *Shigella*.
4. Royal Fork *Shigella* Outbreak, Washington, 2001: A total of eight culture-confirmed *S. sonnei* cases had eaten at the Royal Fork restaurant located in Mount Vernon, WA, USA, between January 13 and 20, 2001.

   The Communicable Disease Epidemiology section of the Washington State Department of Health (WDOH) found that a food worker at the Royal Fork restaurant was also infected with *S. sonnei*. The infected food worker had recently returned from Mexico. On her return, she suffered *Shigella*-like symptoms until approximately 6 January and returned to work at Royal Fork on 10 January after her symptoms had subsided. WDOH learned that the infected food worker was in charge of restocking the salad bar, and

she did not routinely wear gloves during this process. "*Shigella sonnei* was most likely transmitted to restaurant patrons by an infected food worker through the vehicle of romaine lettuce served on the salad bar."

5. Subway Restaurant *Shigella* Outbreak, Chicago, 2010: A *Shigella* outbreak at a Subway restaurant in Lombard, IL, USA, has caused at least 116 confirmed cases of *S. sonnei* and likely greater than a thousand total illnesses. The DuPage County Health Department investigators found that two employees of the defendant's Subway restaurant tested positive for the same strain of *Shigella* that caused the outbreak. These individuals had been ill with gastrointestinal symptoms related to their *Shigella* infections before the outbreak. The poor hygienic practices by the ill employees caused widespread contamination of patrons' food.
6. Other examples of shigellosis outbreaks spread by food workers: Todd *et al*. had analyzed 816 outbreaks where food workers were implicated in the spread of foodborne disease. They discussed the size, severity settings, factors contributing to outbreaks, and descriptions of different outbreak categories.

Foods Implicated in Outbreaks

Shigella is commonly transmitted by foods consumed raw, for example, lettuce or as nonprocessed ingredients such as those in a five-layer bean dip, salads (potato, tuna, shrimp, macaroni, and chicken), icing on cakes or exported raspberries, milk and dairy products, and poultry are among the foods that have been associated with shigellosis.

BACTERIA

Staphylococcus aureus

ECD Todd, Ewen Todd Consulting LLC, Okemos, MI, USA

Glossary

Bacteremia Bacteria entering the bloodstream through a wound, an existing infection, or through a surgical procedure or injection.

Cellulitis Spreading bacterial infection just below the skin surface.

Danger zone The temperature range in which foodborne bacteria can grow is known as the danger zone. According to the 2009 US Food and Drug Administration Food Code, the danger zone is defined as 5 and 57 °C (41 and 135 °F). However, other jurisdictions consider the danger zone between 5 and 60 °C (41 and 140 °F).

Emetic reflex center Vomiting is a complex, coordinated reflex orchestrated by the vomiting center of the brain. It responds to external signals. The central nervous system plays a critical role in the physiology of nausea and vomiting, serving as the primary site that receives and processes a variety of emetic stimuli. The central nervous system also plays a primary role in generating efferent signals that are sent to a number of organs and tissues in a process that eventually results in vomiting.

Enterotoxin (staphylococcal) A soluble exotoxin produced by some strains of *Staphylococcus*; a cause of food poisoning or intoxication.

Meningitis A serious inflammation of the meninges, the thin, membranous covering of the brain and the spinal cord.

Nasopharynx Is part of the pharynx above the soft palate that is continuous with the nasal passages. The pharynx is the membrane-lined cavity behind the nose and mouth, connecting them to the esophagus.

Osteomyelitis Is the inflammation of the bone and/or marrow due to infection by bacteria like *Salmonella* or *Staphylococcus*, caused by a complication of surgery or injury, or infection through the bloodstream.

Pulsed-field gel electrophoresis It is an electrophoretic technique in which the gel is subjected to electrical fields alternating between different angles, allowing very large DNA fragments to pass through the gel, permitting efficient separation of mixtures of such large fragments.

Sepsis It is a systemic response typically to a serious, usually localized, infection especially of bacterial origin that is usually marked by abnormal body temperature and white blood cell count, tachycardia (abnormally rapid heart rate), and tachypnea (rapid breathing).

Staphylococcal scalded skin syndrome (SSSS) It is a disease, caused by a type of bacteria, in which large sheets of skin may peel away. SSSS primarily strikes children under the age of five, particularly infants. Clusters of SSSS cases (epidemics) can occur in newborn nurseries, when staff in those nurseries accidentally pass the causative bacteria between patients. It can also strike other age groups who have weakened immune systems.

Toxic shock syndrome It is an acute infection characterized by high fever, a sunburn-like rash, vomiting, and diarrhea, followed in severe cases by shock, that is caused by a toxin-producing strain of *Staphylococcus aureus,* occurring chiefly among young menstruating women who use vaginal tampons.

Vagus nerve A nerve that supplies nerve fibers to the pharynx (throat), larynx (voice box), trachea (windpipe), lungs, heart, esophagus, and intestinal tract, as far as the transverse portion of the colon. The vagus nerve also brings sensory information back to the brain from the ear, tongue, pharynx, and larynx.

Background

Staphylococcus aureus was first identified in 1880 from pus in a knee joint abscess. Since then we know that *S. aureus* is a very frequent microorganism in humans and animals with approximately 20–50% of persons being long-term carriers (including food and hospital workers), mainly as a part of the normal skin flora and in anterior nares of the nasopharynx, but also the throat and hair. These resident bacteria do not cause disease. However, damage to the skin (such as food workers and hospital staff scrubbing hands too roughly) or other injury may allow the bacteria to overcome the natural protective mechanisms of the body, leading to infection. These include skin infections such as pimples, impetigo, boils, cellulitis, carbuncles, and abscesses. Extensive infected pimples can lead to a staphylococcal scalded skin syndrome.

These infections can be long-lasting if not treated, but they are not as serious as when the pathogen invades the body causing bacteremia and sepsis. Toxic shock syndrome and endocarditis can quickly become fatal without antibiotic treatment, but *S. aureus* can also cause pneumonia, meningitis, and osteomyelitis. It is often the cause of postsurgical

 doi:10.1016/B978-0-12-378612-8.00115-3

wound infections. Many strains are resistant to antibiotics and one of the most recent concerns in hospitals is nosocomial methicillin-resistant *S. aureus* which can be fatal for immunocompromised patients.

Characteristics

Staphylococci are Gram-positive, nonspore forming, facultatively anaerobic, nonmotile, catalase-positive or negative, small, spherical bacteria from pairs to, grape-like clusters, from where the name *Staphylococcus* comes from (staphyle, meaning a bunch of grapes, and kokkos, meaning berry).

Staphylococci grow in foods as well as being present in animals with a range from 7 °C to approximately 48 °C, with its optimum at 35 °C, at a preferred pH range of 7.0–7.5, but it can grow as low as pH 4.5. Staphylococci are able to grow at low levels of water activity, for example, as low as 0.8. Thus, it is highly tolerant to salts and sugars and has historically been responsible for foodborne disease outbreaks illnesses from contaminated hams (salt) and pies (sugar). In addition, *S. aureus* does not need to grow to be a concern, because it can survive for extended periods in a dry state and subsequently contaminate wounds and foods. *S. aureus* produces a large variety of virulence factors. These include coagulases that clot plasma and coat the bacterial cell to inhibit phagocytosis; hyaluronidase that breakdown hyaluronic acid to help spreading the pathogen in tissues; deoxyribonuclease (DNase) that attacks cellular DNA; Protein A that binds IgG of the host's antibodies; the golden colored carotenoid pigment that acts as a bacterial antioxidant; and staphylococcal enterotoxins (SE) that act as superantigens capable of stimulating T-cells (at least 21 SEs have been described, with some of them proven to be emetic).

Clinical Manifestations

From a disease perspective, some staphylococcal species, mainly *S. aureus*, produce the heat-stable emetic SEs to cause gastroenteritis in humans (nausea, vomiting, abdominal cramps, and diarrhea) on ingestion of food containing these enterotoxins, often called staphylococcal food poisoning. The incubation period of illness ranges from 30 min to 8 h, but is usually within 2–4 h. The onset of symptoms depends on susceptibility of the individuals to the SEs, the amount of contaminated food eaten, the amount of toxin in the food ingested, and the general health of the patients. In severe cases, patients may present with headache, muscle cramping, severe fluid, and electrolytes loss with weakness and low blood pressure or shock. Patients usually recover within 2 days, but can take longer in severe cases, which may require hospitalization. Death from staphylococcal food poisoning is rare, although it has occurred among the elderly, infants, and severely debilitated people, or if the amount of the toxin is excessive. For instance, in 1998, approximately 8000 individuals gathered to celebrate a priest's ordination in Brazil. Within hours of food consumption, 4000 patients experienced acute gastroenteritis, and 396 required admission to hospitals, and 16 died through multisystem shock while hospitalized. The trace-back investigation implicated food preparers who were culture positive for enterotoxigenic *S. aureus* as the source of contamination. When a food is contaminated and *S. aureus* is allowed to grow, it can produce these SEs that remain active in the food even if the organism is no longer viable, such as being destroyed through cooking (some SEs can remain stable at 100 °C for 30 min). These single-chain proteins (MW 26 000–29 000) are resistant to proteolytic enzymes, such as trypsin and pepsin, allowing them to pass through the digestive tract. There are five main enterotoxin serotypes: SEA, SEB, SEC, SED, and SEE that demonstrate an emetic activity soon after ingestion, but there are several, but more rarely encountered in food. The SEs stimulate the emetic reflex center probably through the vagus nerve. The intoxication dose of SE is less than 1.0 μg of preformed enterotoxin, and there have been reports of illnesses following ingestion in the nanogram range (100–200 ng in highly sensitive people). This toxin level is reached when *S. aureus* populations typically exceed 100 000 CFU g^{-1} in food. However, the level determined on analysis of the incriminated product may not have been the highest level achieved by the pathogen because of population die-off or the food had been heated. Nevertheless, any level >1000 CFU g^{-1} is an indication of gross insanitary conditions, such as because of human contamination followed by time–temperature conditions that allow growth. Standards in foods for *S. aureus* vary, but are often ≤ 10 CFU g^{-1} for prepared foods. *S. aureus* does not compete well where there are many other microorganisms, and therefore standards or guidelines for uncooked food usually do not apply.

Epidemiology

Staphylococci are ubiquitous in the environment and they can be found in the air, dust, sewage, water, milk, and food, or on food equipment, environmental surfaces, and animals, as well as present as human colonizers. As such, staphylococci are expected to exist in any and all foods that are handled directly by humans or are of animal origin, and are impossible to prevent arriving or eradicating from food processing and service operations. Many of the 32 *Staphylococcus* species and subspecies are potentially found in foods due to environmental, human, and animal contamination. Because of this, *S. aureus* foodborne disease outbreaks are typically the third or fourth most frequent in many countries (e.g., after *Salmonella, Clostridium perfringens,* and sometimes *E. coli* O157), where such diseases are monitored and recorded; these outbreaks are typically associated today in home or foodservice prepared food. In the US, it is estimated that staphylococcal food poisoning causes approximately 241 188 illnesses, 1064 hospitalizations, and 6 deaths each year. However, this is unlikely to be completely accurate because those ill do not complain or seek medical attention because of the short duration of the illness; the investigation of an illness complaint or outbreak may be incomplete; misdiagnosis of the illness, which may be symptomatically similar to other types of rapid-onset food poisoning, such as caused by *Bacillus cereus* emetic toxin; lack of health department resources to investigate a short-term, self-limiting

illness; and inadequate collection of samples for laboratory analyses and/or improper laboratory examination.

Analytical Methods for Organisms and/or Toxins

During investigations of possible staphylococcal illnesses, *S. aureus* can be isolated from stool specimens, but unless some typing is done, these may be unrelated to the causative organism because *S. aureus* is not unusual in stools of healthy individuals. Enrichment isolation and direct plating for counts can be performed on selective media, such as mannitol-salt and Baird Parker agars and Petrifilm™ rapid *S. aureus* count plate method where numbers are expected to be >100 CFU g^{-1}. The most probable number procedure is recommended for monitoring of products expected to have smaller numbers. Phage-typing was widely used in the UK for typing isolates but used less frequently elsewhere. More recently, multilocus sequence typing , pulsed-field gel electrophoresis (PFGE), and other DNA profile methods have also been used for comparing isolates. Serological methods, typically ELISA-based, are available for detection of preformed enterotoxin in foods, and the enterotoxigenicity of *S. aureus* isolates. This is especially useful if the suspected food item has been heated in any way to destroy the pathogen.

Route of Transmission

Outbreaks usually occur today because of mistakes made by food preparers. Among these, there are first those that lead to contamination of food, such as:

- direct contact with workers with hand or arm lesions caused by *S. aureus*;
- coughing and sneezing;
- touching hair and beards;
- contact with pets;
- contact with contaminated equipment, and food- and nonfood-contact surfaces; and
- contact with sores on hands, nose wiping, and fingernails.

Foods of animal origin may also be contaminated at source, for instance, milk may carry *S. aureus* following mastitis of cows. Furthermore, there are those that lead to growth of the organism. In this regard, a common mistake which is frequently the cause of staphylococcal food poisoning is that foods that require considerable handling during preparation are kept above refrigeration temperatures for an extended period after preparation. For instance, frequently implicated foods are sliced meat, puddings, pastries, and egg sandwiches. The contaminated foods may not smell bad or look spoiled in order to produce the toxins, and thus may seem quite acceptable to consume. More specific examples include contamination of starter cultures for cheese, where the inoculated milk allows rapid growth before the curd forms and the product is too acidic with low water activity for further growth; barbecued chickens stored for many hours in the 'danger zone'; and cream-filled pies displayed in shop windows under warm ambient conditions.

Examples of Outbreaks

1. In October and November 2009, six household staphylococcal food poisoning outbreaks were notified in six French metropolitan départements. A total of 23 persons of 26 persons who had consumed cheese (attack rate 88.5%) suffered from nausea, vomiting, abdominal cramps, and diarrhea, in some cases associated with fever. The period between the ingestion of a cheese and the onset of symptoms ranged from 1.25 h to 8 h. A soft cheese made from unpasteurized cow milk was the common source of these outbreaks as all cases had eaten the same cheese (the coagulase-positive staphylococci isolates from the contaminated cheese samples showed the same SE gene pattern, the same biotype, the same PFGE profile, and also the same antibiogram). Cheese samples were available from six outbreaks and the staphylococcal food poisoning diagnosis was confirmed through (1) the high count of coagulase-positive staphylococci, (2) the detection of SE type E in the incriminated cheese type, and (3) the detection of the SEE gene in coagulase-positive staphylococci isolates from the suspected cheese samples. The SEE amount found in one of the cheese samples was 0.45 ng g^{-1}. Because, those ill ate about 200 g, the total amount of ingested SEE could be estimated to 90 ng. This was the first report of food poisoning outbreaks caused by SE type E in France.
2. In 2009, 21 persons experienced either vomiting and/or diarrhea within 12 h of eating at a Kansas restaurant in June, 5 people experienced bloody diarrhea, and 3 others sought medical care in the emergency department. The incubation period ranged from 1 h to 11 h with a median of 4 h. Several menu items were significantly associated with the illness: The cannelloni, the pasta sampler, which contains lasagna, manicotti, and cannelloni, and any chicken entree. The ingredients of the cannelloni included ground beef, spinach, mozzarella, ricotta, parmesan, and romano cheeses hand-rolled in a sheet of pasta topped with marinara sauce. An inspection of the restaurant found five critical violations: (1) inadequate cold holding temperatures, (2) refrigeration units not holding proper cold hold temperatures, (3) improper cooling of cooked foods, (4) no date markings on any refrigerated foods, and (5) open drinks in the food preparation area. Four noncritical violations were observed: (1) improper thawing, (2) blocked hand washing sink, (3) no food thermometers, and (4) improper storing of in-use utensils. A sample of cannelloni was collected during the food inspection and tested positive for *S. aureus* enterotoxin. *Staphylococcus aureus* was also isolated from the sample. No employee reported any gastrointestinal symptoms. During the inspection of the establishment, multiple food items were above proper cold holding temperatures. The cheese filling for the cannelloni was at 54 and 57 °F, raw chicken was at 79 °F, and ready to eat chicken was at 54 °F, which are all temperatures that *S. aureus* exhibits rapid growth and toxin production.
3. In December 2010, there were four outbreaks associated with the consumption of dessert items (tiramisu, cakes, cobblers, decorated cookies, tarts, pastries, and pies) from

an Illinois wholesale and retail sales bakery. Approximately 100 people reported becoming ill after consuming these at a company event, catered party, a restaurant, and a holiday party. The bakery had failed to clean and sanitize equipment in a manner that would protect against contamination of food and food-contact surfaces. Unfortunately, these problems were not resolved satisfactorily because in June 2011, multiple enterotoxigenic strains of *S. aureus* were found in environmental samples of the bakery and in the topping used to finish its cakes. The US Food and Drug Administration stated in a warning letter to the bakery that the cleaning and sanitation operations were ineffective, and that the firm was operating under insanitary conditions, which may reasonably cause contamination of food with this organism, and which may lead to toxin formation, and that foods that can support the rapid growth of undesirable microorganisms – particularly cream-filled pastries – were being held too long at unsafe temperatures.

4. The Snow Brand outbreak in Japan in June, 2000 was unusual, in that it was a large-scale incident involving commercial dairy food (low-fat milk and milk beverages made from skimmed milk powder) made by Japan's premier dairy foods company. There were 14 780 cases, but no viable organisms were found in the products, only very low levels of enterotoxin (0.05–1.6 ng ml^{-1}) in the incriminated milk products. From the source product (skimmed milk powder), SEA was detected at 4 ng g^{-1}. The reason for the contamination was defective temperature control because of a power outage that stopped the production line at the Hokkaido plant where the raw material was produced. This toxic material was sent to the next level of production line without being discarded and created toxic skimmed milk powder. Dairy products that contained the toxic material were produced and shipped from the Osaka plant and caused an outbreak throughout the Kansai region of Japan. The delay in making company and public announcements and in recalling the product allowed exacerbated the problem. Various faults were subsequently documented. When the number of bacteria in the produced skimmed milk powder exceeded safety standard, the material was considered to be safe to be reused if sterilized (which would not affect the activity of SE), and the new skimmed milk powder was produced out of the toxic material and shipped to Osaka plant. The plant manager and his staff not only did not have full knowledge about enterotoxin, but also lacked the basic knowledge that toxin generated from bacteria did not lose its toxicity by heating. There was also a lack of basic knowledge of food sanitation, and corporate standards were not strictly kept. This incident caused Snow Brand to lose consumer confidence and the sales of the largest dairy product manufacturer plummeted. The total deficit for the period of this fiscal year reached 52.9 billion yen and the company had to close two operations including the Osaka plant, and eventually merged operations with Nestlé.
5. Other species of the genus *Staphylococcus* have been rarely implicated in foodborne outbreaks. For instance, *S. intermedius*, normally considered a veterinary animal pathogen, was isolated from butter blend and margarine implicated in a 1991 outbreak. SEA was detected in both clinical and food isolates implicated in this food-related outbreak involving more than 265 cases in the western US.

Staphylococcal Enterotoxin as a Bioterrorism Agent

It has been argued that SE could be used as a biological agent either by contamination of food/water or by aerosolization and inhalation. Breathing in low doses of SE type B may cause fever, cough, difficulty in breathing, headache, and some vomiting and nausea. High doses of the toxin have a much more serious effect. However, although SEs are relatively easy to produce, there are more effective biological agents that would likely be used first.

Prevention of Staphylococcal Intoxication

Prevention of foodborne intoxication with *S. aureus* is based on prevention of contamination of the food and of prevention of growth of the organisms. Food operators should be trained in good hygienic practice, but in particular to be instructed to:

- Wash hands and under fingernails vigorously with soap and water before handling and preparing food.
- Wear hair nets and beard constraints.
- Not prepare food if they have a nose or an eye infection.
- Not prepare or serve food for others if they have wounds or skin infections on their hands or wrists.
- Wear gloves as appropriate to the operation but take care to wash hands frequently and change gloves to minimize the build-up of *S. aureus* at the warm, moist glove–skin interface.
- Prevent cross-contamination of raw and cooked food.
- Keep pets away from food preparation areas.
- Keep kitchens and food-serving areas clean and sanitized.
- If food is to be stored longer than 2 h, keep hot foods hot ($>57\,^{\circ}C/135\,^{\circ}F$) and cold foods cold ($<5\,^{\circ}C/41\,^{\circ}F$ or under).
- Store cooked food in wide, shallow containers and refrigerate as soon as possible.

BACTERIA

Streptococcus

Z Hossain, Bangladesh Council of Scientific and Industrial Research (BCSIR), Dhaka, Bangladesh

Glossary

Contamination The introduction or occurrence of a contaminant in food or food environment.
Foodborne disease Any disease of an infectious or toxin nature caused by or thought to be caused by consumption of food or water.
Food handler Any person who handles, prepares, or serves food, be they domestic food handlers (preparing family food) or professional food handlers, such as those working in food service establishments (cooks and waiters), retail stores, supermarkets, etc.
Hazard A biological, chemical or physical agent in, or condition of, food with the potential to cause an adverse health effect.
Incidence The rate or range of occurrence or influence of something, especially of something unwanted.
Infection The invasion and multiplication of microorganisms such as bacteria, viruses, and parasites that are not normally present within the body.
Monitoring The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a critical control point is under control.
Pathogen An organism capable of causing disease.
Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Background

Certain foodborne illnesses are the precursor of some potentially life-threatening diseases in humans. The occurrence of such illnesses can be partly attributed to infections with *Streptococcus* species. Streptococci are spherical, Gram-positive, extracellular bacteria, which usually exist in pairs or long chains. These microbes belong to the phylum Firmicutes and fall under the lactic acid bacteria group. The diseases caused by these bacteria include strep throat, pneumonia, scarlet fever, rheumatic fever, cellulitis, necrotizing fasciitis, and meningitis, especially neonatal meningitis. *Streptococcus* was associated with one of the first discovered diseases treatable by antibiotics. This genus of bacteria has played an inevitable role in the history of microbiology and molecular biology being the paradigm for many microbial studies around the globe. In 1880, both French biologist Louis Pasteur and George Miller Sternberg in the USA independently isolated the bacteria that caused pneumonia. The pathogen was eventually named *Streptococcus pneumoniae* in 1974. The name streptococci has derived from the Greek word *Streptos* meaning twisted or easily bent, like a chain, and was given by a Scottish doctor, Alexander Ogston, who observed a group of spheroid bacteria arranged in chains. Griffith's landmark experiment, which is recognized as the foundation of genetics, also employed *S. pneumoniae* to study the transfer of virulence from pathogenic to nonpathogenic bacterial strains. An ancient physician, Hippocrates also known as the Father of Medicine is credited for the first mentioning of the flesh-eating bacteria while describing the relative symptoms in early stages of the infection.

In 1884, these chain-forming bacteria were named *Streptococcus pyogenes* by Rosenbach. Later the discovery of serotyping of hemolytic and nonhemolytic structures by the American microbiologist Rebecca Lancefield in 1933 helped with subgrouping of α-, β-, and γ-hemolytic types of *Streptococcus* by their serotypes. Much of public attention to streptococci has resulted from the emergence of new virulent strains of these pathogens causing epidemics in recent years. Sulfonamides used to be the first treatment of choice for streptococcal diseases during 1930s. However, many of the strains of this pathogen became resistant to this treatment within a decade. The great discovery of penicillin by Alexander Fleming in 1928 led to the introduction of antibiotics in treating diseases caused by these bacteria. During World War II, penicillin was successfully used to prevent lethal outbreaks of streptococcal diseases, such as rheumatic fever.

Characteristics of the Organisms

Nomenclature/Taxonomy and Classification

The term *Streptococcus* refers to the spheroidal architecture of these microorganisms forming bead-like chains or twists. As these microorganisms can also appear in pairs, diplococci are indeed streptococci. Staphylococci are, however, segregated from this genus because of their distinct morphological and phenotypic characteristics. The genus *Streptococcus* belongs to the class Bacilli and the family Streptococcaceae while comprising an enormous number of species widely distributed in

the animal kingdom. Whereas some of these species afflict humans and animals, others are being exploited as industrially beneficial microbes.

According to the extent of hemolysis, i.e., α (partial), β (complete), and γ (no hemolysis), and surface antigen (group antigen) recognition by antibodies, streptococci are subdivided into groups consisting of one or more species. Twenty different serotypes (Groups A to V, except I and J) have been described as Lancefield groups based on the specific composition of cell-wall carbohydrates. The most significant Lancefield groups are β-hemolytic streptococci (BHS) A and B, and the α- or γ-hemolytic D. However, the typical α-hemolytic streptococci *S. pneumoniae*, *S. mutans*, and other so-called *viridans* species do not possess such group antigens, and are independent of Lancefield classification. The only group A *Streptococcus* (GAS) species that accounts for some of the major β-hemolytic streptococcal diseases is known as *S. pyogenes*. *Streptococcus agalactiae*, which is a particular problem among pregnant females and neonates, is the only member of group B *Streptococcus* (GBS). After recent reclassification, many group D streptococci (GDS) have been categorized under the genus *Enterococcus*. The only nonenterococcal GDS *Streptococcus bovis* and *Streptococcus equinus* are clinically important because of their association with human illnesses. Other BHS, which sporadically become etiological agents of human diseases, mainly include groups C and G. *Streptococcus equi* subsp. *zooepidemicus* (from *Streptococcus zooepidemicus*) and *Streptococcus dysgalactiae* subsp. *equisimilis* (from *Streptococcus equisimilis*) are two major human-specific group C *Streptococcus* (GCS) species. The only group G *Streptococcus* (GGS) occasionally prevalent in human infections is *Streptococcus canis*. The nongroupable *viridans* (from Latin *viridis* meaning *green*) streptococci, also well known as oral streptococci, embrace diverse species including two members of mutans streptococci, such as *S. mutans* and *Streptococcus sobrinus*. Current classification of these bacteria based on their 16S ribosomal ribonucleic acid (rRNA) analysis has greatly overcome common confusions arising from similar results in biochemical identification tests.

Morphology

Streptococci are coccoid bacterial cells microscopically, and stain purple (Gram-positive) when Gram staining technique is applied. They are nonmotile and non-spore forming. These cocci measure between 0.5 and 2 μm in diameter. As cellular division of *Streptococcus* spp. occurs along a single axis or plane, these bacteria grow in pairs or chains. After 18–24 h of incubation at 35–37 °C on blood agar, typically grayish-white, smooth, glossy, and translucent colonies appear with zones of α/β-hemolysis or no hemolysis. α-Hemolysis produced by many species of *Streptococcus* is characterized by a partial breakdown of the red blood cells (RBCs) in the medium, and is seen as a green zone surrounding the colony resulting from pigmentation of hemoglobin within RBCs. Although the term α-hemolysis is still used for this appearance, the property is due to oxidization of iron in hemoglobin molecules (reduction to methemoglobin), not lysis of RBCs. *Streptococcus pyogenes* or GAS forms doomed, round, and entire pinpoint

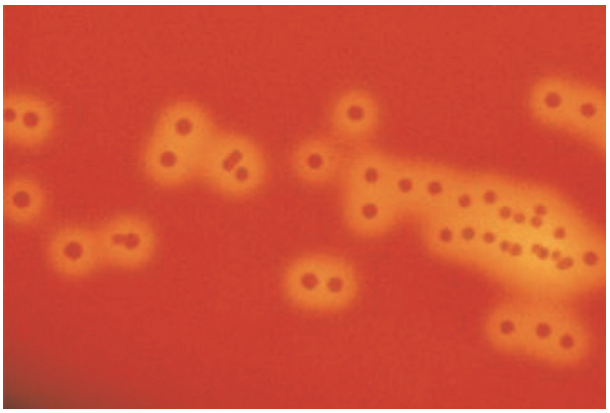

Figure 1 β-Hemolysis produced by colonies of *S. pyogenes* on blood agar.

colonies that exhibit complete hemolysis, as indicated by a clear zone surrounding the colony several times greater than the diameter of the colony itself. Some strains may produce mucoid colonies (Figure 1). *Streptococcus pyogenes* are spherical to ovoid microorganisms measuring up to 1 μm in diameter. GBS or *S. agalactiae* colonies can be flat, grayish-white or orange, mucoid, and creamy. When incubated aerobically this group of streptococci may render less obvious β-hemolysis also known as α-prime hemolysis, which is represented by a small zone of clear hemolysis surrounded by an area of partial lysis on blood agar. Colonies of some β-hemolytic GCS, such as *S. equi* are larger and more mucoid than those of most classical *Streptococcus*. Also, the human variant *S. dysgalactiae* subsp. *equisimilis* is known as the large-colony type of group C, which shares a range of phenotypic characteristics with *S. pyogenes* as well as *S. agalactiae*. However, these bacteria are normally found as nonhemolytic *in vitro*. The GDS produce usually α- or nonhemolytic colonies of 1–2 mm in diameter. Viridans group streptococci (VGS) produce tiny, α-hemolytic colonies on blood agar. Although *S. mutans* is normally found as α- or γ-hemolytic, some β-hemolytic strains have also been identified. *Streptococcus pneumoniae* (also known as pneumococci) colonies are circular with entire margins, often elevated with depressed centers. These α-hemolytic colonies are commonly mucoid on primary isolation. Cells undergo autolysis on extended incubation, and the center of colony tends to disappear. Heavily encapsulated pneumococci can have larger colonies (several millimeters in diameter) than less heavily encapsulated strains. As these bacteria are often seen as pairs of cocci, they are well regarded as diplococci. Nonetheless, some strains of *S. pneumoniae* may also be observed as single cocci or in short chains. Most streptococci generally have a rigid cell wall with typical Gram-positive peptidoglycan layer, inner plasma membrane with mesosomal vesicles, cytoplasmic ribosomes, and a nucleoid. Some strains including *S. pneumoniae* and *S. pyogenes* contain polysaccharide capsule composed of hyaluronic acid (HA). The cell wall of *S. pyogenes* possesses a group-specific C-polysaccharide and two major classes of type-specific proteins, M and T antigens. The minor classes of type-specific proteins include F, R, and M-like or M-associated protein antigens. Many streptococcal species can sometimes have pilus- or

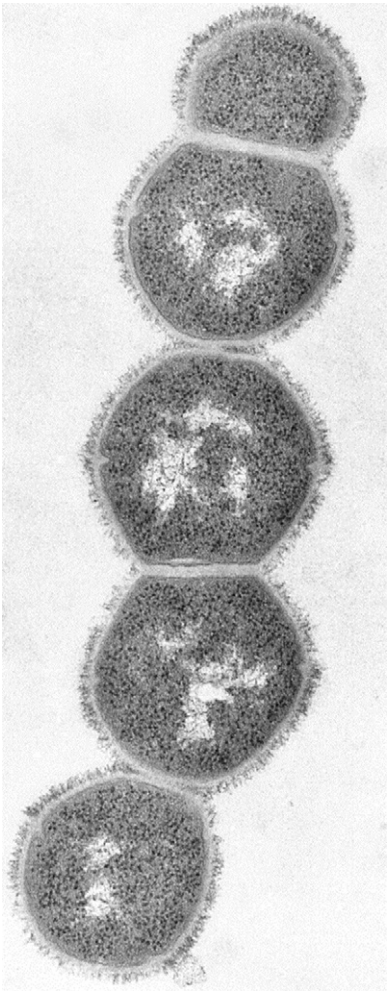

Figure 2 Electron micrograph of *S. pyogenes* with fimbriae surrounding the cell wall.

fimbria-like structures projecting from the surface of the bacteria, such as M protein-containing fimbriae of *S. pyogenes* (Figure 2). These structures are known to promote epithelial colonization and play a distinct role in virulence. For further discussion on this topic, see Section Streptococcal Toxins and Other Virulence Factors in Pathogenesis.

Metabolism and Physiology

Strains of *Streptococcus* are facultative anaerobes, but hemolytic activity of these bacteria increases in the anaerobic environment, i.e., hemolysins, which lyse the RBCs, are more stable in the absence of oxygen. They are catalase, oxidase, and nitrate negative. These bacteria depend largely on glycolysis for adenosine triphosphate (ATP) synthesis. Streptococci are chemoorganotrophic, i.e., their metabolism is fermentative producing mainly lactic acid, ethanol, and acetate from carbohydrates without the production of gas. However, *S. equinus* does not ferment lactose or grow in litmus milk. *Streptococcus pyogenes* has shown higher consumption of oxygen at thriving pH in the presence of glucose. Conversely, the percentage of glucose and galactose converting to lactic acid increases with a decrease in pH value (<6.5). Galactose is more slowly metabolized at high pH than glucose for *S. pyogenes* despite entering the pathway of glycolysis. Also, the end products of galactose fermentation vary radically from those of glucose fermentation, i.e., less lactate and more formate, acetate, and ethanol. *Streptococcus agalactiae* utilizes an aerobic pathway for glucose oxidation, and produces lactic and acetic acids, acetylmethylcarbinol, and carbon dioxide. *Streptococcus mutans*, which adheres to teeth in large numbers, is able to ferment dietary sugars into acids. These strains use an anaerobic type of energy metabolism regardless of their growth conditions. Therefore, ferrous iron is believed to boost their tolerance to oxygen-free atmosphere. Many viridans streptococcal species and certain *S. bovis* strains are able to synthesize dextrans from glucose. Streptococci require nutritionally rich media for growth. For example, they grow ideally on brain–heart infusion agar in the presence of 5–10% CO_2 (capnophiles). Growth of these nutritionally fastidious bacteria is enhanced by the addition of blood or serum. Therefore, these microorganisms are unable to synthesize many basic building blocks. Later in the growth cycle, streptococci produce hyaluronidase (Hyl), an enzyme that cleaves HA, a basic constituent of the bacterial capsule. The precise role of Hyl is still dubious, but it is assumed that the enzyme enables the bacterium to utilize host HA (found in the connective tissue) or its own capsule as a carbon (energy) source. Most streptococcal species produce leucine aminopeptidase, which hydrolyzes the substrate leucine-β-naphthylamide to form β-naphthylamine. Besides, GAS synthesize pyrrolidonyl arylamidase (PYRase) that hydrolyzes the substrate L-pyrrolidonyl-β-naphthylamide to form β-naphthylamine. *Streptococcus pyogenes* is notably sensitive to bacitracin, whereas most other groups are resistant. The GBS hydrolyze sodium hippurate. Both GAS and GBS do not usually grow on bile esculin. Strains that possess group D antigen are able to grow in the presence of 40% bile salts, and produce black precipitate by hydrolyzing esculin when grown on bile esculin. Nonenterococcal strains are intolerant to 6.5% sodium chloride (NaCl). Pneumococci are bile soluble, but susceptible to optochin. Viridans and other typical streptococci can survive in the presence of optochin. However, nearly all oral streptococci are bile insoluble, and do not grow on bile esculin. Exceptionally, *S. mutans* strains are capable of growing in a bile-supplemented medium. Most classical streptococci exhibit negative tolerance to 6.5% NaCl.

Streptococcal Toxins and Other Virulence Factors in Pathogenesis

Diverse virulence factors are associated with streptococcal pathogenicity within the host. This section will mainly focus on toxins and other pathogenic components related to GAS, being the paradigm for study of foodborne streptococcal infections. GAS strains synthesize a number of distinctive toxins and enzymes. This synthesis is thought to be mediated by lysogenic bacteriophages. Although the true mechanisms and functionality of these factors are not very clear, implication of some surface proteins in the microbial adherence to epithelial cells and colonization is quite evident. Some of the essential

virulence substances produced by GAS are exotoxins that include cytolytic toxins (streptolysins O and S) and erythrogenic or pyrogenic exotoxins (superantigens or immunomodulators). Other pathogenic cellular proteins comprise M protein family, streptokinase (fibrinolysin), deoxyribonuclease B (DNase B) or streptodornase, protein streptococcal inhibitor of complement (SIC), SpeB, F protein, and C5a peptidase (ScpA). Pyrogenic exotoxins (SpeA and SpeC) are responsible for the development of acquired hypersensitivity to streptococcal components and endotoxin shock. These superantigens are involved in nonspecific activation of T cells, and have been implicated in streptococcal toxic shock syndrome (STSS). Streptolysin S, a nonantigenic, oxygen-stable, cardiotoxic polypeptide, lyses different types of mammalian cells including RBCs. It is also associated with GAS leukotoxicity. Streptolysin O is inactive in the presence of oxygen. This cytolysin influences leukocytic functions, induces rapid antibody response, and also plays a vital role in the initiation of rheumatic fever. It is one of the key components of the bacterial β-hemolytic trait. Certain cellular components are also associated with infection and disease progression. Lipoteichoic acid (LTA), which is a major cell wall constituent of Gram-positive bacteria, is involved in adherence to epithelial cells. It is toxic to a wide range of host cells. M protein, one of the most important virulence factors for GAS incorporated in fimbriae, appears to exert an immunotoxic effect on human platelets and neutrophils. This component also prevents opsonization by the alternative complement pathway. It has been marked as the primary cause of antigenic shift and antigenic drift among GAS. More than 130 types of M protein have been recognized so far. F protein, a major adhesin of GAS, mediates adhesion to fibronectin on epithelial cells of skin and throat. ScpA is responsible for chemotactic signal destruction. SpeB, an exotoxic cysteine protease, cleaves host tissue matrix proteins (e.g., fibronectin), and is involved in modulation of fibronectin-dependent internalization of *S. pyogenes* by means of proteolysis. SIC protein interferes with complement function and inactivates antibacterial peptides. Streptokinases catalyze the transformation of plasminogen to plasmin, thereby dissolving fibrin and other proteins. DNases protect the pathogen from killing by neutrophil in extracellular traps. In GBS or *S. agalactiae*, hemolysin is a major virulence factor. Also, the polysaccharide capsule, surface-localized proteases ScpB and CspA, superoxide dismutase and LTA play crucial roles during different stages of GBS infection and in evasion of phagocytosis. The M-like protein SzP synthesized by *S. equi*, the clonal descendant of *S. zooepidemicus*, is implicated in virulence and antiphagocytosis. The sticky water-insoluble dextran molecules produced by viridans streptococci are potentially capable of adhering to heart valves by binding to the fibrin-platelet aggregate (thrombus) during an infective endocarditits. Such adherence by mutans streptococci in the mouth enhances corrosive acid production by plaque-forming bacteria leading to dental caries. HA (capsule) in many strains of streptococci is believed to evade adaptive immune response and phagocytic action of leukocytes by mimicking HA in the host connective tissue. Streptococcal Hyl that hydrolyzes the capsule is possibly implicated in the detachment of the organism from biofilms. This enzyme, as a spreading factor, is thought to play a crucial role in disseminating streptococcal virulence within the host environment.

Survival and Growth Characteristics in Food and Environment

Although the primary reservoir for *S. pyogenes* is humans, these bacteria may also be found in cattle. Humans can be infected through transmission from infected cattle, such as mastitic cows via raw or unpasteurized milk. This pathogen is capable of infecting cows to cause mastitis, and infected udder tissues can shed the bacterium into milk, where it is likely to survive for a long period. Foods that have been associated with outbreaks of disease caused by this microorganism include various dairy products, cooked sea food, and eggs. Some ready-to-eat (RTE) foods or food products, such as potato/egg/shrimp salads have been found as sources of *S. pyogenes*-associated outbreaks. These strains also survive in some vacuum-packaged RTE cheeses and meats, including beef bologna, turkey luncheon meat, and beef summer sausage, stored at low temperatures (5–8 °C) for several hours to few days. Contamination of these foods can result from handling or processing by infected individuals. These pathogens cause infections particularly when the food is left at room temperature for too long, allowing the bacteria to multiply to harmful levels. Moreover, pyogenic streptococci may multiply in raw meat at ambient temperatures. The potential duration of survival of GAS on a dry surface ranges from 3 days to 6.5 months. These microorganisms have been found to be viable approximately 18 days in ice cream, and 4 days in raw and unpasteurized milk at 15–37 °C. Also, they can survive 2–12 days in butter at room temperature. The bacteria can last for several days in cold salads at room temperature. Moisture content of certain food products, such as cottage cheese may reduce growth rate and survival period of *S. pyogenes*. This is probably due to quicker development of acidity in moisture food. Similarly, these microbes have been found dead within 5 h when inoculated in some sports drinks and fermented milk-containing beverages that had a considerably low pH (approximately 3). Therefore, acidic pH in food products drastically affects survival of these pathogens. GBS or *S. agalactiae* is found as a commensal organism in the lower gastrointestinal (GI) and vaginal tract. However, a high pH in these environments can stimulate GBS survival and biofilm production that may lead to sheer chance of a health hazard. Biofilm formation is thought to be strategy of these pathogens for prolonged survival within a given environment. Oral streptococci, particularly *S. mutans* are naturally present in the human oral microbiota. Hence, they acquire unique capacity to survive in the rapidly fluctuating harsh environment of the oral cavity. In addition, the bacteria endure exposure to a variety of antimicrobial drugs and toxic compounds during their growth. Mutans streptococci grow in biofilms on the surfaces of the teeth known as dental plaque (**Figures 3** and **4**). These microorganisms can also be competent in nutrition-limiting conditions. Quorum sensing, a microbial system of interaction with neighboring cells through small soluble signal peptides, has been revealed as a precursor for the development of competence in *S. mutans* and *S. pneumoniae*. Studies have suggested that some strains of *Streptococcus* in the environment can sometimes be inhibitory to other species of the same genus. This characteristic could be a means of survival of these bacteria under nutrient-limiting or other adverse conditions.

Figure 3 Greasy and sticky dental plaque on teeth surfaces.

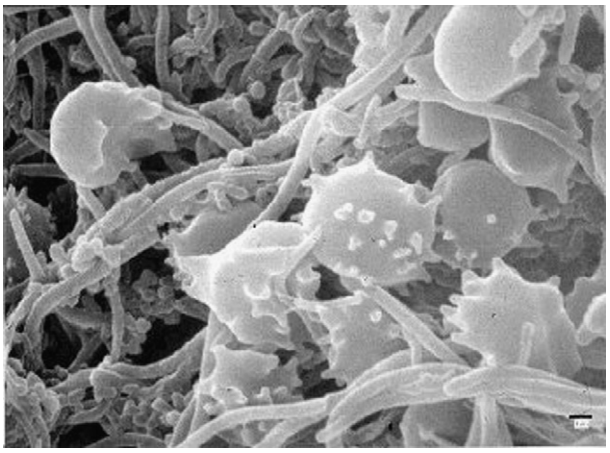

Figure 4 Scanning electron micrograph illustrating oral microbiota in dental plaque.

These organisms may persist outside the living host for months, especially in a damp environment. Streptococci do not grow at 10 °C, and the growth of majority of these strains does not usually sustain at high temperatures, such as ≥50 °C. Survival at 60 °C for 30 min with pH 9.6 differentiates group D enterococcal species from nonenterococcal strains.

Resistance to Different Factors and Survival in the GI Tract

Over the years, many streptococci have developed resistance to different host immune system as well as a variety of bactericidal compounds. Emergence of new resistant strains has received significant medical attention. Certain strains of GAS have shown resistance to a number of antibiotics, including macrolides, lincomycin, tetracyclines, chloramphenicol, and cotrimoxazole. The typically thick Gram-positive peptidoglycan layer and streptococcal encapsulation exert major influences on diverse bactericidal actions. Also, the inherent genetic plasticity of streptococci further helps them with adaptation to harsh environmental conditions. *Streptococcus mutans* cells cohabiting in dental biofilms appear resistant to various stresses induced by hosts, including low pH, high osmolarity, oxidation, exposure to organic acids, and antibiotics. The fact that certain M proteins of GAS crossreact antigenically with heart has withheld the use of GAS vaccines. More importantly, antigenic variation in these proteins between strains makes it difficult for the host to choose a common immune response to *S. pyogenes*. Hydrogen peroxide (H_2O_2) production is a phenotype of many members of the genus *Streptococcus* playing a definite role in virulence as well as antagonism within biofilm matrix. This compound has been postulated to cause direct damage to host tissues infected with *S. pyogenes*. Yet, H_2O_2-nonproducing strains of *S. pyogenes* may become resistant to intracellular killing by granulocytes. Like other commensal microflora, GBS and some strains of group C as well as viridans group have natural capacity to persist and colonize in the GI system of humans. Synthesis of certain surface proteins in *S. agalactiae* facilitates the bacteria with survival in the GI tract by interaction with proteins of the extracellular matrix. The Lmb protein is associated with binding of these organisms to human laminin. Furthermore, superoxide dismutase secreted by these bacteria has been found to reduce their susceptibility to killing by macrophages. Likewise, the relationship of protein G, a surface protein produced by GCS and GGS, with the bacterial survival in the GI tract is likely. It is thought that protein G may act as an environmental sensor for a well-adapted gene expression.

Clinical Manifestations

Among the BHS, mainly groups A and B are considered highly pathogenic to humans. Infections that do not involve food as a vehicle of transmission are not addressed in this article. The most common species of the genus potentially related to foodborne outbreaks, regardless of frequencies, are *S. pyogenes* and *S. equi* subsp. *zooepidemicus*. Of these, *S. pyogenes* primarily involves infections in the upper respiratory tract. Although some nonenterococcal group D strains, such as *S. bovis* are found in the normal flora of human GI tract, their transmission due to ingestion of food materials has not been clearly reported. Viridans streptococci, including *S. mutans* constitute part of the microflora residing in the mouth, GI tract, and vagina of healthy humans. Many of these strains can be sometimes virulent and become opportunistic etiological agents of diseases, particularly in immunodeficient or immunocompromised conditions. Consumption of food products or drinks containing saliva from carriers could literally be incriminated in some serious viridans-associated morbidity. None of the streptococcal diseases appears to occur from water sources.

Streptococcus pyogenes or GAS accounts for diverse suppurative infections after entering vulnerable human tissues. It is considered the most pathogenic bacterium in the genus *Streptococcus*. GAS is the causative agent of different acute infections, such as pharyngitis, scarlet fever, pyoderma (erysipelas and impetigo), otitis media (middle ear infection), meningitis, and sinusitis. Postinfectious complications include rheumatic fever and acute glomerulonephritis (AGN). This bacterium also functions as a host of some life-threatening invasive diseases, like necrotizing fasciitis (wound infection), myositis, STSS, puerperal fever (sepsis), and bacteremia. Some GAS infections are asymptomatic. Most symptomatic infections manifest as pharyngitis, which can occur in approximately 1–3 days after ingestion of contaminated food.

Acute Pharyngitis

Pharyngitis, also referred to as strep throat, streptococcal pharyngitis, or tonsillitis, is the most widespread *S. pyogenes*-associated disease. The disease is suppurative or purulent, but noninvasive. Infection typically involves the pharynx, including tonsils.

Signs and Symptoms

Symptoms of illness are generally mild, except otherwise complicated. The disease clinically presents with sore throat (with or without white patches/exudates), red throat (erythema), high fever, chills, runny nose (rhinorrhea), difficulty swallowing (dysphagia), painful swallowing (odynophagia), abdominal pain, nausea, vomiting, malaise or general discomfort, and headache. Inflamed tonsils followed by swelling may also occur in patients. Swollen glands (neck), a sign of tender cervical lymphadenopathy, are normally associated with prolonged pharyngitis. Coryza and cough have been found to be less implicated in foodborne streptococcal pharyngitis than the endemic airborne pharyngitis. However, submandibular nodal enlargement, a swelling of lymph nodes beneath the mandible or lower jaw, and tonsillar swelling are more likely for the former category. Clinical manifestation of foodborne pharyngitis could be relatively severe and confined to the pharynx compared to the other (Figure 5).

The symptoms usually begin to resolve in 3–5 days. However, if they sustain, scarlet fever, an acute systemic disease demonstrating the involvement of multiple sites, may develop with a deep erythematous rash on the skin and strawberry tongue. The rash is due to the synthesis of erythrogenic or pyrogenic toxins by the bacteria. It resembles typical sun burn and blanches with pressure. Initially, the rash is visible as itchy, tiny red bumps on the face, neck, and trunk. It further spreads to the chest, abdomen, and back, then all over the body with the consistency of sandpaper. The rash may look redder in the body creases and groin areas. These manifestations are usually accompanied by few or many classical symptoms of pharyngitis. In addition, the tongue may become pale and swollen, while coated with inflamed red papillae giving it an appearance like a strawberry (strawberry tongue). The fever is normally above 101 °F, and starts ceasing within 3–5 days after its onset. The illness may resolve in about a week with the help of appropriate treatment. Signs of rash will, however, take about another week to disappear. Scarlet fever has been documented quite rarely since 1940s.

Figure 5 Acute streptococcal pharyngitis presenting with red pharynx and swollen tonsils.

Carrier Duration

Untreated pharyngitis patients usually remain infective for 7–10 days during the acute phase of illnesses. The organism can be infectious for a week thereafter unless antibiotics are used. *Streptococcus pyogenes* is capable of remaining in the body of the carrier in its asymptomatic but transmissible state for weeks or months.

Dose of Infection

Infectious dose of GAS is still unknown, but appears relatively low. Fewer than 1000 organisms are considered capable of causing a successful procedure of infection.

Sequelae/Chronic Effects and Complications

Suppurative or purulent sequelae may involve peritonsillar and paranasal abscesses. Pneumonia occurs as an occasional complication, particularly in patients with the history of preceding or concomitant viral infections. Otitis media and sinusitis are secondary to direct extension from a GAS infection in the upper respiratory tract. Acute meningitis may occasionally occur due to antecedent pharyngeal infection, particularly in children within a few hours to a few days. Bacteremia, an invasion of the bloodstream by pyogenic streptococci, may follow an upper respiratory tract infection (URTI) sporadically, but more commonly result from a pyodermal (skin) infection. Rare complications include endocarditis, a disease affecting the lining of heart chambers and the heart valves, and hematogenous spread brain abscess. The occurrence of GAS is relatively established in the skin and soft tissues. Septic arthritis, a poststreptococcal reactive arthritis, may result from bacteremic spread of *S. pyogenes* while increasing the risk of rheumatic heart disease (RHD). The presenting clinical features of such complications are generally those of the corresponding diseases.

Acute rheumatic fever (ARF) is the most frequent nonsuppurative follow-on of an uncontrolled GAS infection with potential for more serious physical conditions. It is a delayed sequel to GAS pharyngitis affecting the collagen. ARF is widely hypothesized as an aberrant immune response (autoimmune disease) because it triggers binding of the crossreactive antistreptococcal antibodies to host tissue antigens. The bacterial M protein and host human leukocyte antigen molecules play a contributing role in the autoimmune phenomena. The onset of ARF usually appears between the first and the fifth week (latent period) after an infection has been caused by *S. pyogenes*. The disease is most often characterized by the sudden occurrence of fever accompanied by an acute inflammatory course, which involves the connective tissue, blood vessels, and joints, primarily those of lower limbs. ARF usually manifests with sore throat, progressive inflammatory reaction of the joints (migratory polyarthritis), and occasional redness with defined margin on the skin (erythema marginatum). Common complaints accompanying this condition are muscle pain, swelling of joints, malaise, and unsteady gait (difficulty walking). Subcutaneous nodules may also develop. Swelling may migrate

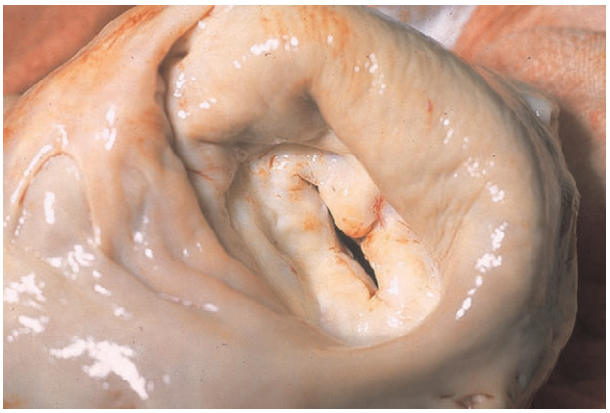

Figure 6 Narrowing (stenosis) of the mitral valve orifice as a result of acute rheumatic fever.

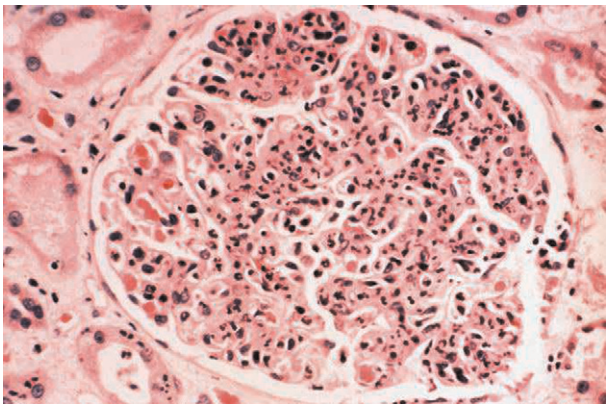

Figure 7 Photomicrograph of a glomerulus presenting APSGN with necrosis and accumulation of neutrophils.

from one joint to another. A central nervous system manifestation diagnosed by emotional instability and involuntary spastic movements (chorea) may also arise occasionally. Nervous involvement may result in fatigue, abdominal pain, vomiting, nose bleed, restlessness, difficulty breathing, tremors, and difficulty speaking. An untreated course of ARF may account for RHD referring to the inflammation of the heart (carditis) resulting in chronic valvular damage, predominantly incriminating the mitral valve (mitral stenosis). This condition may even lead to cardiac failure (Figure 6).

Another clinically significant complication of streptococcal pharyngitis is known as AGN, often referred to as acute poststreptococcal glomerulonephritis (APSGN). It is also a disease of the host immune complex as the crossreactive antibodies specific to streptococcal epitopes bind to antigens of the glomerular basement membrane. The onset of the disease usually takes place more than 1 week (approximately 10–14 days) after the streptococcal infection. AGN is marked by active inflammation and proliferation of the renal (kidney) glomeruli potentially causing damage to the basement membrane, mesangium, or capillary endothelium. The disease is clinically defined as sudden onset of smoky, dark-brown colored urine with RBCs (hematuria) and an excess of serum proteins (proteinuria), RBC casts, and depressed serum complement. A set of other manifestations include hypertension, tissue swelling (edema), and decreased glomerular filtration rate or azotemia. The scenario is often accompanied by renal salt and water retention. Patients, especially children, are also likely to suffer concurrent sore throat, diminished urine output, abdominal pain, fatigue, lethargy (drowsiness), headache, hyperventilation (increased breathing), and weight loss. Unresolved APSGN may address long-term kidney failure (Figure 7).

Risks of Misdiagnosis

ARF could be often confused with the most common rheumatic disease, rheumatoid arthritis. Also, many ARF cases go unnoticed or overlooked during the early stage of the onset of illnesses, and the patients may receive only empirical or supportive treatment, which may even worsen the prognosis of the actual disease. Similarly, if the etiology of AGN remains undefined, there are possibilities that treatment regime will not target corrective control of the underlying streptococcal infection first. Interstitial cystitis and overactive bladder syndrome are some of the undiagnosed conditions associated with AGN. Common exclusion of some potentially major causes of glomerulonephritis-related risks includes scarlet fever, bacterial endocarditits, and infection with *S. equi* subsp. *zooepidemicus*. Some of the severe gastric conditions may also be overlooked during diagnosis, such as irritable bowel disease, celiac disease, and diabetic diarrhea.

Infection with Group C Streptococci

Among the species belonging to this group, only *S. equi* subsp. *zooepidemicus* is known to cause human opportunistic infections from food sources. It is most often associated with acute group C streptococcal pharyngitis, which resembles manifestations of *S. pyogenes*-triggered pharyngitis. Major clinical presentations observed are sore throat, pharyngeal exudates, cervical lymphadenopathy, moderate fever, chills, and malaise. A number of superficial and deep clinical infections only occasionally can be attributed to this pathogen. These include endocarditis, pericarditis, cellulitis (skin infections), pneumonia, meningitis, septic arthritis, bacteremia, and septicemia. Abdominal pain may also be present in some patients. The disease is infrequently followed by a nephritic sequela (AGN), particularly if untreated. Nevertheless, GCS-induced nephritis is relatively severe.

Infection with Group G Streptococci

These bacteria are capable of colonizing the mouth, throat, intestines, genital tract, and skin of humans. *S. canis*, an example of GGS although originating from animals, can cause sporadic infections in humans through contamination of food. Infections with these organisms may also clinically present as sore throat, pharyngitis, cellulitis and sepsis. Symptoms of pharyngitis range from mild URTI with coryza to exudative pharyngitis. A great deal of manifestations normally resembles GAS infection. This condition is often accompanied by fever and lymphadenopathy. GGS may trigger a wide range of complicated infections that include bacteremia; inflammation of the connective tissue surrounding a joint (bursitis), bone and bone marrow (osteomyelitis), and lining of the abdomen (peritonitis); meningitis;

septic arthritis; and endocarditis. ARF and APSGN have not been found as implicated in chronic phases of group G infection.

It is important to note that, due to lack of a precise description of clinical manifestations and confusing biochemical identification methods relating to groups C and G streptococci, infections are most often misdiagnosed as GAS derived. Thus, it turns out to be difficult to calculate true incidences and control such infections.

Oral Streptococcal Infections

Numerous viridans streptococcal species, including *S. mutans* normally colonize in the mouth of humans while existing in harmony with other oral commensals. Certain strains of viridans category, such as *Streptococcus anginosus* or anginosus group can cause purulent infections, including brain abscess and suppurative intraabdominal abscess. Septic shock (also called α-strep shock syndrome), neonatal sepsis, meningitis, and osteomyelitis can also be triggered by these pathogens. Oral streptococci have always been considered to be of low virulence. However, some of these strains can sometimes be opportunistic, and become etiological agents of life-threatening diseases, like infective valve endocarditis by entering into the bloodstream following tooth extraction or other traumatic events of the mouth.

Disease of the Oral Health

Streptococcus mutans or other cariogenic streptococci, such as *Streptococcus sanguinis* could be potentially the causative agent of an oral infection if present in salivary substances from an infected individual mixed with food or drinks. High salivary *S. mutans* count (>105 colony forming units) is likely to pass the infectious bacteria to an unaffected person, especially children. Dental caries or tooth decay is strongly associated with *S. mutans*, which is normally present in dental plaque of humans. It is defined as demineralization and destruction of hard tissue of the teeth, enamel, dentin, and cementum. Occurrence of a dental caries largely depends on the time of the tooth surface exposure to acidic by-products fermented by the bacteria. A lesion presenting as a chalky white spot on the tooth, also known as microcavity, is the early sign of demineralization of the tooth enamel. A dull-brown lesion represents an active caries, which eventually leads to cavities or holes on the teeth and swelling on the gums. Common clinical symptoms of the disease are pain and discomfort when chewing food, difficulty in facial movement, sensitivity of tooth, jaw pain, discoloration on tooth surface, inflammation on the face, and mild fever. Dental caries can also manifest with bad breath and foul tastes. Such pyogenic oral infectious processes can be acute or chronic. During an acute carious state, the dental caries spreads laterally causing a rapid early deterioration of the pulp tissues. The pain is intense, and the dentin is light yellowish in color. There is only limited lateral spread in case of a chronic caries, and the involvement of the tooth pulp is a much slow process. Therefore, the cavity is shallow with no pulp tissue implication. Oral pain is generally not involved in this type of caries (Figure 8). Other plaque-derived forms of infection include inflammation of the gum tissue (gingivitis), gingival recession (retraction of gum tissue), bleeding gums, and more severe periodontal diseases as a result of loss of gum tissue and underlying bone.

Figure 8 Acute dental caries illustrating destruction of tooth tissue while forming deep cavity on the tooth.

Prolonged untreated dental caries may confer a risk of bacteremia, which in turn triggers the likelihood of an opportunistic heart valve endocarditis. Also, highly virulent *S. mutans* strains have been proposed to be implicated in the aggravation of ulcerative colitis. Such possibilities should not be ruled out without an accurate pathological explanation.

Infective Endocarditis (IE)

The disease IE, also referred to as native valve endocarditis (NVE), occurs when VGS begin to colonize the heart valves after adherence to the valve surface, where they develop a vegetation (abnormal outgrowth). VGS-related NVE is often subacute, i.e., subacute bacterial endocarditis (SBE). IE of this nature typically affects only abnormal valves. The most common clinical presentations of SBE are low-grade fever and chills. Other complaints include malaise, weight loss, anorexia, headache, myalgia, night sweats, shortness of breath, cough, abdominal syndromes, and joint pains, especially back pain. Patients with VGS-endocardial infections may develop suppurative extracardiac complications, such as splenic abscess and septic arthritis. Severe valvular insufficiency during the course of the disease may lead to congestive heart failure. Delayed therapy accounts for additional systemic manifestations that incorporate local tissue destruction and embolic phenomena, as sterile or infected emboli, a detached intravascular mass capable of blocking the blood flow in a blood vessel. Embolic stroke may also result in neurological abnormalities. Symptoms secondary to embolism comprise acute meningitis, painless hematuria, infarction of the kidney or spleen, unilateral blindness, and myocardial infarction. Besides, IE can become a pathological basis of various immunological syndromes (secondary autoimmune effects), such as glomerulonephritis and vasculitis.

The risk of misdiagnosis of SBE is quite high. A major concern is the residual valvular damage due to a previous endocardial attack. Many of its manifestations could be muted due to indiscriminate use of antibiotics or predisposing conditions in vulnerable individuals, such as elderly or immunocompromised people.

Epidemiology

Geographical Distribution, Prevalence, and Incidence

Foodborne pharyngitis has become a mounting concern due to recent reports of severe outbreaks in different parts of the world. GAS or *S. pyogenes* is the predominant etiological agent of bacterial pharyngitis because of its highly contagious potential. Also, it is the only causative agent of the disease for which antibiotic therapy is plainly indicated. Other groups, including C, G, and F, constitute approximately 10% of all cases of this disease, but related symptoms cannot be differentiated from GAS pharyngitis. *Streptococcus pyogenes* is globally distributed, and is a frequent colonizer of the oropharynx of healthy humans, especially children. Asymptomatic colonization is less common in adults. Certain strains of this group demonstrate a predilection for the respiratory tract, but it has not been confirmed whether or not ingestion of food mostly is the portal of entry for those pathotypes. Human carriage rates have been estimated to be approximately 5–15%. *Streptococcus pyogenes* underlies acute pharyngitis in a range of 15–30% of pediatric patients. According to a recent meta-analysis, the degree of GAS positivity in throat culture has been found to be 37% in school-aged children presenting with sore throat. The prevalence of GAS in a nonspecific adult population has been assessed as 5–10%. Incidences of GAS-associated URTIs peak at approximately 5–15 years of age. Clinical presentations of these infections are variable according to different geographical settings. The disease normally appears during late winter and early spring in regions of temperate climates. Although GAS infections were the cause of serious morbidity and mortality until the middle of the twentieth century, the number of incidences considerably declined afterwards. However, recent striking resurgence of such infections and accompanying consequences has vigorously changed public attitude to the pathogenic potential of GAS. Evolution of new virulent strains of streptococci is thought be at least partly responsible for this scenario. During 1985–2002, World Health Organization (WHO) estimated over 600 million cases of symptomatic GAS pharyngitis globally each year. Rates of severe GAS infection have thrived to 3 per 100 000 population in the northern European countries. In India, there could be as many as 20–30 million cases of streptococcal pharyngitis every year. GAS foodborne pharyngitis has increasingly occurred over the past few decades. There are occasional but significant reports of foodborne GAS outbreaks in various countries. The Centers for Disease Control and Prevention have recently mentioned over 11 000 cases of foodborne streptococcal illness in the USA each year. According to recent global observations, the prevalence of acute late sequelae of *S. pyogenes* infections, i.e., rheumatic fever and AGN has shifted from temperate to tropical climates. Increased individual cases of ARF had been reported in several parts of the USA since the early 1980s, but incidences steadily declined in the 1990s with the use of penicillin as a prophylaxis. However, the episode of GAS pharyngitis has sustained in that country. It has been estimated that the incidence of ARF is 3% following epidemic pharyngitis, whereas 1 per 1000 population following sporadic pharyngitis. Acute cases of GAS pharyngitis activate RHD in 6 million individuals yearly. The prevalence of RHD has been calculated to be higher in sub-Saharan Africa (5.7/1000), in aboriginal populations of Australia and New Zealand (3.5/1000), and in southcentral Asia (2.2/1000) than in developed countries (0.5/1000). AGN has, however, appeared to be triggered by only certain nephritogenic serotypes of *S. pyogenes*. The apparent clinical attack rate for epidemic infections with nephritogenic streptococci is approximately 10%. Incidences of AGN may vary between less than 1% and 10–15%. The median annual poststreptococcal AGN incidence in children has been estimated to be 24.3 per 100 000 in less-developed countries and 2 per 100 000 in more developed countries, thereby calculating an estimate of 470 000 global cases of APSGN occurrence annually, with 97% in less-developed countries. The incidence of IE has been estimated at 2–6 cases per 100 000 general population every year. Viridans and other streptococci account for at least 45% of all cases of NVE worldwide. Viridans streptococci are the most frequent cause of SBE.

Mortality

Infections, including URTI caused by *S. pyogenes* claim at least 517 000 deaths around the world annually, of which rheumatic fever-associated issues alone cause 233 000 deaths. The death rate among those who develop invasive diseases is approximately 13%. The case fatality rate due to APSGN is relatively high in developing countries, with India and Turkey reporting approximately 2% and 0.08%, respectively.

Transmission

Streptococcus pyogenes is exclusively a human pathogen. Transmission of these bacteria from animals to humans is very rare, but human strains are more likely to infect animals (reverse zoonosis) instead. The main routes of GAS entry are oral, respiratory, and percutaneous. Food handlers, who are symptomatic or asymptomatic carriers of this bacterium, are a major source of foodborne transmission. Ingestion of unpasteurized milk, a variety of milk products, RTE foods, such as cold salads and meats contaminated with this organism, has emerged as one of the leading portals of entry of GAS. Sharing of foods, drinks, or related utensils (glasses, cups, etc.) may spread the pathogenic bacteria among individuals. *S. equi* subsp. *zooepidemicus* is a commensal microorganism of horses, but can be transmitted to humans through ingestion, aerosols, or the skin. Consumption of unpasteurized milk (often from mastitic cows) or dairy products is strongly linked to human infections with this equine pathogen. Drinking of unpasteurized milk from cows with mastitis has been associated with severe *S. equi* infections in humans. Although extremely rare, feeding of breast milk to infants may be a portal of entry for *S. agalactiae*. Human saliva, respiratory droplets, or oral blood is now addressed as a major source of foodborne infections with VGS. Prechewing or premastication of food items or herbs can be adversely implicated in the transfer of potentially virulent streptococcal strains, including *S. pyogenes* and *S. mutans*, to infants or older children. The practice of oral prewarming or precooling of food by mothers or caregivers could also be dangerous to pediatric health. Additionally, horizontal

acquisition of these bacteria can take place via food or drink containers, baby feeding nipples, and other feeding essentials.

Foodborne Outbreaks

In 2003, an outbreak of sore throat was reported in Sätila, Sweden involving 153 people, who ate sandwich-layer cakes. *Streptococcus pyogenes* isolated from patients under medical care was found to have spread from the wounds on a caterer's fingers. Two years later a case–control study assessed foodborne epidemics of tonsillopharyngitis among residents of female dormitories in Iran. When the study was conducted in a dormitory, 11 ($n=17$) throat swabs from students as well as 2 throat samples from the asymptomatic cooks tested positive for GAS. Deoxyribonucleic acid (DNA) fingerprinting revealed that the prevalence of GAS in those students was due to transmission of the identical strain from a cook. A similar occurrence was detected among inmates of a rural correctional center in New South Wales, Australia in December 1999. Curried egg rolls contaminated with GAS by food handlers were suggested to be implicated in the outbreak. Moreover, seven foodborne outbreaks caused by GAS pharyngitis have been reported in Japan since the late 1990s. An outbreak of scarlet fever due to chicken meat has occurred in China. Incidences of infections with groups C and G because of ingestion of different food products, especially unpasteurized milk or milk products have also been recorded sporadically. Consumption of fresh goat cheese contaminated with *S. equi* subsp. *zooepidemicus* has been associated with a recent outbreak in Finland. In Hong Kong, several cases have been related to group C infection resulting from eating raw or cooked pork. One large epidemic of severe acute nephritis in Brazil was linked to consumption of unpasteurized cheese, which had been contaminated with *S. equi* subsp. *zooepidemicus*. Three casualties out of 133 confirmed cases died, whereas 7 required dialysis and 96 were hospitalized. In two unrelated episodes of pharyngitis, an egg salad and a chicken salad separately have been incriminated as the sources of infection with GGS. These events resembled group A pharyngitis, except the typical sequelae.

Factors of Vulnerability

People of all ages are prone to infections with BHS in general. No age or race susceptibilities have been observed. However, school-aged children are a priority risk group. The frequency of pharyngitis in adults may be influenced by season, epidemiological background, domestic exposure to vulnerable children, and age. Elderly or immune-arrested individuals are highly susceptible to these infections. Predisposing conditions, such as skin lesions, burns, and wounds play an important role in the spread of the disease. Adults are, however, at least risk of a first attack of ARF, even if they have an undiagnosed or untreated episode of streptococcal pharyngitis. Other possible factors may comprise climate, indoor crowding, low-economic status, poor hygiene, and general attitude to prophylaxis. ARF has been determined as a particular problem among low-income communities with poor living conditions. RHD usually impacts children. Similarly, AGN is more common in children than adults. Males are twice as much susceptible to APSGN as females. Diabetes mellitus and aging are prime risk factors for adult APSGN. NVE is most likely to attack individuals with damaged heart valves or the history of endocarditis. Localized or systemic injury may also reduce host resistance. Prolonged use of high sugar-containing milk, juice, or liquid, or intake of high caries-risk diet may contribute to the occurrence of dental caries. Clinical oral health practices, including dental prophylaxis, tooth extraction, and gingival surgery, are considered a significant risk factor for NVE. Intravenous drug abuse greatly increases the option for an endocardiac attack.

Analytical Methods

First-step diagnosis of infections with streptococci depends largely on the characteristic clinical phenomena presented by the infected individual. A rapid antigen detection test (RADT) can be done to determine streptococcal pharyngitis. Laboratory detection methods initially involve isolation of *Streptococcus* strains (culture) from specimens (i.e., throat swab, blood, sputum, and food, as appropriate), and classification based on the hemolytic property. Gram staining is still considered a landmark tool for the definitive identification of the type of bacteria involved. Serological detection is performed by the precipitin test or enzyme-linked immunosorbent assay to confirm precise Lancefield group antigen. Biochemical tests are helpful in presumptive screening for phenotypic properties of the bacteria. Group A can be differentiated from other BHS by bacitracin sensitivity and PYRase production (note: other than group A, all enterococci synthesize this enzyme). Hippurate hydrolysis and Christie–Atkins–Munch-Petersen (CAMP) reaction separate group B from A. **Table 1** represents typical biochemical characteristics of different groups of streptococci. Identification of rheumatic fever and glomerulonephritis is performed by antistreptococcal antibody titers. Antistreptolysin O and anti-DNase B titers are important markers for the recognition of these late sequelae. However, age and geographic locale of the patient should also be taken into consideration while interpreting these values. Analysis of 16S rRNA patterns and polymerase chain reaction-based sequence amplification methods appear to be quite supportive in molecular diagnostics of streptococcal diseases. Rigorous investigations should be carried out to assess a possible foodborne outbreak of streptococcal pharyngitis. Certain DNA fingerprinting techniques, such as pulse-field gel electrophoresis can be a useful tool to determine primary sources of infection. Phage typing methods provide further insight into the status of specific streptococcal strains during epidemiological studies.

Control/Preventive Measures

Incidences of streptococcal pharyngitis can be reduced by avoiding common exposure to potential hazards. Improvement of personal hygiene and living standards may also slash the frequency of occurrences. Food-processing industries and food service providers must ensure aseptic packaging/

Table 1 Biochemical features of different groups of *Streptococcus*

Group	*Hemolysis*	*PYRase*	*Bacitracin*	*Hippurate*	*CAMP*	*Bile*	*Optochin*	*NaCl*
A	β	Positive	Sensitive	Negative	Negative	No growth	Resistant	Intolerant
B	β, α-prime	Negative	Resistant	Positive	Positive	No growth	Resistant	Variably intolerant
C	β, γ	Negative	Resistant	Negative	Negative	No growth	Resistant	Intolerant
D	α, γ	Negative	Resistant	Negative	Negative	Growth	Resistant	Intolerant
G	β	Negative	Resistant	Negative	Negative	No growth	Resistant	Intolerant
V	α, γ	Negative	Resistant	Negative	Negative	No growth (except *S. mutans*)	Resistant	Variably intolerant
P	α	Negative	Resistant	Negative	Negative	No growth	Sensitive	Intolerant

handling of all food products. Regular cleaning of food contact surfaces is also necessary in mass catering facilities. Infected food handlers should be identified and restricted from access to all aspects of consumer service. Boiling or pasteurization of milk before consumption or commercial distribution is highly recommended. A negative response to all categories of uncertified RTE food products outside home may aid in significant prevention of many streptococcal outbreaks. Prechewing or prewarming/cooling of food or drinks fed to children needs to be discouraged. Mothers should relinquish kissing babies on their lips because of the extreme possibility of salivary transfer of streptococci. Acquisition of streptococcal infections in all age groups can be at least partly prevented by ceasing to share foods, such as ice cream and bottled beverages. Reduced tendency to carbohydrate-rich diet and adequate attention to oral heath may effectively decline complaints of dental caries.

Easily approachable laboratory facility will encourage people about diagnosis of GAS infections. Strict action plans for infection control and surveillance of compliance can prevent possible spread of *S. pyogenes* or other strains of streptococci within the healthcare facility. Public alertness through health education and pragmatic training to health workers as well as caregivers will support the alleviation of streptococcal disease burden. Early diagnosis, detection, and treatment of underlying conditions in patients, particularly vulnerable individuals, are likely to help minimize post-streptococcal complications and mortality.

Antimicrobial therapy has been found to be quite impressive in controlling group A infections. Penicillin, as a gold standard therapy, shows great efficacy in preventing rheumatic fever. According to the guideline by the Infectious Diseases Society of America, penicillin or amoxicillin is recommended as the preferred treatment for GAS pharyngitis. Clindamycin is suggested to those hypersensitive to penicillin. Supportive treatment of clinical symptoms benefits management of residual damages triggered by streptococcal infections. Traumatic dental procedures should be accompanied by appropriate prophylaxis. Tonsillectomy does not appear to be efficient in limiting the spread of GAS.

Development of a GAS vaccine has always been frustrating to researchers because of the widespread diversity of M protein group A serotypes. However, efforts are being made to find a suitable vaccine candidate. Several modified prototypes of GAS vaccine have recently undergone some clinical trials. WHO is developing standard protocols for monitoring the efficacy of these vaccines.

Research Avenues

Association of diverse GAS seropathotypes with multilatitudinal occurrences clearly suggests that a major antigenic shift is directly responsible for the emergence of new virulence strains. Therefore, it is important to know the underlying genetic configuration associated with such molecular diversity. Furthermore, determination of bona fide incidences of streptococcal pharyngitis due to ingestion of contaminated food is a prerequisite for the epidemiological assessment of the specific disease burden and relative nature of *Streptococcus* virulence.

Glossary

Case fatality rate (CFR) CFR (case fatality rate or case fatality ratio) is the proportion of fatalities within a selected population over the course of the disease. CFR is typically stated as a percentage and signifies a measure of risk.

Cholera toxin (CT) The cholera toxin (CT) secreted by *Vibrio cholerae* is an oligomeric complex composed of six protein subunits: a single enzymatic A subunit and five receptor binding B subunits.

GM-1 ganglioside GM1 is a prototype ganglioside (monosialotetrahexosylganglioside) and its oligosaccharide groups extend beyond the surfaces of the intestinal cell membrane. These carbohydrates act as specific receptors for cholera toxin secreted by *V. cholerae*.

Horizontal gene transfer Transfer of genes (also known as lateral gene transfer) between bacterial cells through transformation, conjugation, transduction etc., which can be detected by analysing G + C contents, codon usage, amino acid usage, and gene position.

Lateral flow system A type of capillary based sandwich immunochromatographic assay with built-in controls for the rapid detection of a pathogen or antibodies from liquid clinical specimens used for medical diagnostics.

Ligated rabbit ileal loop An *in vivo* technique used in the confirmation of enterotoxins produced by diarrheagenic bacteria. The sterile culture supernatant from the test organisms is inoculated into a ligated segment of ileum may induce the onset of intestinal fluid accumulation as early as 4–18 h due to elevated cyclic adenosine monophosphate.

Quorum sensing A system of stimulus and response that can be directly correlated to the population density of *V. cholerae* or any other bacteria. *V. cholerae* generally use quorum sensing to coordinate gene expression according to the cell density either in the gut or in the aquatic environment.

Rugose *V. cholerae* The rugose variant forms of *V. cholerae* have corrugated colonies, well-developed biofilms and exhibit increased levels of resistance to osmotic and oxidative stresses. *V. cholerae* can undergo phenotypic variation in response to environmental stresses, resulting in rugose and smooth colonial variants phase.

Toxigenic *V. cholerae* *V. cholerae* strains that produce cholerae toxin and the infection caused by these strains are characterized by a severe watery diarrhea due to the effect of this toxin. Generally, *V. cholerae* O1, O139 and some of the non-O1 and non-O139 strains belongs to this group.

Introduction

Toxigenic *Vibrio cholerae* that produces cholera toxin is responsible for the deadly disease 'cholera,' which is coded as 001 in the International Classification of the Diseases. *Vibrio cholerae* is well-known as a waterborne pathogen and is also increasingly recognized as the cause of foodborne infections. Its close association with marine fauna and flora leads to transmission of diarrhea through seafood. Like other foodborne pathogens, transmission of *V. cholerae* occurs through secondary contamination coupled with its long-term survival in foods. In the US, the estimated illness caused by toxigenic *V. cholerae* is approximately 54 per year and the foodborne transmission is 90%. The ecological fitness and change in the genomic constitution by horizontal gene transfer makes the organism robust to meet the challenges posed by the environment as well the host's defense mechanisms. Successive appearance of classical and El Tor biotypes, emergence of a novel serogroup O139, and acquisition of some of the classical biotype features by the recent El Tor strains are the important events in the changing epidemiology of cholera. Improper control measures and deteriorating status of drinking water, sanitation, and hygiene in many developing countries will perpetuate the disease cholera.

This article will focus on the clinical microbiology, epidemiology, pathogenesis, and molecular aspects of *V. cholerae*.

Historical Outline

Toxigenic *V. cholerae* has been associated with cholera, a devastating diarrheal disease which occurs in the form of epidemics and pandemics. There is no clear indication when and where the disease cholera originated. Based on the disease symptoms it appears that cholera was rampant in many parts of the world around the sixteenth century. The period from 1817–1961 was described as the history of the seven pandemics (Table 1) and each pandemic affected almost all the countries in the world. The duration of each pandemic was

 doi:10.1016/B978-0-12-378612-8.00117-7

Table 1 Details of seven cholera pandemics

Pandemic	*Period*	*Number of years prevailed*	*Approximate number of affected countries*
1	1816–26	11	21
2	1829–51	23	36
3	1852–60	9	37
4	1863–75	13	46
5	1881–96	16	24
6	1899–23	25	24
7	1961–till date	>49	Ongoing

not uniform, as the pandemicity was based on the intensity rather than the extent of time. The classical biotype was involved in sixth and seventh pandemics. Although strains of the El Tor biotype caused sporadic infections and cholera epidemics as early as 1910, it was not until 1961 that this biotype was recognized as the causative agent of seventh cholera pandemic. Though *V. cholerae* was first visualized by Pacini in 1854 and then by Koch in 1884, the virulence properties of this pathogen remained unknown for many years. In 1959, S.N. De first showed that the enterotoxin produced by *V. cholerae* evokes fluid accumulation when cell-free filtrates are tested in ligated rabbit ileal loops. Later this toxin was purified to homogeneity and named as choler toxin (CT).

A novel *V. cholerae* serogroup O139, synonym Bengal, was identified in 1992 from the Indian subcontinent which spread to other Asian countries in the following years. Emergence of O139 serogroup was considered as the beginning of eighth pandemic, but due to its slow disappearance from late-1990s in many countries, this view was not considered. Extension of El Tor biotype from the Indian subcontinent and Haiti to the continents of Africa and subsequently South America makes the seventh pandemic both temporally and spatially the longest and most widely spread pandemic of cholera.

Taxonomy and Characteristics of *V. cholerae*

Vibrios belong to the large bacterial class *Gammaproteobacteria* within the phylum *Proteobacteria*. The family *Vibrionaceae* consist of seven genera and the genus *Vibrio* has more than 50 species of which 11 are of clinical importance including *V. cholerae*. The somatic O antigen is heat-stable and is composed of an amino acid sugar D-perosamine (4-amino-4,6-dideoxy-D-mannose) in which the amino groups are acylated by 3-deoxy L-glycero-tetronic acid. The different O groups are referred to as serogroups. For serogrouping, only the somatic (O) antigen is used, as the flagellar (H) antigen is homogenous in all the *Vibrio* species. The two serogroups, O1 and O139, are associated with epidemic cholera and linked to its ability to produce CT, the main toxin responsible for the disease. Based on the three antigenic factors designated A, B, and C, the O1 serogroup is divided into three serotypes; Inaba, Ogawa, and Hikojima. Ogawa strains produce the A and B antigens and a small amount of C, whereas Inaba strains produce only the A and C antigens. The rare Hikojima subtype contains all three factors, thereby reacting with both Inaba and Ogawa antisera. Inaba strains are mutant of the Ogawa O antigen encoding gene *rfbT*, and the conversion from Ogawa to Inaba may be due to the antiOgawa immune selective pressure.

Vibrio cholerae O1 is classified into two biotypes, classical and El Tor. The characteristics used to distinguish the biotypes are hemolysis, agglutination of chicken erythrocytes, Voges–Proskauer reaction, inhibition by polymyxin B (50-U), susceptibility to classical IV, and El Tor V phages. After the emergence of the O139 serogroup, the isolates that were identified as *V. cholerae* on the basis of biochemical tests but that were negative for O1 and O139 serogroups are referred to as non-O1, non-O139 strains. The non-O1 *V. cholerae* was previously referred to as noncholera vibrios or non-agglutinable vibrios. On the basis of the differences in lipopolysaccharide somatic antigens, this large group has been divided into more than 200 serogroups. Phage typing of *V. cholerae* O1 and O139 are not much in use as this assay is confined only to the Reference centers.

Clinical Symptoms of *V. cholerae* Infection

Human volunteer studies demonstrated that 10^3–10^4 of *V. cholerae* O1 administered with sodium bicarbonate buffer (to neutralize the stomach acidity) develop diarrhea and the lower inocula correlated with a longer incubation period and decreased stool volumes. Food has a buffering capacity comparable to that of sodium bicarbonate, thereby increasing the chances of infection when contaminated food/water is consumed. Patients infected with CT-producing *V. cholerae* (mainly O1/O139 serogroups) develop the most severe clinical manifestations of the disease, termed cholera gravis. Depending on the inoculum size, the incubation period of the infection varies between few hours up to 5 days. The main symptoms include vomiting, profuse effortless watery diarrhea (500–1000 ml h^{-1}), anorexia and abdominal cramps due to hypokalemia at the acute stage. This stage may rapidly lead to tachycardia, hypotension, and vascular collapse due to dehydration. The other external symptoms include weak peripheral pulses, poor skin turgor, sunken eyes, wrinkled hands and feet. Signs of dehydration can be detected with higher plasma protein concentration, hematocrit, serum creatinine, urea nitrogen, plasma specific gravity, severe acidosis manifested by depression of blood pH and plasma bicarbonate and an increased serum anion gap. Owing to prolonged circulatory collapse, ischemic renal tubular necrosis may also be seen. Children may develop hypoglycemia with coma and convulsions.

The nontoxigenic *V. cholerae*, mostly belong to the serogroups other than O1 and O139, but cause milder diarrhea commonly known as gastroenteritis. The non-O1 non-O139 strains are also associated with invasive extraintestinal disease, septicemia, formation of ascites with generalized abdominal tenderness and high white blood cell count (WBC) with polymorphonucleocytes. Compared with patients with nonbacteremic infections, patients with non-O1, non-O139 bacteremia are more likely to have cirrhosis and thrombocytopenia.

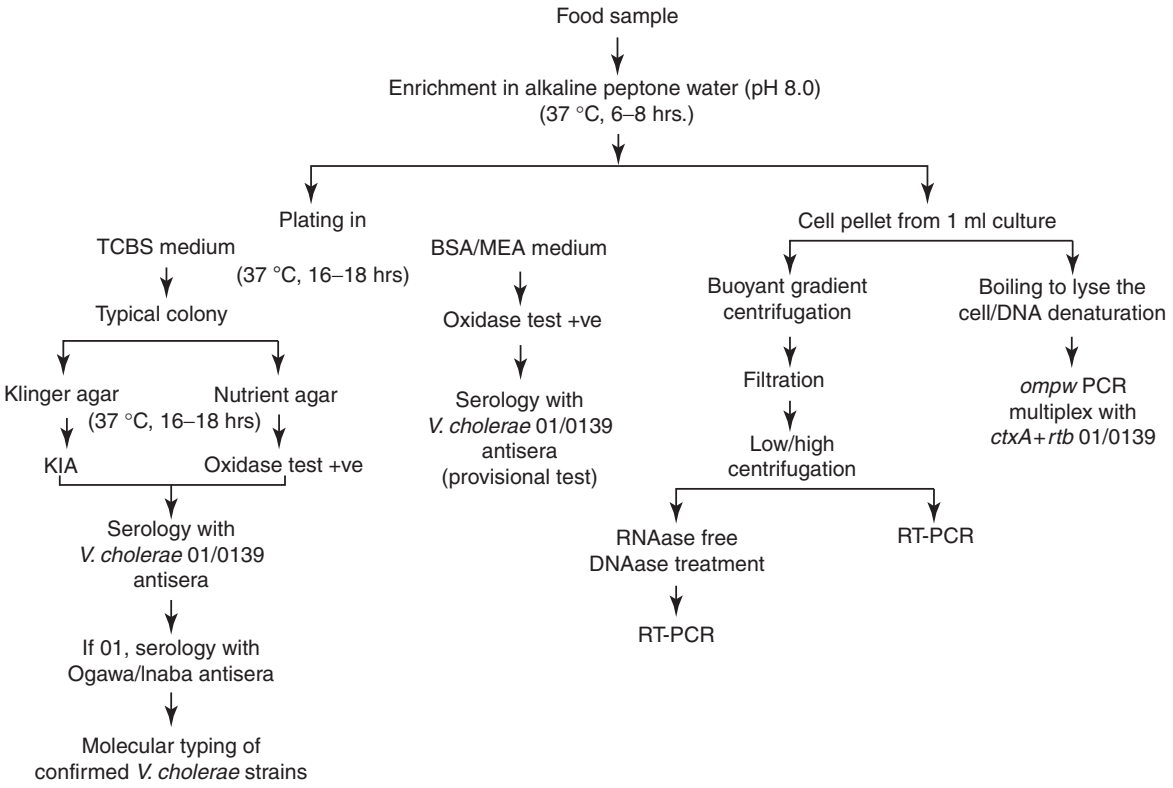

Figure 1 Flow chart showing the isolation and identification of *V. cholerae* from foods using culture and molecualr methods. BSA, bile salt agar medium; KIA, Klinger iron agar; MEA, meat-extract agar; PCR, polymerase chain reaction; RT-PCR, real-time polymerase chain reaction; TCBS, thiosulphate-citrate-bile salts-sucrose.

Detection Methods

Culture Methods

A stepwise method for the isolation and identification of *V. cholerae* is shown in Figure 1. Unlike clinical stool specimens, the concentration of *V. cholerae* in food samples may not be very high and hence an enrichment step is essential. Alkaline peptone water (APW) is the most commonly used enrichment broth with alkaline pH (8.4–9.2). Usually, enrichment lasts for 6–8 h at 37 °C, as excess incubation in APW may result in overgrowth of other organisms. If the plating cannot be done within this stipulated time, a secondary enrichment in APW is necessary to inhibit the growth of background organisms. The most commonly used plating medium for *V. cholerae* is thiosulfate-citrate-bile salts-sucrose (TCBS) agar, which is available from several commercial sources. The sucrose fermenting *V. cholerae* isolates are readily detected on this medium as large, golden yellow, smooth colonies (Figure 2). For the presumptive identification, nonselective media such as bile-salt agar (BSA) and meat-extract agar (MEA) can be used in parallel with the TCBS agar. But these nonselective media are not commercially available. Selective media that are being used for the isolation of members of the family *Enterobacteriaceae* are not suitable for isolation of *V. cholerae*.

For routine identification of suspected colonies, few biochemical tests are mandatory. Either conventional tests or commercial systems can be adopted for identification and the tests should be very simple, rapid, and specific. A crucial test for distinguishing *V. cholerae* from members of the *Enterobacteriaceae* is the oxidase test, in which, *V. cholerae* gives a positive response. Fresh colonies obtained directly from BSA or MEA agar can be used for oxidase test and growth from TCBS agar should not be used. Suspected *V. cholerae* colonies from the isolation plate can also be tested in the Kligler iron agar (KIA)

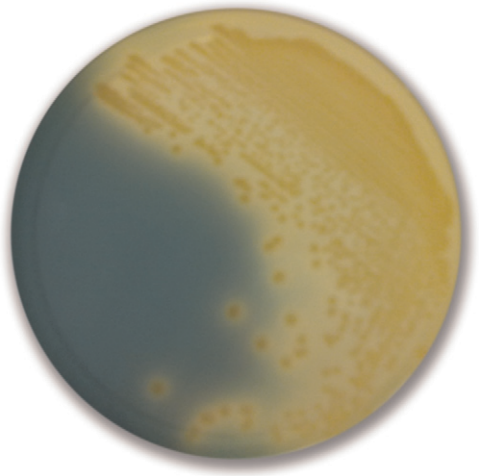

Figure 2 Typical sucrose fermenting colonies of *V. cholerae* in TCBS medium after 16 h of growth at 37 °C.

medium for confirmation. Typical *V. cholerae* yielding an alkaline slant over acid but with no gas or H_2S are then tested for oxidase activity. The key confirmation of *V. cholerae* O1/O139 is agglutination with antisera raised against the respective serogroup. Confirmed O1 strains should be tested with Ogawa and Inaba antisera for completion of the serological testing. Satisfactory serological results can be obtained from colonies picked from nonselective media or KIA medium.

Immunological Methods

Several direct methods are available based on antigen–antibody reactions for the detection of *V. cholerae* O1 and O139 either by using stool specimens or enriched cultures of food samples. Fluorescent antibody technique, coagglutination tests, and lateral flow-based detection systems for the detection of O1 or O139 are now commercially available. Cholera SMART kit (New Horizons Diagnostics Corp, USA) and Crystal VC (Span Diagnostics, India) are colloidal gold-based lateral flow immunoassay for the detection of *V. cholerae* O1/O139 strain within 10–20 min. At times, it is crucial to confirm production of CT by *V. cholerae*. With tissue culture assay employing Chinese hamster ovary or Y-1 adrenal cells elongation cells caused by the action of CT which can then be confirmed by neutralization of the activity using antiCT antibody. Enzyme-linked immunosorbent assay (ELISA) using purified ganglioside M-1 (GM1) as the capture molecule or a highly sensitive bead ELISA, which uses polystyrene beads coated with antiCT antibody as the solid phase are being used in many reference laboratories. A latex agglutination for the detection of CT is less time-consuming than the ELISA, with excellent sensitivity and specificity. For the detection of *V. cholerae* O1 from foods, an enzyme immunoassay has been formulated with specific rabbit antiserum, immobilized target bacterial cells and beta-D-galactosidase-labeled goat antirabbit immunoglobulin G as tracer. Animal models are also available for confirmation of CT-producing strains of *V. cholerae*, but these models are prohibitive as one cannot accommodate many strains in the assay in addition to the animal ethical issues.

Molecular Methods

For screening larger number of isolates, deoxyribonucleic acid (DNA) and oligonucleotide probes are useful as it reduces the labor and screening time. The molecular approach confirms *V. cholerae* as pathogenic strains if the DNA probes are targeted toward virulence genes such as CT encoding gene (*ctx*). Molecular methods are routinely used in food industry because majority of the *V. cholerae* strains isolated from environmental and food are nonpathogens as they lack recommended virulence marker genes. Polymerase chain reaction (PCR) technique has also been used to detect *ctx* or other virulence gene sequences. Several PCR methods are now available using multiplex format with virulence genes along with species-specific targets such as *ompW* and biotype-specific *tcpA* or *hlyA*. Detection of these genes directly from the stool or food samples is not advisable as the sample may contain substances that can be inhibitory to the PCR. To overcome this hindrance, extraction of DNA/RNA (ribonucleic acid) from the samples is recommended following quick extraction protocols, which are now available in the form of silica column or quick spin purification kits. PCR can amplify target DNA from both viable and nonviable cells of *V. cholerae*. Detection of pathogens in clinical and food samples is important to ensure that positive test results are associated with viable bacteria. Positive results caused by dead cells may lead to misguided decisions concerning the effectiveness of treatment and destruction of the suspected foods.

Combination of multiplex PCR with a colorimetric microwell plate sandwich hybridization assay using phosphorylated and biotinlylated oligonucleotide probes are specific and sensitive for the detection of the microbial pathogens in shellfish. Immobilized oligonucleotide array that targets mutation regions of the 23S rRNA gene or amplified PCR products are being used for the identification of bacteria causing foodborne infections including *V. cholerae*. Similarly, DNA microarray-based identification system in combination with multiplex PCR targeting *ompU*, *toxR*, *tcpI*, and *hlyA* is also available for the detection of *V. cholerae*.

Real-time PCR (qPCR) assay that identify the *ctxA* or any other marker gene from viable toxigenic *V. cholerae* can also be adopted as an alternative method for standard culture methods. Before real-time quantitative PCR, buoyant density gradient centrifugation followed by filtration and low- and high-speed centrifugation is recommended to separate bacteria from complex food materials as well as to remove compounds that inhibit rapid detection methods. Loop mediated isothermal amplification PCR assay that was designed with five primers targeting *ompW* seems rapid and specific in detection of *V. cholerae*. Unlike normal PCR, there is no cycling process involved in this technique. Detection of viable but nonculturable (VBNC) state of *V. cholerae* O1 is difficult with the existing molecular methods. The transcriptome-based RT-PCR analysis detects increase in the expression mRNA of VC0230 (iron(III) adenosine-triphosphate-binding cassette (ABC) transporter), VC1212 (*polB*), VC2132 (*fliG*), and VC2187 (*flaC*) in the VBNC state. Thus, these genes appear to be suitable markers for the detection of *V. cholerae* VBNC.

Virulence Features and Pathogenicity of *V. cholerae*

CT is directly responsible for the characteristic symptoms of cholera. The pathogenesis of cholera begins with colonization of toxigenic *V. cholerae* in the upper intestine and secretion of CT. This toxin is composed of two types of subunits, a 56-kDa oligomer composed of five identical 'light' B subunits ('B' for binding) responsible for receptor binding and a single 'heavy' 28-kDa toxic active A subunit ('A' for active toxin). Monosialoganglioside GM1: (Gal(β1–3)GalNac(β1–4)(NeuAc(α2–3)Gal(β1–4)Glc)-ceramide acts as a cell membrane receptor for CT. First, the CT binds to the GM1 receptors on host cells through its pentamer B subunit followed by translocation of A subunit to the cytosol of the target cell. The A subunit catalyzes the adenosine diphosphate (ADP)-ribosylation of the host G protein Gsα, which in turn activates host cell adenylate cyclase. This is accomplished by elevating cAMP levels in intestinal cells through the activation of a G-protein (Gsα) that controls host cell adenylate cyclase activity. The cyclic adenosine

monophosphate (cAMP) that accumulates in target cells activates protein kinases, which in turn phosphorylate membrane proteins one of which is the cystic fibrosis transmembrane conductance regulator chlorine and bicarbonate conductance channel. Active Cl^- and HCO_3^- transport into the lumen of the intestine produces an osmotic movement of water out of the tissues resulting profuse secretory diarrhea.

V. cholerae non-O1, non-O139 serogroups (otherwise known as noncholera vibrios are ubiquitous in the aquatic environment and fauna living therein. The reported asymptomatic carriage rate is approximately 4% among persons involved in high-risk activities and their contribution in several outbreaks have been published in many findings. Unlike O1 and O139, the non-O1, non-O139 serogroups does not appear to be a single virulence mechanism similar to the heterogeneity seen among diarrheagenic *Escherichia coli*. The pathogenic mechanisms of non-O1, non-O139 serogroups are different from that of O1 and O139 serogroups as they lack the *ctx* gene cassettes but heat-stable enterotoxin (Stn), El Tor-like hemolysin (Hly) plays a role in human pathogenesis. Clinical strains of *V. cholerae* rarely carry the heat-stable enterotoxin encoding genes (*stn/sto*) but sequence type (ST) positive strains are detected in high proportions with environmental *V. cholerae* O1, O139, and non-O1/non-O139 strains. Type three secretion system is one of the other possible virulence factors commonly found in non-O1, non-O139 serogroups (30–40%). Prevalence of putative accessory virulence genes (*mshA*, *hlyA*, and *RTX*) both in the clinical O1/O139 serogroups as well as non-O1, non-O139 serogroups supports a hypothesis that these genes impart increased environmental fitness. Hemagglutinin/protease and mannose-sensitive hemagglutinin are the other possible virulence factors among non-O1, non-O139 vibrios. In several instances, it was shown that the non-O1, non-O139 serogroups carry *ctx* and associated with cholera-like diarrhea. Considering the importance of non-O1/non-O139 *V. cholerae* isolated from the aquatic environment or food samples they should be screened for the presence of *ctxA*, *stn/sto*, *tcpA*, and other virulence marker genes for the human health risk assessment.

Risk Factors and Reservoirs

Several risk factors have been identified for the prevalence and spread of cholera, which include population displacement and refugee crisis, heavy rain and floods, traditional funeral rituals and feasts, water storage in large mouthed containers, ice made up of contaminated water, lack of previous disease exposure in endemic regions, asymptomatic carriers/food handlebars, etc. *Vibrio cholerae* is ubiquitous in the water and sediments of various aquatic water bodies including costal, estuarine, and freshwater systems. Because of its widespread distribution, foods are easily contaminated at various levels of food preparation. The distribution of non-O1, non-O139 vibrios is very common in these environments. Isolation of O1 and O139 from the environments is reported during epidemic and interepidemic periods due to fecal contamination. Overall, the most commonly noted risk factor for cholera outbreaks was transmission through foods that account for 32 and 71% in South America and East Asia, respectively. In several reports, seafood is responsible for many sporadic cases and epidemics of *V. cholerae* infections and strains are generally devoid of *ctx*. The exoskeleton chitin of copepods, shrimps, and crabs are made up of mucopolysaccharide, a preferential substrate of *V. cholerae* that enhances adherence through their production of chitinase.

Survival Strategies

Quorum sensing helps the bacteria for cross communication and alters their gene expression in concordance with several ecological factors. In several findings it was shown that quorum sensing is important in the infectious cycle of *V. cholerae* in humans and passage through acid barriers in the stomach. The colonized cells of *V. cholerae* O1 on shrimp carapace showed remarkable resistance to the effects of high temperatures, low pH, and desiccation conditions. This increased resistance to extreme environmental conditions of *V. cholerae* O1 may have significant implications on food safety and contamination of edible parts of shrimps. It has been suggested that its environmental persistence is associated with conversion of *V. cholerae* into VBNC state or rugose type and these forms of *V. cholerae* enhance their survival in many adverse conditions. It is noteworthy to mention here that the rugose variants can survive in the presence of high concentrations of chlorine and other disinfectants.

Epidemiology Cholera with Reference to Contamination of Foods

In cholera endemic countries, the case fatality rate (CFR) remains $<5\%$ but in some African countries the CFR is approximately 50% during peak outbreak periods. In many cholera outbreak investigations, water was recognized as the primary source for transmission. In the past 60 years, outbreaks of cholera have been documented with consumption of contaminated food. Transmission of cholera may vary from place to place, influenced by local customs and practices. Molluscan and crustacean seafood are generally contaminated in its natural environment at the time of harvest or during preparation. Food items initially free from *V. cholerae* may become contaminated when mixed with water, other contaminated food, or through foodhandlers.

In Guatemala, the 1991 cholera epidemic was significantly associated with contaminated street-vended food items. Foodborne outbreaks of cholera occur mostly in developing countries and have potential cause of large morbidity and mortality that require considerable public health and acute care resources. Storing contaminated meals at ambient temperatures, the common practice in most of the developing countries, allows the growth of *V. cholerae*. Many epidemiological studies have shown that food plays an important role in the transmission of *V. cholerae*, and different foods have been incriminated in many epidemic outbreaks of cholera.

The Guinea-Bissau cholera epidemic in 1994 that resulted in 15 878 reported cases and 306 deaths was strongly associated with eating at a funeral with a nondisinfected corpse. A huge cholera epidemic in western Kenya in 1997 with 14 275 cholera admissions and 547 deaths was due to use of contaminated water from Lake Victoria or from a stream, sharing food with a person with watery diarrhea, and

attending funeral feasts. Ingestion of undercooked, contaminated fish has long been known to be associated with cholera transmission. Household epidemiological studies indicate that cholera infection is more likely to occur through patient's/carrier's hands rather than by consumption of contaminated foods. Undercooked seafood continues to account for most US cholera cases. In majority of the cases, *V. cholerae* non-O1, non-O139 is involved in the seafood associated cholera-like diarrheal infection and asymptomatically infected foodhandlers play a great role in the transmission of cholera. Travelers to epidemic countries may be at increased risk of contracting cholera if they ingest contaminated food or water. It has been estimated that approximately 0.2 cases per 100 000 European and North American travelers suffer from cholera without any fatalities. Violations of retail food establishment rules and regulations, and underutilization of safer, post-harvest processed shellfish resulted in significant increase in the incidence of *V. cholerae* mediated infections in the USA.

Molecular Typing Methods

Molecular typing has become an essential component to compliment epidemiological data, and hence many methods have been established for the identification of DNA finger prints of *V. cholerae*. Following are some of the currently used methods in the molecular epidemiology of cholera.

PCR-Based Typing

Though PCR is used for the detection of several virulence encoding genes, this assay is also employed for strain typing in which DNA fragments can be amplified (100–>35 kb) even if the template DNA is in minute quantity. Several PCR methods such as random amplification of polymorphic DNA (RAPD) with the use of single oligo, amplified fragment length polymorphism (AFLP) technique with two sets of restriction enzyme-primer combinations, enterobacterial repetitive intergenic consensus sequence that targets arrangements of conserved sequences in most of the bacteria are used in typing *V. cholerae*. The advantage of such PCRs is that they can be used in laboratories with minimal facility. Several studies performed with RAPD-PCR using *V. cholerae* O1 has shown the genetic dissimilarity in many Asian and African countries. The AFLP analysis supported that a single clone of pathogenic *V. cholerae* has caused several cholera outbreaks in Asia, Africa, and Latin America during the seventh pandemic. Generally, PCR assays are rapid and simple means of typing strains for epidemiological studies. However, consistency of the results of PCR is subject to various experimental parameters such as concentrations of the template DNA, Taq polymerase enzyme, annealing temperature, and number of PCR cycles.

Mobile Genetic Elements

Mobile genetic elements (MGE) such as plasmids, integrons, and integrating conjugative elements are used in molecular typing of *V. cholerae*. This is not a routine fingerprinting method, but it gives information on movement of antimicrobial resistance genes in *V. cholerae* strains as they are mostly located in MGEs. Conjugative plasmid IncC was found to be responsible for multidrug resistance in *V. cholerae* O1 associated with many cholera outbreaks in Africa. Integrons, the gene capture and expression systems and integrating conjugative elements which are chromosomal self-transmissible MGEs are specifically detected in El Tor strains indicating they may be considered as a recent evolutionary trend.

CTX Prophage and CT Genotypes

Analysis of CT prophage is important to determine the evolution of toxigenic strains of *V. cholerae*. The CT encoding gene (*ctxAB*) reside in the genome of a lysogenic filamentous phage known as CTXΦ, which is located on a 4.5 Kb 'core region' of the CTX element (Figure 3). Adjacent to the core is the RS2 region encoding open reading frame (ORF) *rstR*. Based on the allelic types, the *rstR* is classified as $rstR^{class}$, $rstR^{ET}$, and $rstR^{calc}$, respectively for classical, El Tor, and O139 strains. Using *ctx* restriction fragment length polymorphism (RFLP), the structure, organization, and location of the CTX prophages can be determined. Identification of distinct strains of *V. cholerae* O1 belongs to biotype classical and El Tor, and O139 demonstrates the evolutionary significance and clonal dynamicity of the pathogen (Figure 3).

RFLP, the structure, organization, and location of the CTX prophages were identified in many *V. cholerae* O1 as well O139 strains isolated from different geographical regions. The unique clonal nature of the US Gulf Coast *V. cholerae* O1 was identified with 6–7 kb *Hin*dIII restriction fragments that contained *ctx* gene. Unlike classical or El Tor vibrios, the assembly of *ctx* in O139 strains differed with three or more copies of this gene. The CTX genetic element was different in *V. cholerae* O139 strains that resurged in Calcutta and Bangladesh in 1996, China, from 1993–99. Of recent *V. cholerae* O1 Inaba from India, presence of CTX prophage was detected in a single site of the chromosome with at least two RS elements. Interestingly, *V. cholerae* O1 El Tor isolated from Mozambique carried a classical type (CTX^{class}) prophage and the genomic

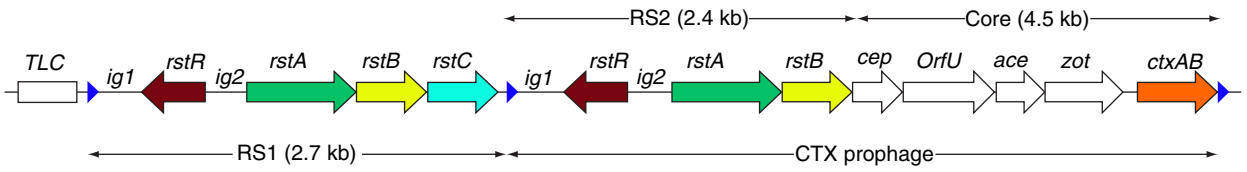

Figure 3 Typical genetic structure and arrays of CTX prophage in *V. cholerae*. Small black triangles in between the genome sequence indicate the repeat regions flanking the integrated phage DNA.

analysis of CTX prophage together with chromosomal phage integration sites showed that these strains carried two copies of prophages located in the small chromosome in tandem.

DNA sequencing of *ctxB* of *V. cholerae* O1 and O139 strains identified several CT genotypes. The CT genotype 1 was found in classical biotype worldwide and El Tor biotype strains associated with the US Gulf Coast. The El Tor strains from Australia belong to CT genotype 2 and 3 was common in the seventh pandemic El Tor strains including the Latin American epidemic strains. Emergence of El Tor strains having CT genotype 1 was reported from India, Bangladesh, Vietnam, and also from few African countries. The epidemiological significance of this trend is related to several recent cholera outbreaks with increased severity of the illness and also for a tendency for the outbreak to become protracted. Identification of new CT genotypes such as 4–6 in *V. cholerae* O139 strains in also considered as a novel genetic trend.

Ribotyping

This method exploits the DNA polymorphism of rRNA genes (*rrn*) in the chromosome of *V. cholerae* after digestion with *Bgl*I. Universal probe generated from the *E. coli* (pkK3535) RNA is used to screen the restriction patterns of bacterial DNA. The *rrn* operons and their flanking regions cause ribotype variation in *V. cholerae* O1 due to recombinational events. This typing method has identified 7 and 20 ribotypes among classical and El Tor biotypes, respectively. Analysis of *V. cholerae* O139 strains isolated in India and Bangladesh revealed four different ribotypes. *Vibrio cholerae* O1strains isolated after the emergence of O139 and reemerged O139 strains in India and Bangladesh showed newer ribotypes. This change in the ribotype profiles was correlated well with the new antimicrobial resistance patterns, which indicated successive replacement of different clones of *V. cholerae* O1/O139 in these regions.

Multilocus Sequence Typing

In multilocus sequence typing (MLST), the genetic variations of *V. cholerae* at several housekeeping genes are indexed after nucleotide amplification and sequencing. MLST data is highly suitable for software based analysis and hence can be adopted in the long-term epidemiological studies. However, standardized methods are not adopted in the MLST for the universal use, as the target genes varies from 3 to 26.

Results of split decomposition analysis of three housekeeping genes, *mdh*, *dnaE*, and *recA* showed that widespread recombination plays an important role in the emergence of toxigenic strains of *V. cholerae* O1. With the Argentinean *V. cholerae* O1 isolates, six distinct genetic lineages identified among seven housekeeping loci. The *gyrB*, *pgm*, and *recA*-based MLST analysis performed better than pulse-field gel electrophoresis (PFGE) as there was clear clustering of epidemic serogroups. MLST analysis using nine genetic loci showed that the Mozambique isolates that harbored classical CTX prophage had the ST identical to that of El Tor N16961, a representative of the current seventh cholera pandemic. However, MLST of *V. cholerae* is incoherent as many investigations did not follow the specific set of genes in the analysis.

Variable Number of Tandem Repeat (VNTR) Loci

In many housekeeping genes, the DNA regions known as VNTR are cataloged on the basis of their repeat unit. VNTR is otherwise called simple sequence repeats . This repetitive DNA contains monomeric sequences and arranged in a head-to-tail configuration. These repeat loci are highly conserved and hence the discrimination power is more compared with that of MLST. Five VNTR loci of *V. cholerae* strains collected between 1992 and 2007 from different areas in India showed that each VNTR locus was highly variable, with 5–19 alleles. The eBURST (based upon related sequence types) analysis of sequence types revealed four large groups of genetically related isolates with two groups containing O139 serogroup and the other two groups including O1strains. VNTR also helped to track the spread of specific genotypes across time and space. Genetic relatedness of *V. cholerae* collected from 2004–05 from Bangladesh showed minimal overlap in VNTR patterns between the two communities that was consistent with sequential, small outbreaks from local sources. VNTR-analysis of nontoxigenic *V. cholerae* that caused outbreak in Rostov region in 2005 showed that they differed from previous outbreaks and formed separate group with strains isolated from patients, carriers, and environment. Phylogenetic analysis of the combined VNTR data also showed a clear discrimination between the clinical O1 and O139 strains and the environmental isolates.

PFGE

PFGE has proven to be highly effective molecular typing technique for different foodborne bacterial pathogens. Database for PFGE patterns for various foodborne pathogens have been established, and being used by many PulseNet groups all over the world. PFGE was shown to be useful for the identification of spread of specific clones of many pathogens. In the PFGE, suspected sources of the pathogens have been identified, followed by implementation of timely interventions to prevent further spread of the pathogens. In the US and other countries, considerable reduction of foodborne infections was observed after the inception of PulseNet program. International PFGE typing protocol for *V. cholerae* was established for generation and submission of subtype patterns to the database.

Most of the published works shows in-house PFGE typing scheme and cannot be compared with data generated by others due to variation in several parameters. However, in the PFGE, various parameters are controllable including the electrophoretic programs. PFGE patterns of representative *V. cholerae* O1, El Tor strains from Australia, Peru, Romania, and the US were different from Asian countries, such as Bangladesh, India, and Thailand, indicating a close genetic relationship or clonal origin of the isolates in the same geographical region. In India, Thailand, Iran, South Africa, clonality of *V. cholerae* O1 tends to differ during each cholera outbreak.

In Italy and Albania, cholera epidemic occurred during 1994 after more than a decade. PFGE analysis indicated that the strains from both the countries belonged to the same clone that was part of the larger global spread of epidemic ribotype 6 strains, which started in southern Asia in 1990. PFGE-type patterns of Peruvian *V. cholerae* O1 strains isolated during 1991–95 suggest that genetic changes are occurring in Latin American cholera epidemic, more frequently than previously reported. *Vibrio cholerae* O1 strains that appeared in India after the O139 appearance had new pulsotypes in which the H type was the predominant one. Pulsotypes A–C dominated before 1992 and F type was common among the O139 serogroup. Pulsotype H was stable for a long time in India and was associated with several cholera outbreaks since 1993. This trend was the same in Bangladesh and Thailand, though the pulsotype nomenclature was different. Pulsotype IV, which was a new clone introduced after 1993 from overseas was frequently present in both domestic and imported cases from 1994 to 1997 in Aichi, Japan.

PFGE was used to identify the clonality and spread of *V. cholerae* O1 in Kenya. The PFGE profiles of Iranian *V. cholerae* O1strains were similar to that of Pakistan, Nepal, and India, suggesting the dissemination of common clones in this region. Nontoxigenic *V. cholerae* O1 strains isolated between 1998 and 2000 from Mexico differed in the PFGE patterns compared with Latin America and US Gulf Coast clones. The outbreak associated nontoxigenic *V. cholerae* O1 strains from India had more resemblance with O139 serogroup rather than classical or El Tor *V. cholerae*. The El Tor hybrid strains from Mozambique that appeared during 2004–05 are different from the Bangladeshi hybrid strains and overall the El Tor hybrid strains differed markedly from conventional classical and El Tor strains. The PFGE patterns of toxigenic O139 strains isolated from turtles in Sichuan, China, during 2004 were identical with the patterns of strains that appeared in the outbreaks, thereby indicating the sources of infection causing these outbreaks.

Prevention and Control Measures

As death occurs in 50–70% of the untreated severe cholera cases, adequate rehydration therapy in mandatory. In severe cases, rehydration can be accomplished by intravenous infusion of fluid followed by oral rehydration with oral rehydration solution (ORS). Various modifications to the standard ORS have been successfully made that include hypoosmolar or hyperosmolar solutions, rice-based ORS, zinc supplementation, and the use of amino acids, including glycine, alanine, and glutamine. The precise rates of fluid administration should be adjusted according to the patient's state of hydration and volume of the stool. Antimicrobial agents such as tetracycline and fluoroquinolones are effective in reducing the volume of the stool and duration of the diarrhea.

Preservation of foods from contamination of *V. cholerae* without spoiling their natural flavor, esthetic, and nutritive values is always a big challenge. Some of the normal practices such as addition of lime juice to foods thereby reducing pH toward acidic kills most *V. cholerae*. Many modern techniques such as high pressure processing, cold temperatures, ionizing irradiation, exposure to chlorine or iodophor, etc. decontaminates most of the vibrios. Preventive measure such as restricting the consumption of oysters during summer months, cleanliness of cutting boards, microbial monitoring of shellfish/shrimp growing areas, postharvest practices including depuration and relaying in offshore waters can reduce *V. cholerae* mediated infections.

WHO's Strategic Advisory Group of Experts on immunization recently recommended that cholera vaccination should be considered in endemic areas targeting the higher-risk population to reduce the disease burden. However, this vaccination should not interrupt the provision of other priority health interventions to control and prevent cholera outbreaks.

Two oral cholera vaccines are now available i.e., Dukoral and Shanchol and their characteristics and other details are described in Table 2. mORCVAX vaccine is basically identical to that of Shanchol, except it was made by a different

Table 2 Available oral cholera vaccines and their characteristics

Cholera vaccine	*Characteristics*	*Vaccine schedule*
Dukoral[a]	Vaccine: Monovalant vaccine with formalin and heat-killed whole cells of (1×10^{11} bacteria). *Vibrio cholerae* O1 consisting of both Ogawa and Inaba serotypes and classical and El Tor biotypes along with recombinant cholera toxin B subunit (rCTB) 1 mg Usage: Given with bicarbonate buffer, 150 ml for adults and 75 ml for children aged 2–5 years to protect the CTB Expected protection: After 7 days	2 doses $\geq$7 days apart 1 booster dose for every 2 years for adults and children $\geq$6 years. For children 2–5 years, 1 booster is recommended for every 6 months
Shanchol/mORCVAX[b]	Vaccine: Bi vaccine with formalin and heat-killed whole cells of *V. cholerae* O1 consisting of both Ogawa and Inaba serotypes and classical and El Tor biotypes along with the O139 serogroup, without cholera toxin B subunit Usage: Can be given directly without bicarbonate including children $\geq$1 year Expected protection: After 7 days	Two liquid doses 14 days apart for individuals aged $\geq$1 year with booster dose after 2 years 1 booster dose for every 2 years for adults and children $\geq$6 years. Booster dose for children for every 6 months is not required

[a]Not licensed for children aged $<$2 years.
[b]Identical vaccines in terms of *V. cholerae* strains different manufacturers using different methods.

manufacturer with different methods. The protective efficacy (PE) of Dukoral cholera vaccine was more than 80% with two doses of vaccine irrespective of the age groups. Because CTB is structurally and functionally similar to the heat-labile toxin produced by enterotoxigenic *E. coli* (ETEC), Dukoral vaccine gave 67% protection against ETEC, which is another enteric pathogen commonly found in developing countries. The PE of Shancol vaccine for all age groups after two doses was 66% and the overall effectiveness after 3–5 years was 50%. Overall, vaccination can be considered as an additional preventive tool by the health authorities to prevent cholera outbreaks and its spread to newer areas.

Information regarding cholera outbreaks and characteristics of the strains would help many clinicians and laboratory works to prevent its spread and proper management of cholera. Though official notification of cholera outbreaks by WHO Member States is mandatory under the International Health Regulations, the reporting by many countries is incomplete due to political and economical reasons that also include tourism and food export. The online forum, Program for Monitoring Emerging Diseases supported by the International Society for Infectious Diseases complements the WHO cholera reports and provides detailed information on subnational, monthly, and temporal distribution of cholera cases.

Glossary

High pressure processing A nonthermal process using water under very high hydrostatic pressure to produce packaged foods that are safer, longer lasting, more natural, and better tasting.

Kanagawa phenomenon (KP) A well-defined β-type hemolysis produced by *Vibrio parahaemolyticus* on Wagatsuma agar medium. KP considered as a marker for virulence of clinical isolates of *V. parahaemolyticus* and has been related to the production of the thermostable direct hemolysin. KP is a useful marker to distinguish pathogenic from nonpathogenic strains.

Pandemic strain of *Vibrio parahaemolyticus* Genetically defined strains with specific changes in *toxRS* region commonly seen in serovars O3:K6, O4:K68, O1:K25, and O1:KUT.

Pulsed-field gel electrophoresis (PFGE) A kind of gel electrophoresis with the voltage periodically switched among three directions; one that runs through the central axis of the gel and two that run at an angle of 120° either side. The pulse times are equal for each direction resulting in a net forward migration of the large fragments of DNA. PFGE is a gold standard technique for genotyping of pathogenic organisms in epidemiological studies.

Postharvest processing After harvesting, common food-processing technologies such as quick freezing, heat–cool pasteurization, and high hydrostatic pressure may be used to reduce pathogenic/spoilage bacteria in the oysters to nondetectable levels.

Ribotyping A standard technique for genotyping of pathogenic bacteria in epidemiological studies exploiting variation in the highly conserved structural rRNA molecules (16S, 23S, and 5S) and their copy numbers.

Thermostable direct hemolysin (TDH) TDH has been considered a major virulence factor of *Vibrio parahaemolyticus.* It is a protein toxin, which has been reported to show intestinal toxicity, cardiotoxicity, hemolytic activity, and cytolethal activity. TDH is known for its intractable property of being reactivated by heating at high temperatures.

TDH-related hemolysin (TRH) In *Vibrio parahaemolyticus*, TRH is regarded as an important virulence factor that has an amino acid sequence that is approximately 67% homologous with thermostable direct hemolysin. Also a hemolytic toxin, TRH is produced by KP-negative *V. parahaemolyticus* and is suspected of playing an important role in the diarrhea caused by this organism.

Type III secretion system (TTSS) TTSS is a protein appendage of several Gram-negative bacteria that mediate interactions with their hosts and allows bacteria to deliver protein effectors across eukaryotic cellular membranes. In pathogenic *V. parahaemolyticus*, TTSS delivers a variety of effectors directly into the host cytosol, allowing them to manipulate host cellular processes and subvert them for their benefit.

Introduction

Though commonly found as an autochthons halophilic bacterium in marine environments, *Vibrio parahaemolyticus* is known as an agent of gastroenteritis associated with the consumption of contaminated seafood. This bacterium was first identified in Japan in 1950 by Tsunesaburo Fujino from a foodborne outbreak due to the consumption of semidried sardines. Emergence of a novel clone of O3:K6 in 1995 and its subsequent spread to many countries causing several diarrheal outbreaks marked the first pandemic of *V. parahaemolyticus* infection. The global spread of this pandemic strain along with its genetically related serovars have been related to the consumption of seafood. Association of water temperature in the epidemiology of *V. parahaemolyticus* infections caused by this pathogen has been reported in many temperate regions, but no such correlation has been found in tropical countries.

Mechanisms of virulence in *V. parahaemolyticus* are well established. Strains of *V. parahaemolyticus* from environmental sources generally lack virulence gene markers. Pathogenesis of *V. parahaemolyticus* is conventionally associated with the production of thermostable direct hemolysin (TDH), which is responsible for the β-hemolysis of human erythrocytes in a special Wagatsuma agar medium. The reaction is known as the 'Kanagawa phenomenon (KP).' Other putative virulence factors are the polysaccharide capsule, TDH-related haemolysins (TRH), cytotoxins, and adherence factors. However, virulence

factors, such as TDH, TRH, or both, are associated with strains that cause infectious diarrhea. Production of TDH is associated with KP. Type III secretion system (TTSS) is a protein appendage found in several Gram-negative bacteria and help the bacteria to infect. In *V. parahaemolyticus*, two sets of genes, for TTSS1 and TTSS2, were identified on the large and small chromosomes, respectively. TTSS1 showed it to be involved in the cytotoxicity to HeLa cells, whereas TTSS2 has a role in enterotoxicity in a rabbit model. Several molecular typing techniques such as polymerase chain reaction (PCR), deoxyribonucleic acid (DNA) fingerprinting using ribotyping, and pulsed-field gel electrophoresis (PFGE) have been successfully introduced for rapid detection and spread of this pathogen from clinical specimens and suspected food samples. Several techniques have been in use for the elimination of *V. parahaemolyticus* from seafood at the industrial level. This article gives an understanding on the epidemiology, virulence features, use of different detection and typing methods, and control of *V. parahaemolyticus* in seafoods.

Taxonomy and Characteristics of *V. parahaemolyticus*

Vibrios belong to the large bacterial class Gammaproteobacteria within the phylum *Proteobacteria*. The family *Vibrionaceae* consists of 7 genera, and the genus *Vibrio* has more than 50 species, of which 11 are of clinical importance. *Vibrio parahaemolyticus* is a Gram-negative straight or curved rod-shaped facultative anaerobic bacterium, which is motile by means of a single polar flagellum. They do not form endospores or microcysts and are oxidase-positive, utilize D-glucose as a sole or main source of carbon and energy. Like other vibrios, *V. parahaemolyticus* is a halophile (salt requiring) and sodium ions stimulate their growth. This *Vibrio* can grow well from neutral to alkaline pH, therefore the pH values of both selective and enrichment media are generally adjusted from 8–8.8. pH less than 7.0 are lethal to this organism. Serotyping scheme for subspecies identification of this pathogen is well established with the combination of somatic (O) and capsular (K) antigens and serotyping is done using commercially available antisera that include 11 different O antigens and 71 different K types. Phage typing of *V. parahaemolyticus* is not in use.

Pandemic Strains

An abnormal increase in the *V. parahaemolyticus* O3:K6 mediated diarrheal cases were recorded in February 1995 at the Infectious Diseases Hospital in Kolkata, West Bengal, India. After this report, genetically identical O3:K6 were reported from sporadic cases/foodborne outbreaks from Bangladesh, Chile, France, Japan, Korea, Laos, Mozambique, Peru, Russia, Spain, Taiwan, Thailand, and the USA. Owing to its fast spreading nature to several countries, this serovar was labeled as 'pandemic strain.' Almost during the same period, other serovars, such as O4:K68, O1:K25, and O1:KUT (untypeable K antigen) that had identical molecular characteristics, such as the presence of *tdh*, new *toxRS* gene allele, and PFGE profile similar to that of the O3:K6 serovar were identified. In Peru, apart from the pandemic serovars O3:K6, O3:K68, O3:K58, and OUT (untypeable):K6 also possessed the pandemic markers. One of the O3:K6 strains was isolated in 1996, indicating that the pandemic strain was present in Peru almost during the same time that it caused the first outbreak in Kolkata in February 1996. The emergence of pandemic strains might be due to the serotype conversion from O3:K6 to O4:K68 involving recombination event with a region much larger than the O- and K antigen-encoding gene clusters. In addition, pathogenicity islands and mobile elements are also likely involved in the evolution of pandemic strains of *V. parahaemolyticus*.

DNA microarray-based analysis indicated that approximately 86% of the genes from the whole genome sequenced pandemic strain RIMD2210633 were conserved in all the strains. At least 65 genes over 11 loci were specifically identified in the pandemic strains compared with any of the nonpandemic strains, suggesting that the difference between pandemic and nonpandemic strains is not due to a simple or single genetic event. Only the genes in the 80-kb pathogenicity island (Vp-PAI) on chromosome II, including two *tdh* genes and a set of genes for TTSS were detected in the KP-positive pathogenic strains. Pandemic strains have four specific genomic islands, which are considered as potential factors of the pandemicity. When the origin and function of 24 genes in the insertion element VP-PAI-1 were analyzed, two were found only in *Vibrio vulnificus* and *Shewanella* sp. The 8 kb genomic segment with the two genes showed synteny. These two genes are associated with cold adaptation in *Shewanella* sp., which can grow even at 4 °C.

Clinical Symptoms of *V. parahaemolyticus* Infection

Gastroenteritis, wound infections, and septicemia are the major clinical syndromes caused by *V. parahaemolyticus*. Gastroenteritis symptoms include diarrhea, abdominal cramps, nausea, vomiting, headache, and low-grade fever. Sometimes the diarrhea may be bloody, with stools described as 'meat washed' because the stool is reddish in color. The illness is generally self-limiting and lasts for approximately 3 days in immunocompetent patients. The incubation period for *V. parahaemolyticus* infection may vary from 4–96 h. *Vibrio parahaemolyticus* causes though rarely necrotizing fasciitis, especially in patients with underlying disease, such as chronic renal failure, diabetes mellitus, and malnutrition. Early diagnosis and appropriate antibiotic therapy are essential to save the patient's life, because clinical evolution can be fulminant and mortality rates are high (43%). Multidrug resistance is not reported in *V. parahaemolyticus* and the organism is susceptible to most of the antimicrobials used in the treatment of diarrhea.

Detection Methods

Isolation and identification of *V. parahaemolyticus* from clinical specimens are well established. Isolation of this pathogen from fishery products and other food samples is often hampered by the lack of standardized methods. Presently, the conventional assay system is supplemented with highly

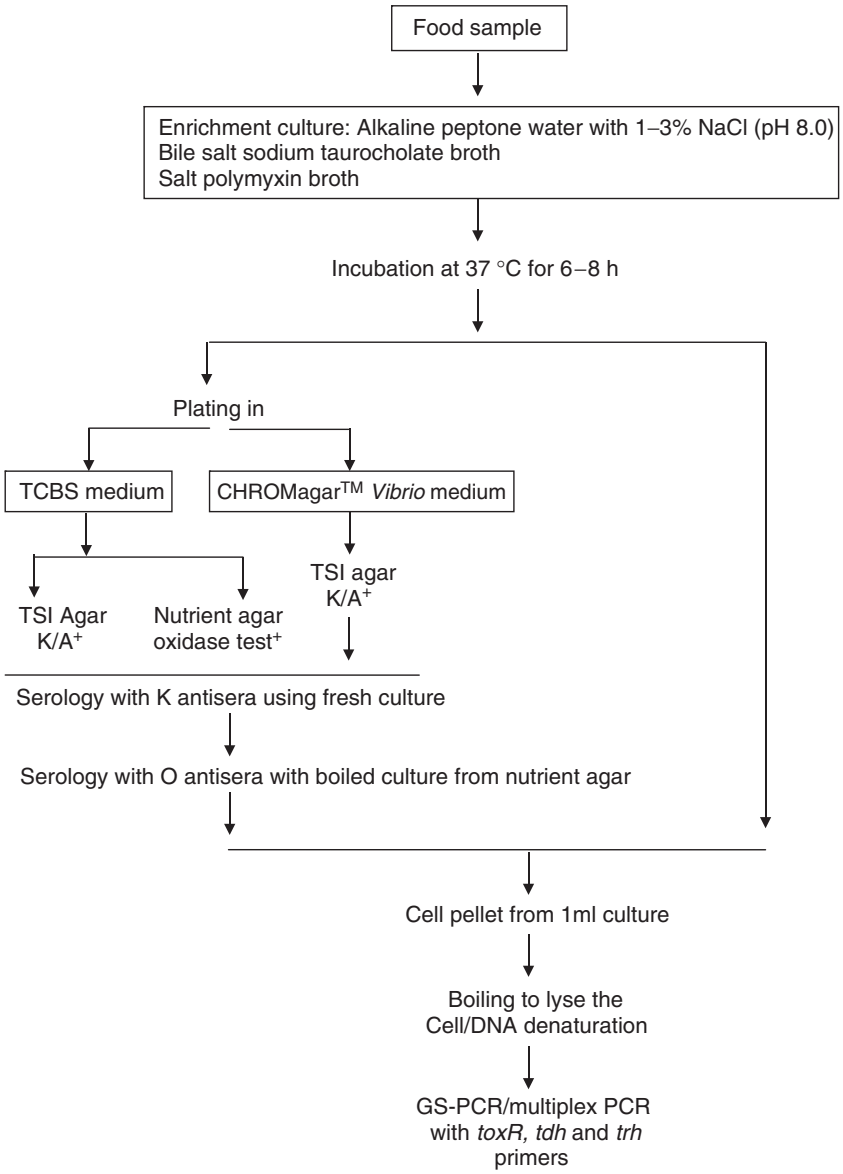

Figure 1 Flowchart showing a stepwise procedure for isolation of *V. parahaemolyticus*.

sensitive immunological and molecular detection methods for the specific identification of *V. parahaemolyticus*.

Culture Methods

Methods for the isolation and identification of *V. parahaemolyticus* are shown in Figure 1. The density of *V. parahaemolyticus* in food samples may not be very high and hence an enrichment step is essential. Alkaline peptone water (APW) with pH of 8.0–8.7 supplemented with 1–3% NaCl is most suitable for the initial enrichment. Usually, enrichment is for 6–8 h at 37 °C, as excess incubation in APW may result in overgrowth of other organisms. If plating cannot be done within this stipulated time, a secondary enrichment in APW is necessary to inhibit the growth of background organisms. Other broth media such as bile salt sodium taurocholate (ST) broth and salt polymyxin broth (SPB) are also useful for enriching *V. parahaemolyticus* from seafood. Use of ST broth was shown to give better results than APW for isolating toxigenic *V. parahaemolyticus* from seafood. The most commonly used plating medium for *V. parahaemolyticus* and *Vibrio cholerae* is thiosulfate–citrate–bile salts–sucrose (TCBS) agar, which is available from several commercial sources. The nonsucrose fermenting *V. parahaemolyticus* strains are readily detected in this medium as large dark sticky green colonies (Figure 2). Compact Dry VP comprising peptone, NaCl, bile salts, antibiotics, chromogenic substrates, and polysaccharide gum as a cold water-soluble gelling is a ready-to-use culture medium for enumeration of *V. parahaemolyticus*. Blue–green colonies can be counted after 18–20 h of incubation at 35 °C. Better results were reported when two-step enrichment, one in APW followed by SPB in which CHROMagar *Vibrio* was used as the selective medium.

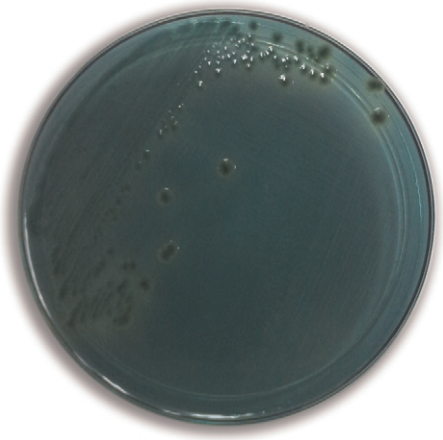

Figure 2 Sucrose nonfermenting pure culture of *V. parahaemolyticus* in TCBS medium.

For routine identification of suspected colonies, biochemical tests are mandatory. Either conventional tests or commercial systems can be adopted for identification and the tests should be very simple, rapid, and specific. API 20E and both of the Vitek cards, correctly identify more than 90% of the *V. parahaemolyticus* strains. However, extreme care must be taken in the interpretation of results with commercially available identification systems. It was suggested to increase the NaCl concentration while performing the biochemical tests to get reliable results. Generally, *V. parahaemolyticus* is negative for urease production. However, *trh* or both *tdh*- and *trh*-positive strains invariably produce urease. For KP test, fresh cultures of *V. parahaemolyticus* should be used with commercially available Wagatsuma medium (Eiken, Japan) containing 5% washed human erythrocytes, followed by incubation at 37 °C for 24 h. Positive strains will exhibit *β*-hemolytic zones around the growth. Those with a very narrow hemolytic zone are said to be KP indeterminate. For serotyping, antisera against O and K (poly and monovalent) antisera are available commercially (Denka Seiken Co., Ltd., Tokyo, Japan).

Immunological Methods

Antipolar flagellin monoclonal antibodies (mAbs) are useful for the rapid and selective isolation, concentration, and detection of *V. parahaemolyticus* cells from environmental sources. Cowan I *Staphylococcus aureus* cells coated at low concentration of mAb against *V. parahaemolyticus* polar flagellin specifically coagglutinated with the homologous antigen in 30 s, but not with other vibrios. In an immunomagnetic separation protocol, anti-H mAb exhibited 35–45% binding activity against 10^2–10^3 *V. parahaemolyticus* cells. TDH produced in the culture broth by *V. parahaemolyticus* strains can be detected by using a commercial kit (KAP-RPLA; Denka Seiken) that was based on the reversed-phase latex agglutination reaction with rabbit anti-TDH immunoglobulin G.

Molecular Methods

Pathogenicity of *V. parahaemolyticus* is related to hemolysins such as TDH, TRH, and thermolabile hemolysin. Direct-PCR targeting *tdh* and *trh* after sample enrichment in APW are the most successful methods for the detection of *V. parahaemolyticus*. The other gene targets such as *toxR*, *gyrB*, *tlh*, and the chromosomal fragment pR72H were evaluated for their accurate use in the PCR assay. The target gene *toxR* achieved the highest performance (100%) followed by *tlh* (91%). PCR assays targeting the *gyrB* and pR72H fragment were less reliable and, in some cases, difficult to interpret. PCR based on the detection of *toxR* can identify both pathogenic and nonpathogenic strains whereas *tdh* and *trh* help in the confirmation of pathogenic strains. Other genes such as *rpoA*, *pntA*, and *vpm* were also found to be specific, sensitive, and rapid for the detection of *V. parahaemolyticus* by PCR.

The loop-mediated isothermal amplification (LAMP) assay has shown to be sensitive and rapid in detecting many target genes such as *tdh*, *trh1*, *trh2*, *rpoD*, and *toxR* in less than 2 h. Based on the target gene, the sensitivity of the LAMP assay ranges from 1 to 450 CFU, that is more than 10-fold compared to conventional PCR assay. PCR analysis can be converted into most probable number (MPN) format targeting a stable marker gene for the quick quantification of *V. parahaemolyticus* from food samples. Real-time PCR for simultaneous detection of the species-specific *tlh* and the pathogenicity markers genes such as *tdh* and *trh* are recommended for the identification of *V. parahaemolyticus* from oysters. To eliminate false-negative reporting, an internal amplification control (IAC) has been incorporated to ensure the PCR integrity. This assay was specific and sensitive with < 10 CFU per reaction of pathogenic *V. parahaemolyticus* with a background of $> 10^4$ CFU per reaction of total *V. parahaemolyticus* and can be used in the MPN format. Real-time reverse transcription-PCR method was employed to determine the viable but nonculturable (VBNC) *V. parahaemolyticus* targeting virulence genes coding for the TDH and TTSS2 (VPA1354, VPA1346, and VPA1342) along with the housekeeping genes such as *rpoS*, *pvsA*, *fur*, and *pvuA* for quantification of expression. Combination of multiplex PCR and DNA–DNA hybridization on a microarray with *tlh*, *tdh*, and *fla* gene amplicons and their specific primers, respectively was also successfully tested using chemiluminescence with avidin-conjugated alkaline phosphatase.

Culture-based techniques for the identification of *V. parahaemolyticus* from environmental samples may be misleading as most of the bacterial cells will remain in a state called VBNC. A fluorescence visualization technique, called recognition of individual gene fluorescence *in situ* hybridization (RING-FISH), which targets *tlh* has been useful in the identification of *V. parahaemolyticus*. When coupled with the Kogure method to distinguish viable from dead cells, RING-FISH probe reliably enumerated total, viable *V. parahaemolyticus*.

Based on the phylogenetic difference in the 23S ribosomal RNA (rRNA) gene of various *Vibrio* species, specific DNA probes have been designed and assessed. Reverse line blot assay showed that these probes specifically detected different pathogenic and nonpathogenic vibrios from the marine environments. DNA diagnostic chips with type-specific PCR primers labeled with biotin and oligonucleotide probes have been successfully used in the rapid identification of *V. parahaemolyticus* and other foodborne pathogens in a 96-well format. Matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) has become a

powerful tool for rapidly characterizing bacterial species. Whole-cell MALDI-TOF MS-based proteometric characterization was useful for the rapid identification of *V. parahaemolyticus*. Closely related species like *Vibrio alginolyticus, V. cholerae,* and *Vibrio mimicus* could be differentiated with other signatures of species-identifying biomarker ion such as *rpoB* gene. Construction of phylogenetic trees from MALDI-TOF MS and *rpoB* sequences revealed a very good congruence between both methods.

Rapid multiplexed bead-based mesofluidic system (BMS) distinguishes many foodborne pathogenic bacteria, including *V. parahaemolyticus*. BMS is based on the utilization of isothiocyanate-modified microbeads, which are immobilized with specific amino-modified oligonucleotide probes and placed in polydimethylsiloxane microchannels. When pumped into microchannels, the PCR products will hybridize with the oligonucleotide-modified beads and hybridization signals could be detected using a conventional microarray scanner. The detection procedure can be performed in less than 30 min with high sensitivity and specificity with 500–6000 CFU per ml.

Risk Factors and Reservoirs

Bivalves feed by filtering enormous volumes of water. In this process, it accumulates many marine microbes including pathogenic bacteria and viruses. Many investigations show that presence of *V. parahaemolyticus* and other vibrios from 20 to 38% of the bivalves sampled irrespective of the place and quality of the water. Studies on the seasonal incidence of *V. parahaemolyticus* in Mobile Bay oysters, AL, USA, showed their densities ranging from <10–12 000 per g and were associated with higher water temperatures. Water temperature is inversely related to the prevalence of diverse serotypes of pathogenic strains. In the Great Kwa River estuary Calabar, Nigeria, a trimodal peak in *Vibrio* counts was noticed with 13.6% isolation rates of *V. parahaemolyticus* during the warmer periods. After harvesting, storing oysters at ambient temperatures ($\sim$26 °C) leads to proliferation of *V. parahaemolyticus* to approximately 13- to 26-fold within 24 h with increase in the detection levels up to 40%.

The emergence and spread of *V. parahaemolyticus* pandemic strain in Peru in 1997 was due to El Niño events. This pattern was similar to the previously reported onset of cholera epidemic in 1991. Thus, the movement of oceanic waters seems to be one of the driving forces for the spread of *Vibrio*-associated diseases. El Niño is also suspected for geographic dispersion of pandemic strains in Antofagasta, Chile, and other South American coastal regions. *V. parahaemolyticus* densities in oysters varied seasonally and were found to be positively correlated with water temperature, turbidity, and dissolved oxygen.

Reports on the incidence of *V. parahaemolyticus* in African regions are few. In Limbe and Tiko, Cameroon, of the 236 shrimps examined, 55 (44%) were contaminated with *V. parahaemolyticus*. Gastroenteritis caused by *V. parahaemolyticus* has been associated with foods prepared with seaweeds. Studies carried out in Kii Channel, Japan, showed that seaweeds supported diverse *V. parahaemolyticus* throughout the year and its abundance in seaweeds was at least 50 times higher during summer. In Khanh Hoa province of Vietnam, the observed risk factor for *V. parahaemolyticus* infections was high socioeconomic status indicting its typical foodborne nature rather than its associating with hygiene and sanitation.

Survival Strategies

Growth kinetics of nonpathogenic *V. parahaemolyticus* was more rapid than that of pathogenic *V. parahaemolyticus*, regardless of tested model medium. This may be the reason why the nonpathogenic strains are abundant in the natural environments and bivalves. In shellfish growing areas, densities of *V. parahaemolyticus* is correlated significantly with water temperature than with salinity. In tropical regions, the MPN values of *V. parahaemolyticus* increases in accordance with rise in water temperature. This phenomenon has been reported in many places including southern coasts of Sao Paulo State, Brazil. Studies conducted in Mississippi indicated that there is an intraseasonal variation in the densities of total and pathogenic *V. parahaemolyticus* in oysters and overlying waters during summer. Regression analyses indicated significant associations ($p<.001$) between total *V. parahaemolyticus* densities with salinity and turbidity of the water and in oysters. Algal-derived organic matter and temperature can influence the abundance of different *Vibrio* spp. In microcosm studies, it was proved that the cyanobacterial-derived organic matter represented an important factor regulating growth and abundance of *V. parahaemolyticus* in brackish waters.

VBNC concept has been defined in 1982, which demonstrate the existence of bacteria that lost their capability to reproduce in culture, but stay live, keeping their metabolic activity intact. However, bacteria in VBNC state can multiply and cause infection under suitable conditions. Specific proteins expressed in the VBNC induction/VBNC state or strongly down-regulated in the starved cells were identified. The upregulated proteins are known to be associated with transcription (two homologs of α-subunit DNA-directed ribonucleic acid (RNA) polymerase and phosphoribosylaminoimidazole carboxamide formyltransferase/inosine monophosphate (IMP) cyclohydrolase), translation (ribosomal protein S1, two homologs of elongation factor thermo unstable (EF-TU), and elongation factor guanosine (EF-G), adenosine triphosphate (ATP) synthase (F1α-subunit), gluconeogenesis-related metabolism (dihydrolipoamide acetyltransferase and glyceraldehyde 3-phosphate dehydrogenase), antioxidants (two homologs of peroxiredoxins and AhpC/Tsa family), and a conserved hypothetical protein with unknown function. These proteins may play important roles in the induction or maintenance of VBNC *V. parahaemolyticus*. Concomitant cold and carbon starvation treatment of *V. parahaemolyticus* leads to VBNC state and these stresses are also associated with the expression of cytoskeleton genes such as *mreB*, *minE*, and *ftsZ*.

Owing to its halophilic attribute, *V. parahaemolyticus* is distributed in estuarine and coastal ecosystems all over the world. It has the ability to grow in fluctuating saline environments with the mechanisms of osmoadaptation through two putative compatible solute synthesis systems (encoded by *ectABC* and *betABI*) and six putative compatible

solute transporters (encoded by four *bcct* loci and two *proVWX* loci). To master the hyperosmotic stress of saline environments, *V. parahaemolyticus* not only accumulate osmoprotectants through uptake or endogenous synthesis of compatible solutes, but also remodel its profiles of outer membrane protein to restore its cell membrane. Lysine decarboxylase plays a role in the adaptive acid tolerance response in *V. parahaemolyticus*. Transcriptional analyses of lysine decarboxylase gene operon *cadA* and *cadB* revealed enhanced acid induction by external lysine.

Incidence and Epidemiology of *V. parahaemolyticus* Infection

In Kenya, acute gastroenteritis associated with increase in fish consumption has been reported since 1951 and the incidence of *V. parahaemolyticus* has increased due to foodborne outbreaks. Among vibrios, the proportion of *V. parahaemolyticus* was found to be high (13.6%) in shellfish from the Great Kwa River estuary, Calabar, Nigeria. Shrimps harvested from the coastal waters of Limbe and Tiko, South West Cameroon, were contaminated with *V. parahaemolyticus* (44%), which is in parallel to its incidence (12%) associated with diarrhea. Rural wastewater treatment facilities in the Eastern Cape province of South Africa were reported as potential sources of vibrios including *V. parahaemolyticus* (23.1%). During 2004–05 in Dakar, Senegal, along with *V. cholerae* and *V. parahaemolyticus*, gastroenteritis was also identified due to consumption of contaminated food. In Osaka and Kansai Airport Quarantine Station, *V. parahaemolyticus* was detected among 29 587 (7%) overseas travelers suffering from diarrhea during 1979–95, which was higher than the expected enterotoxigenic *Escherichia coli* level (5.4%).

In February 1996, *V. parahaemolyticus* serovar O3:K6 was first detected in Kolkata that accounted for 50–80% of the acute diarrheal cases. Subsequent to this report, several outbreaks and sporadic cases were reported from many parts of the world. Emergence of this new clone in 1996 was the first documented pandemic spread of *V. parahaemolyticus*. Subsequent to the emergence of O3:K6, other serovars, such as O4:K68, O1:K25, and O1:KUT (untypeable), that had genetic characteristics identical to that of the O3:K6 serotype were recognized. Pandemic serovars O3:K6 and O4:K68 were identified from hospitalized diarrhea patients in Beira, Mozambique, from January to May 2004, which were closely related to the Asian pandemic strains. The other serovars such as O3:K58, O4:K13, O3:KUT, and O8:K41 had different characteristics.

Vibrio parahaemolyticus causing an epidemic in Antofagasta, Chile, was first reported between November 1997 and April 1998 due to consumption of shellfish. O3:K6 strain was detected in southern Chile in 2004, and 8000 seafood-related diarrhea cases were identified. Serovar O3:K6 caused outbreaks in Puerto Montt from 2004 to 2006 with 3600 cases in 2005. In de los Lagos, 3725 diarrheal cases were reported during 2004–05. Cases steadily decreased to a total of 477 in 2007 with 40% were associated with a pandemic strain of a different serovar (O3:K59). In the summer of 2008, diarrheal cases again increased from 477 to 1143 and 98% of the clinical cases were associated with the pandemic O3:K6 serovar.

Bacterial foodborne disease surveillance detected 1082 outbreaks in China during 2005–08 mainly due to *V. parahaemolyticus* infections. Majority of the strains (79%) were identified as pandemic O3:K6. The other pandemic serovars encountered in this study were O1:KUT, O1:K25, O1:K26, and O4:K68 along with new servoars O1:K36, O3:K25, and O3:K68. In Hangzhou, 13 food poisoning outbreaks during 2000–02 were caused by O3:K6 in 11 episodes (84.6%) and O4:K8 with other two outbreaks (15.4%). From 2001 to 2002, 23 different serovars were identified in a case-control study of expatriates and Thai adults. The pandemic strains belonged to three recognized serovars (O3:K6, O1:K25, and O1:KUT) along with a new serovar, O3:K46, which was closely related to the pandemic strains. In Songkhla Province, Thailand, pandemic *V. parahaemolyticus* was constantly high ($>60\%$) from 2000–03 and decreased in 2004–05.

During 1999–2000, large outbreaks of *V. parahaemolyticus* infections were reported in the coast of Galicia in north-western Spain. Environmental investigation has shown that the overall incidence of *V. parahaemolyticus* was 12.5% primarily in areas of reduced salinity close to freshwater discharge points. Characterization of these strains resulted in the identification of same serotypes and identical DNA profiles indistinguishable from the clinical source. In 2005, pandemic *V. parahaemolyticus* O3:K6 strain was introduced in France through contaminated seafood. Recurrent presence of pandemic serovars O3:K6 and O1:KUT were reported in Italy during 2008.

Molecular Typing Methods

PCR-Based Typing

PCR-based typing has good discriminative ability and can be used as a rapid means of comparing *V. parahaemolyticus* strains for epidemiological investigation. The random amplification of polymorphic DNA (RAPD) with the use of single shot primer has identified genetic variability within *V. parahaemolyticus* strains from clinical and seafood samples. Strains from Chinese seafood samples harboring *tdh* and *trh* were separated into distinct groups. Fingerprinting of *V. parahaemolyticus* from sporadic diarrhea patients and seafood in Hangzhou with enterobacterial repetitive intergenic consensus sequence (ERIC)-PCR, and RAPD showed that almost all the O3:K6 strains from food poisoning and sporadic diarrhea patients were close to each other, and there were difference between O3:K6 strains from clinical and O3:KUT strains from environment. The pandemic (O3:K6) and nonpandemic seorvars (O3:KUT) from Brazil were separated by the RAPD-PCR into two amplification patterns. The O3:K6 strains isolated from clinical sources in Bangladesh, Taiwan, Laos, Japan, Thailand, Korea, and the USA between 1997 and 1998 showed identical banding profile in an arbitrarily primed PCR. In addition, the other serovars such as O4:K68 and O1:KUT were also identified as the same clone. Cluster analysis of amplicons generated using primers specific for conserved ribosomal gene spacer sequence (RS), repetitive extragenic palindromic sequence (REP), and ERIC indicated that these methods apparently differentiated *V. parahaemolyticus* strains and grouped them into 15, 27, and 27 patterns, with discrimination

indexes of 0.91, 0.97, and 0.98, respectively. REP-PCR is preferable to ERIC-PCR because of the greater reproducibility of the fingerprints, whereas RS-PCR may be a practical method because it generates fewer amplification bands and patterns than the alternatives.

Ribotyping

Ribotyping exploits the DNA polymorphism of rRNA genes (*rrn*) in the chromosome of *V. parahaemolyticus*. Universal probe generated from the *E. coli* RNA is used to screen the restriction patterns of genomic DNA of the test strains. *V. parahaemolyticus* has 11 copies of ribosomal operons and the intergenomic *rrs* recombination is very high in this species. Pandemic O3:K6, O4:K68, and O1:KUT serovars that emerged after 1996 from different countries were indistinguishable in the ribotyping analysis, whereas the O3:K6 and O1:KUT serovars isolated before 1995 had different profiles. This result also indicated that the O4:K68 and O1:KUT strains most likely originated from the pandemic O3:K6 clone with different serovar background. Ribotyping of *Eco*RI and *Pst*I profiles of *V. parahaemolyticus* O3:K6 from two US outbreaks of oyster-associated gastroenteritis in 1998 with the use of a Qualicon riboprinter showed involvement of a single strain closely related to the Asian clone. In contrast, multiple strains were involved in the Texas outbreak and genetically distinct from the north-eastern and Asian clone.

Multilocus Sequence Typing (MLST)

MLST of *V. parahaemolyticus* with housekeeping genes from both the chromosomes has been applied to *V. parahaemolyticus* strains. Several sequence types were identified, which are available in the database (http://pubmlst.org/vparahaemolyticus). In the eBURST (based upon related sequence types) analysis, three major clonal complexes were identified with strains originating from the Pacific and Gulf coasts of USA and the third clonal complex consisted of strains of pandemic clone all over the world. MLST of *V. parahaemolyticus* associated with foodborne illness in Florida has identified 13 novel sequence types and 7–9 novel alleles for each locus. MLST diversity appears primarily due to frequent recombination rather than mutation, with the estimated ratios of 2.5:1 and 8.8:1 by allele and site, respectively.

Variable Number of Tandem Repeat (VNTR) Loci

In housekeeping genes, regions known as VNTR are classified on the basis of their repeat units. These repeat loci are highly conserved and hence the discrimination power is more compared to that of MLST. VNTR-based fingerprinting discriminated clinical O3:K6 strains from different outbreaks and sporadic cases in Tokyo during 1996–2003. Multiple-locus VNTR analysis (MLVA) displayed between 2 and 15 alleles at each of 8 loci and shown to have high resolution and reproducibility for typing of *V. parahaemolyticus*. VNTR assay was applied to clinical and environmental *V. parahaemolyticus* strains from Chile with 24 potential loci on both chromosomes. In this analysis, 59 MLVA groups were identified, providing differentiation among very closely related strains.

Pulse-Field Gel Electrophoresis (PFGE)

PulseNet is an International molecular subtyping network for foodborne disease surveillance closely monitored by the Centers for Disease Control (CDC, USA). In this network, the member laboratory performs molecular subtyping of pathogens using a standardized method PFGE after comprehensive testing process allowing the sharing of data with other members as well as with the CDC. A standard PFGE protocol is available for subtyping *V. parahaemolyticus* for use in PulseNet activities. Comparative analysis of the PFGE profiles generated by different laboratories demonstrated that the protocol is both reliable and reproducible.

Phylogenetic analysis of *Not*I PFGE profiles showed that the 1998 O3:K6 and O4:K68 strains from India and Thailand formed a cluster with 78–91% similarity indicating a close genetic relationship between the two different serovars. In 1999, *V. parahaemolyticus* caused a large outbreak associated with raw oyster consumption in Galicia, Spain. O4:K11 and O4:KUT serovars were identified in this outbreak, which were not related to the pandemic serovars. Norwegian environmental trh^+ and/or tdh^+ strains were different from prototype trh^-/tdh^- strains. However, the clinical strains of O3:K6 and O3:KUT were identical or related to a pandemic reference strain. Large epidemics of diarrhea associated with seafood consumption and *V. parahaemolyticus* occurred for the first time during 2004–05 in Puerto Montt, Chile. PFGE analysis confirmed that the epidemics were caused by the O3:K6 pandemic serovar in this region. Pandemic serovars of *V. parahaemolyticus* O3:K6 and O4:K68 spread to Beira, Mozambique, in 2004–05. In the PFGE, these strains were closely related to the pandemic strain that emerged in Asia in 1996. The O3:K58, O4:K13, O3:KUT, and O8:K41 strains showed unique characteristics different from the pandemic clone. The *Sfi*I PFGE patterns of *V. parahaemolyticus* strains from Taiwan showed 115 different patterns grouped into 13 types with dissimilarity value of <15. Type I consisted exclusively the pandemic O3:K6 strains and genetically closely related strains. *V. parahaemolyticus* associated diarrheal outbreaks were reported from Shenzhen, China, in 2007–08. In these outbreaks, O3:K6, O4:K8, and O1:KUT serovars accounted for 67.9%, 7.5%, and 6.1%, respectively. Identical PFGE patterns were recorded from six locations.

Pathogenesis

Pathogenic *V. parahaemolyticus* are known to produce TDH, TRH, or both. TDH exists as a tetramer in solution and possesses β-hemolytic activity. TRH is further differentiated into TRH1 and TRH2 on the basis of genetic and phenotypic differences. Almost all the clinical *V. parahaemolyticus* strains display β-type hemolysis on Wagatsuma agar and thus are known as KP^+ strains, which has been considered an important marker to distinguish pathogenic strains from nonpathogenic ones. TDH has been considered as a major virulence factor of gastroenteritis because it has biological activities, including cytotoxic and enterotoxic activities. Five variants of the *tdh* genes have been identified, of which *tdh*1 and *tdh*2 are associated with KP, and the rest are negative for KP. These *tdh* variants share 97% sequence identity. The *trh*

gene shares approximately 68% sequence identity with the *tdh* gene. The *trh* sequence variants can be separated into two groups: the *trh*1 and *trh*2 that share 84% sequence identity.

Vibrio parahaemolyticus has two sets of TTSS genes on chromosomes 1 and 2 (TTSS1 and TTSS2, respectively). TTSS1 is responsible for cytotoxicity, whereas TTSS2 is a major contributor to enterotoxicity and is present only in KP^+ strains. Tissue culture assay and animal models with nonfunctional mutant TTSSs *V. parahaemolyticus* strain harboring *tdh*, showed that TTSS1 alone was involved in cytotoxic activities in all the cell lines. TTSS1 and TDH played a significant role in lethal activity in a murine infection model. The TTSS1 induces rapid cellular death that initiates with acute autophagy. TTSS2 and TDH had cytotoxic effects on a limited number of cell lines. *In vitro* studies demonstrate that TTSS1 genes are positively regulated by ExsA and negatively regulated by ExsD.

TTSS translocon complex is composed of several associated proteins, which form a translocation channel through the host cell plasma membrane and deliver effector proteins into host cells. In *V. parahaemolyticus* there is only one gene (the VPA1362 gene) in the TTSS2 region that is homologous to other translocon protein genes. VPA1362 (designated VopB2) and VPA1361 (designated VopD2) are the TTSS2-dependent secretion proteins. Functional analysis of these proteins showed that they are essential for TTSS2-dependent cytotoxicity, for the translocation of one of the TTSS2 effector proteins (VopT), and for the contact-dependent activity of pore formation in infected cells *in vitro* and enterotoxicity *in vivo*. VPA1327 (*vopT*), a gene encoded within the proximity of TTSS2, is partly responsible for cytotoxic effect in Caco-2 and HCT-8 cells. VopT is an adenosine diphosphate (ADP)-ribosyltransferase effector protein secreted via TTSS that has approximately 45% and 44% identity with the ADP-ribosyltransferase domain of ExoT and ExoS, respectively. TTSS2 was found to be necessary not only for the secretion, but also for the translocation of the VopT into host cells.

The genes for TTSS2 have not been found in *trh*-positive (KP^-) strains, which are also pathogenic for humans. However, in a *trh*-positive *V. parahaemolyticus* strain, a novel TTSS was identified, which was found strongly associated with enterotoxicity in animal experiments. Phylogenetically, this novel TTSS is closely related to TTSS2 of KP^+ *V. parahaemolyticus* though it belongs to a distinctly different lineage.

Vibrio parahaemolyticus induces a rapid remodeling of macrophage actin and activates RhoB guanosine triphosphatase (GTPase). This effect was identified on TTSS1 that regulated translocation effector protein VP1686 into the macrophages. This remodeling of actin is shown to be necessary for increased bacterial uptake and triggering an 'eat-me-and-die' signal to the host, that is, initiation of apoptosis in macrophages. The ability of *V. parahaemolyticus* to inhibit Rho family GTPases also causes cytoskeletal disruption in HeLa cells. The inhibition of Rho family GTPase activation was identified both in clinical and environmental strains and was dependent on TTSS1. In addition, Rho inhibition was accompanied by a shift in the total actin pool to its monomeric form. These phenotypes were not found in Vp1686 deletion mutants indicating that the inhibiting actin polymerization may be a downstream effect of Vp1686-dependent GTPase inhibition.

Norepinephrine (NE) is released when a host of physiological changes are activated by a stressful event. NE controls the functions of the gastrointestinal tract, but its role in the pathogenicity of enteropathogens is not clear. NE stimulated the cytotoxic activity of *V. parahaemolyticus* in Caco-2 cells and the transcription of the TTSS1-related genes *vscQ* and *vscU*. In rat ileal loop model, the enterotoxicity of *V. parahaemolyticus* was increased by NE through interaction with $\alpha(1)$-adrenergic receptors. These results indicate that $\alpha(1)$-adrenergic receptors on the intestinal epithelium appear to interact with *V. parahaemolyticus* enterotoxicity.

In many Gram-negative bacteria, the type 2 secretion system (T2SS) is responsible for the transport of a diversity of proteins from the periplasm across the outer membrane into the extracellular space. Cholera toxin is one of the T2SS secreted proteins in *V. cholerae*. The T2SS consists of three subassemblies, one of which is the inner membrane complex, which contains multiple copies of five proteins, including the bitopic membrane protein EpsL. The 2.3 Å resolution crystal structure of the periplasmic domain of EpsL from *V. parahaemolyticus* showed 56% identical in sequence to its homolog in *V. cholerae*. Capsular polysaccharide (CPS) aids in adherence to epithelial cells and plays an important role in the initiation of pathogenesis of *V. parahaemolyticus*. The role of CPS in adherence was established by testing the opaque (with CPS) and translucent (with less CPS) colonies, purified CPS, and anti-CPS antibodies. *V. parahaemolyticus* extracellular zinc metalloprotease (VPM) is a putative virulence factor for host infection. It is synthesized from the *vpm* gene as a polypeptide of 814 amino acids with an estimated molecular mass of 89 833 Da, containing a HEXXH consensus motif.

Decontamination and Other Preventive Measures

Vibrio parahaemolyticus is a common cause of shellfish-related gastroenteritis all over the world. Several effective decontamination and other preventive measures are introduced for food safety to obliterate this pathogen. Because the infective dose of *V. parahaemolyticus* is $>10^4$ cells per serving of oysters or other foods, quantification of this pathogen is mandatory at the industrial level. Postharvest processing (PHP) greatly reduce exposure of *V. parahaemolyticus* and other vibrios to oysters and pose a much lower risk of illness to consumers. PHPs such as on-board and dockside icing of oysters are less effective in reducing the levels of *V. parahaemolyticus* in oysters.

The National Shellfish Sanitation Program's (NSSP) PHP for *V. parahaemolyticus* recommends flash freezing, followed by storage at $-21\,^{\circ}C$. In some studies it was demonstrated that storing Pacific oysters at $-10\,^{\circ}C$ was more effective in inactivating *V. parahaemolyticus* than was storing at -20 or $-30\,^{\circ}C$, as the levels of *V. parahaemolyticus* in oysters were reduced after 6 months by 4.55, 4.13, and 2.53 log MPN per g, respectively. In shell stock and shucked oysters, *V. parahaemolyticus* decreased from 5.46 to 0.38 log MPN/g after 75 days of storage at $-30\,^{\circ}C$, and at $-18\,^{\circ}C$ no viable cells were detected after 60 days.

Extended depuration at $15\,^{\circ}C$ for 96 h increased reductions of *V. parahaemolyticus* in American oyster (*Crassostrea virginica*) than at $22\,^{\circ}C$. HPP conditions (pressure level, time, and

temperature) are useful to achieve a 5-log reduction of *V. parahaemolyticus* in live oysters. The recommended pressure treatment processes are $\geq$350 MPa for 2 min at temperatures between 1 and 35 °C and $\geq$300 MPa for 2 min at 40 °C. Treatment with X-ray could control pathogenic bacteria and extend the shelf life of oysters. X-ray (1–5 kGy) significantly ($p < .05$) reduced *V. parahaemolyticus* and inherent microflora on oysters to less than detectable limit (<1.0 log CFU per g). When tested with HPP, *V. parahaemolyticus* O3:K6 was more resistant to pressure than other serovars. In oysters, this serovar required a pressure of 300 MPa for 180 s for a 5-log reduction.

Chlorine dioxide (ClO_2) is considered to be a safe and effective disinfectant and is routinely applied for treatment of drinking water and seafood. Bioaccumulated *V. parahaemolyticus* in different oyster tissues could be disinfected completely after 6 h of treatment with 20 mg l^{-1} of ClO_2. After ClO_2 treatment, the shelf life of oysters was extended to at least 12 days at 4 °C. Pulsed low direct current or alternating low-amperage electric treatments (LAETs) of saline solutions exerts superior inactivation efficacy against *V. parahaemolyticus* owing to the generation of available chlorine. LAET at 263 mA for 100 ms eliminated all *V. parahaemolyticus* cells due to substantial structural damage at the cellular level. Treatment of electrolyzed oxidizing (EO) water (pH 2.7, chlorine 40 ppm, oxidation–reduction potential 1151 mV) inactivates *V. parahaemolyticus*. Rinsing the food contact surfaces with EO water or soaking cutting boards in EO water for up to 5 min could reduce cross contamination of *V. parahaemolyticus* during food preparation. The bactericidal activity of weakly acidic electrolyzed water (WAEW), a type of EO water was effective against *V. parahaemolyticus* when treated with sodium hypochlorite (NaClO), solution containing 35 mg l^{-1} available chlorine concentration (ACC) or WAEW containing 35 mg l^{-1} ACC. WAEW maintains bactericidal activities against *V. parahaemolyticus* under open storage conditions even after 5 weeks and could be used as a postharvest treatment to reduce *Vibrio* contamination in oysters. However, it is recommended that treatment should be limited to 4–6 h to avoid death of oysters.

In challenge studies, feeding shrimps with diets containing the potential probiotics showed its effectiveness by reducing disease caused by *V. parahaemolyticus*. Outer membrane protein antigens such as OmpW, OmpV, OmpU, and OmpK from *V. parahaemolyticus* are immunogenic during *in vivo* infection of fishes and could be the efficient vaccine targets in aquaculture. The US Food and Drug Administration has published a *V. parahaemolyticus* risk assessment for consumption of raw oysters that predicts densities of *V. parahaemolyticus* based on water temperature. This recommendation is further evaluated with the use of remotely sensed parameters for predicting incidence and risk associated with *V. parahaemolyticus* in Gulf Coast oysters. Using the remotely sensed surface temperature data as a basis for risk management/predictions, variations in *V. parahaemolyticus* density in oysters can be predicted.

Vibrio vulnificus

I Karunasagar, Food and Agriculture Organization of the United Nations, Rome, Italy

Glossary

Benthic fish Fish that live at the lowest level of an aquatic body such as sediment surface or subsurface.
Oligonucleotide Short single-stranded DNA or RNA molecules.
Open reading frame (ORF) A sequence of nucleotides in a reading frame (set of consecutive non-overlapping triplets coding for amino acids) and contains a start codon but does not contain a stop codon.
Plankton Small organisms living in a water column.
Plasmid A small DNA molecule that can replicate independently and is outside the chromosome in a cell.
Restriction enzyme An enzyme that cuts DNA at specific nucleotide sequences called recognition sites.

Background

In 1976, researchers at the Centers for Disease Control (CDC) in the USA carried out taxonomic studies on a group of halophilic *Vibrio* spp. isolated from blood cultures that fermented lactose and identified these as new species designated *Vibrio vulnificus* (wound inflicting). This organism can cause wound infections and septicemia that could be fatal in susceptible individuals.

Characteristics of the Pathogen

Vibrio vulnificus is a Gram-negative curved rod-shaped organism inhabiting warm water estuarine environments all over the world. The organism is motile by polar flagellum and can be distinguished from other members of the genus *Vibrio* by its ability to ferment lactose. *Vibrio vulnificus* is characterized by oxidase positive reaction, sensitivity to 10 μg O129, ability to ferment lactose, cellobiose; inability to ferment sucrose and arabinose; positive for ornithine and lysine decarboxylase, negative for arginine decarboxylase, capable of growth at 6% NaCl, but no growth at 8% NaCl. Presently three biotypes are recognized based on a combination of phenotypic, serologic, and host range characters. Biotype 1 strains are indole positive, serologically diverse and are associated with human infections. Biotype 2 strains are indole negative and considered mainly as eel pathogens, but may also be opportunistic human pathogens, being associated with infections in eel handlers. This biotype has three serotypes and strains associated with eel and human infections belong to serotype E. Biotype 3 has five atypical biochemical characters, is genetically clonal and has been isolated from some patients in Israel with wound infection or septicemia. This biotype has not been associated with foodborne infections and reported infections are limited to persons handling tilapia fish.

The virulence of this organism is presumably related to multiple factors such as presence of a polysaccharide capsule, ability to obtain iron from transferrin, ability to produce extracellular enzymes and exotoxin. Pathogens ingested through food encounter highly acidic gastric environment as the first host defense. Exposure of *V. vulnificus* to low acid environments leads to increased expression of lysine decarboxylase, leading to breakdown of lysine to cadavarine, which functions as acid neutralizer and as a superoxide radical scavenger that contributes to oxidative stress tolerance. The capsule has an important role in resistance to host defenses like phagocytosis and nonencapsulated transposon mutants have four times higher lethal dose compared to the wild-type strains. However, most freshly isolated environmental strains are capsulated, irrespective of their virulence to mice. Antibodies specific to capsule are detected in patients with *V. vulnificus* infections. Iron acquisition system plays an important role in virulence of *V. vulnificus*. Mouse lethal doses are greater than 10^6, but drop down to 10^5-fold lower in iron dextran treated mice. Individuals with underlying chronic liver diseases have a higher susceptibility to *V. vulnificus* infections and generally such conditions are associated with impaired iron metabolism. Most iron in human serum is bound to transferrin making it unavailable to invading pathogens and *V. vulnificus* has multiple systems of iron acquisition such as ability to produce both catechol (vulnibactin) and hydroxamate siderophores. The *V. vulnificus* hemolysin has cytotoxicity to a variety of mammalian cell lines and has 60–65% amino acid homology with non-O1 *Vibrio cholerae* hemolysin and *V. cholerae* ElT or hemolysin. Mice injected with *V. vulnificus* hemolysin display lesions similar to that noticed in infected humans. *rtxA1* gene homologous to *rtxA* toxin gene of *V. cholerae* has been identified in *V. vulnificus* and studies in mutants suggest that this toxin could play a role in causing cell necrosis and facilitating invasion of *V. vulnificus* into blood stream by crossing the intestinal epithelium. Enzymes such as

 doi:10.1016/B978-0-12-378612-8.00119-0

Table 1 Methods used for differentiation of clinical and environmental strains of *V. vulnificus*

Method	*Findings*
Sequencing of 492 bp fragment of 16S rRNA gene	Presence of *Alu*I cleavage sites after nt 202 and 244; *Hae*III sites after nt 168 and 372. Most environmental strains have additional *Alu*I site after nt 140 and most clinical strains have additional *Hae*III site after nt 147
Multilocus sequence typing based on six housekeeping genes	Strains divided into Lineage I consisting exclusively of Biotype 1; Lineage II consisting of Biotypes 1 and 2. Most clinical isolates are clustered in Lineage I
PCR based on 700 bp sequence surrounding 200 bp region found in most clinical isolates	Two groups based on the sequence of the portion of open reading frame (ORF) VV0401 in this 700 bp region – C-type (clinical strains) and E-type (environmental strains)

lecithinase, lipase, caseinolytic protease, and DNase are produced by most environmental and clinical strains.

Most of the virulence associated factors are present in over 95% of environmental strains. This has led to further studies on various molecular typing methods to discriminate environmental and clinical strains (Table 1). Differences in the sequence of 492bp fragment of 16S rRNA gene of *V. vulnificus* strains have been recorded. This fragment has cleavage site for the restriction enzyme *Alu*I after nucleotides 202 and 244, and *Hae*III cleavage sites after nucleotides 168 and 372. Most environmental strains have an additional *Alu*I cleavage site after nucleotide 140 and most clinical strains have an additional *Hae*III cleavage site after nucleotide 147. Analysis of clinical and environmental strains using multilocus sequence typing of six housekeeping genes has revealed that two main lineages can be recognized with Lineage I consisting exclusively of Biotype 1 isolates and Lineage II consisting of isolates belonging to Biotype 1 and all isolates of Biotype 2. The proportion of clinical isolates in Lineage 1 is much higher than those in Lineage II and a 33kb genomic island is unique to Lineage I. Partial alignment of the sequence of an open reading frame (ORF) VV0401 referred to as virulence coregulated gene or *vcg* indicates that clinical and environmental strains cluster into two distinct groups, C-type (90% clinical strains) and E-type (93% environmental strains). Polymerase chain reaction (PCR) based on sequence variations in this region can distinguish the two groups of strains. Examination of sequence data for eight genes including virulence associated and housekeeping genes in multiple strains confirms that the C-genotype and E-genotypes can be distinguished.

The complete genome sequence of *V. vulnificus* YJ016 isolated from a case of primary septicemia is available. The genome includes two chromosomes of approximately 3377 and 1857 kbp size and a plasmid of 48 kbp size. Most of the genes coding for putative virulence factors are present in the small chromosome.

Ecology

Vibrio vulnificus is widely distributed in warm coastal environments throughout the world, but detailed ecological studies have been done only in a few countries. This organism can be isolated from coastal marine and estuarine waters, sediment, plankton, various shellfish (both molluscan and crustacean), and finfish species. The abundance varies considerably and is greatly influenced by temperature and salinity. In North America, higher densities are observed in mid-Atlantic, Chesapeake Bay, and Gulf coast waters, where temperatures are warmer throughout the year, whereas densities are lower in Pacific, Canadian, and North Atlantic waters. The lowest temperature at which *V. vulnificus* has been isolated varies geographically, being 8 °C at Chesapeake Bay and <12.5 °C in Gulf coast of the USA. The organism survives in sediment during winter. In warm tropical environments, as in India, salinity is the major factor affecting the abundance of this organism. Effect of salinity can be seen even in temperate waters. In US waters, numbers of *V. vulnificus* were high at salinity between 5‰ and 25‰, but dropped by 58–88% at salinities over 30‰. *Vibrio vulnifucus* can colonize plankton and fish gut. *Vibrio vulnificus* produces chitinase, which might help the organism to colonize zooplankton. 14.1% aquatic birds in Japan are positive for *V. vulnificus*.

The levels of *V. vulnificus* in the USA Gulf coast oysters could be approximately 10^4 cfu g^{-1} during summer months and usually less than 10 per g during winter, and in Indian oysters, 10^3 cfu g^{-1} could be detected when salinities were lower than 25‰. Although the levels in oysters could be 100 times higher than in seawater, numbers exceeding 10^6 per g have been reported from the intestines of benthic fish inhabiting oyster reefs. In Japan, highest densities of *V. vulnificus* ($10^3 \sim >10^6$ MPN 10 g^{-1}) were observed from fish in Lake Shinji. There is no correlation between the prevalence or occurrence of *V. vulnificus* and fecal contamination of waters, hence fecal coliforms/*Escherichia coli* cannot be used as an indicator organism for this pathogen.

Survival in the Environment and Food

Vibrio vulnificus can enter into viable non-culturable (VBNC) phase under conditions of low nutrient or temperature. In the VBNC state, *V. vulnificus* cells are small (0.3 μm) cocci and on resuscitation, they regain rod-shaped (3 μm × 0.7 μm) morphology. Changes in fatty acid composition of cell membrane in *V. vulnificus* in response to lower temperatures has been recorded, with proportional increase in unsaturated fatty acids. Temperature shift from 35 to 5 °C resulted in VBNC state, however, when cells were subjected to 15 °C before downward shift, *V. vulnificus* cells remained viable. *Vibrio vulnificus* cells prestarved for 24 h before exposure to 5 °C remained culturable, but cells starved for the same period at

5 °C entered VBNC. VBNC *V. vulnificus* cannot be resuscitated after temperature upshift to 22 °C in nutrient rich broth, but can be revived in media supplemented with pyruvate or catalase and this has been attributed to increased sensitivity of cells in VBNC state to hydrogen peroxide. 10^5 VBNC cells injected intraperitoneally were lethal to mice.

Vibrio vulnificus does not grow in oysters at temperatures below 13 °C and prolonged refrigeration could lead to reduction in numbers. Although some investigators noted that levels in refrigerated shellfish became nondetectable (<3 per g) in 14–21 days, others observed survival in artificially contaminated oysters for 14 days at 2 °C, suggesting that refrigeration cannot be relied upon for elimination of this pathogen in oysters. The rate of decline in refrigerated oyster shellstock has been estimated to be 0.041 log unit per day. 4–5 $\log_{10}$ reduction in numbers of natural *V. vulnificus* population in oysters occur when frozen to −40 °C and stored for 3 weeks. However cold adaptation at 15 °C may reduce the effectiveness of freezing. A combination of vacuum packaging and freezing can bring down *V. vulnificus* counts by 3–4 $\log_{10}$ units in 7 days and though numbers continue to decline till day 7, complete elimination cannot be achieved.

Vibrio vulnificus is sensitive to temperature with 6 $\log_{10}$ reduction in numbers occurring when subjected to 50 °C for 5 min in shucked oyster meat. Natural population of *V. vulnificus* (4.3×10^3 cfu g^{-1}) can be reduced to nondetectable levels by exposing them to 50 °C for 10 min. D-values at 47 °C are 3.44–3.66 min for opaque colonies and 3.18–3.38 min for translucent colonies. *Vibrio vulnificus* cells are inactivated at pH 2.0. *Vibrio vulnificus* is sensitive to ionizing radiation and irradiation doses of 1.0 kGy applied on whole shell oysters can reduce the cell numbers from 10^7 cfu g^{-1} to undetectable levels. Hydrostatic pressure of 250 MPa for 120 s reduced *V. vulinificus* >5 $\log_{10}$ units in oysters.

Vibrio vulnificus resides inside various tissues of oysters, hence depuration is ineffective in elimination of this pathogen, but relaying oysters in high-salinity (>30‰) waters for 17–49 days caused a decrease in population from 10^3 cfu g^{-1} to <10 MPN g^{-1}.

Clinical Manifestations

Vibrio vulnificus infections may manifest as wound infections or as primary septicemia. Foodborne infections result in primary septicemia in susceptible individuals and in most instances, these are sporadic. Primary septicemia is a systemic illness in a patient who has no wound infection preceding illness and is characterized by fever and shock and presence of *V. vulnificus* in blood or other sterile site. The incubation period ranges from 7 h to 10 days, with symptoms appearing in 36 h in most cases. Most patients present with sudden onset of fever and chills, generally accompanied with nausea, vomiting, abdominal pain, and hypotension (systolic pressure <85 mm). In over 60% cases, secondary lesions appear, mostly on the legs that often develop into necrotizing fasciitis or vasculitis that may require surgical debridement or amputation. *Vibrio vulnificus* can be isolated from blood and cutaneous lesions. Primary septicemia due to *V. vulnificus* is generally associated with consumption of raw or undercooked molluscan shellfish like oysters. The disease rarely (<5%) occurs in healthy individuals, and liver disease including cirrhosis due to alcohol consumption is a risk factor for *V. vulnificus* infection. Other predisposing factors are diabetes, gastrointestinal disorders (ulcer, surgery), hematological conditions, and immunocompromised condition associated with cancer, therapy with immunosuppressive drugs. The disease has a high fatality rate (approximately 50%), which is the highest among foodborne pathogens. However, the attack rate is low with one illness occurring per 10 000 meals of raw US Gulf coast oysters (containing *V. vulnificus*) served to the highest risk population, i.e., people with liver diseases. Epidemiological data suggests that men are more susceptible than women to *V. vulnificus* infection. Experimental studies with rats suggest the estrogen may play a role in protection, because mortality rate was 82% in normal male rats, 21% in normal female rats, and 75% in ovariectomized female rats.

It is estimated that approximately 100 cases of primary septicemia due to *V. vulnificus* occurs per year in the USA and nearly all the cases have been associated with consumption of raw oysters harvested from Gulf Coast with 90% of cases occurring during April–November. The Korean CDC estimates 40–70 confirmed cases per year and this high rate is suspected to be due to consumption of raw seafood or higher prevalence of predisposing factors. However, in Japan, it is estimated that 12–24 cases occur per year; and in Taiwan, there was a peak occurrence in 2000 with 26 cases per million populations. Records of infection are also available from India, Thailand, Europe, and Australia, but cases are rare. Interestingly, in Japan, oysters are not the primary source, because raw oysters are eaten only in winter and most infections occur during June–November with a peak in July. A mud shrimp *Upogebia major* was the common agent associated with *V. vulnificus* infections.

Vibrio vulnificus may also be associated with wound infections and 69% of these are related to occupational exposures among oyster shuckers and fishermen. Preexisting wounds are generally infected and inflammation is one of the first symptoms that may progress into cellulites and necrosis. Patients may become septicemic and experience fever, chills, mental state changes, and hypotension, but the fatality rate (20–30%) is lower than that for primary septicemia. Occasionally, *V. vulnificus* may also be associated with gastroenteritis. In such cases, the organism is isolated from stools only and illness is characterized by abdominal cramps, vomiting, or diarrhea. Of 422 *V. vulnificus* infections reported in the USA during 1988–96, 45% were wound infections, 43% primary septicemia, and 5% gastroenteritis.

As *V. vulnificus* is common in warm coastal waters, it has been suggested that climate change may widen the geographical range of infections. The outbreak in fish handlers in Israel in 1996 has been linked to warm summer that year. Cases in Europe are rare and are limited to wound infections.

Antibiotic therapy is important for both primary septicemia and wound infections. Tetracycline has been the most effective and in some cases, this antibiotic has been used in combination with third generation cephalosporin or gentamycin or chloramphenicol.

Methods for Detection and Enumeration in Foods

Several methods have been described for isolation and identification of *V. vulnificus* from foods and the environment. Currently, there are no internationally validated methods. The method described in US FDA *Bacteriological Analytical Manual* (BAM) for enumeration of *V. vulnificus* involves most probable number (MPN) analysis using alkaline peptone water, plating the tubes showing growth onto modified cellobiose-polymyxin-B colistin (mCPC) agar, identification of typical colonies by biochemical tests or by colony hybridization using enzyme-labeled DNA probe. Though traditionally, thiosulphate citrate bile salt sucrose (TCBS) agar has been used for isolation of pathogenic *Vibrio* spp., a number of studies have indicated that the selectivity of this medium is not adequate for isolation of *V. vulnificus* from environmental samples. Cellobiose-polymyxin-B colistin (CPC) agar has colistin and polymyxin as selective agents and cellobiose to differentiate *V. vulnificus* from non-cellobiose fermenting Vibrios like *V. cholerae*. Selectivity is further improved by incubation at 40 °C. This was modified (mCPC) by reducing the concentration of colistin from 1.4×10^6 to 4×10^5 U l^{-1}. Other selective agars described for *V. vulnificus* include *Vibrio vulnificus* agar (VV agar), sodium dodecyl sulfate-polymyxin B-sucrose (SPS) agar, *Vibrio vulnificus* medium (VVM) with or without colistin (VVMc), and *Vibrio vulnificus* enumeration (VVE) agar. Some investigators reported higher isolation rate using alkaline peptone water with polymyxin for enrichment and cellobiose-colistin (CC) agar for selective plating. Figure 1 summarizes the steps involved in conventional culture-based isolation or enumeration of *V. vulnificus*. The temperature of incubation varies with the selective agar used. Colony color depends on carbohydrate used. In media containing sucrose (TCBS, SPS), the colonies appear green or bluish green and in media containing cellobiose (CPC, mCPC, CC, VVM), the colonies appear yellow. In VV agar containing salicin, the colonies are gray with dark center and in VVE containing cellobiose, X-Gal (5-bromo-4-chloroindoxyl-β-D-galactopyranoside), the colonies are bluish green. Identification of colonies coming up on selective agars by biochemical tests could be a challenge due to phenotypic plasticity, but systems such as API20E or Biolog have been used. Isolates can also be identified by hybridization with digoxigenin-labeled DNA probe binding to the cytolysin gene *vvhA* or by PCR amplification of *vvhA* gene.

Alternate method described for isolation/enumeration of *V. vulnificus* involves direct plating of samples on nonselective agar, VV agar, followed by colony lifts on whatman filter paper, lysis of colonies, fixing of DNA, and hybridization with alkaline phosphatase-labeled probes binding to *V. vulnificus* cytolysin/hemolysin (*vvhA*) gene. Digoxigenin-labeled *vvhA* probes can also be used. Nitro-blue tetrazolium/5-bromo-4-chloro-3'Indolyl phosphate (NBT/BCIP) substrate is used for color development. For isolation of colonies reacting with the probe, the filter is aligned with the plate the colonies from the area reacting with probe are picked up, isolated by streaking on mCPC or CC agars and confirmed by PCR or probe hybridization (Figure 2). Results with MPN and direct probe hybridization methods have been found to be comparable,

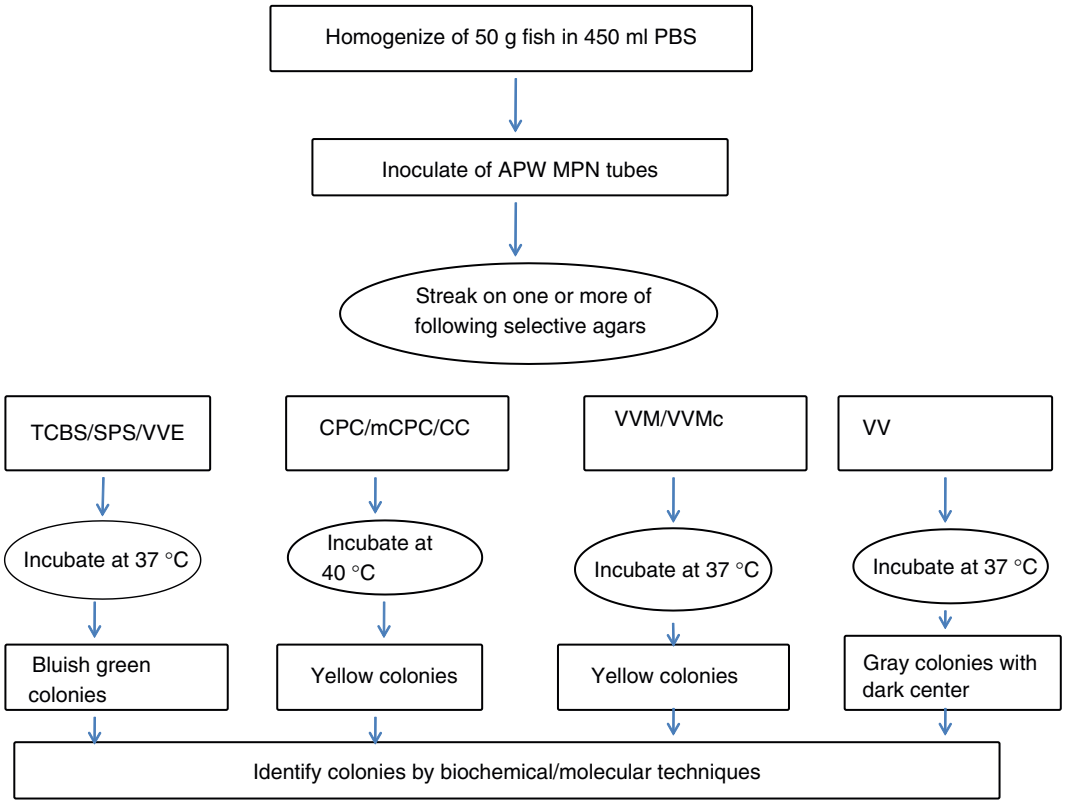

Figure 1 Steps used in conventional method for isolation/enumeration of *V. vulnificus* in seafood.

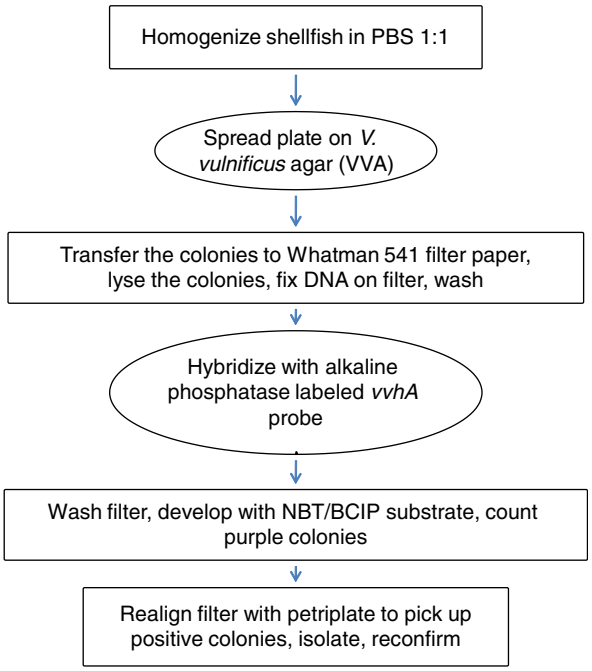

Figure 2 Steps used in enumeration of *V. vulnificus* by colony hybridization technique.

capable of detecting as few as 10 viable cells per 100 g. Digoxigenin-labeled probes binding to *vvhA* gene or 16S rRNA gene in conjunction with selective differential medium VVM could also be used.

A number of PCR-based assays have been used for detection of *V. vulnificus* in seafood and the target for PCR amplification has been various regions of *vvhA* gene or 16S rRNA/23S rRNA gene or gyrB gene. One of the problems in applying PCR for detection of *V. vulnificus* in seafood directly is the inhibition of reaction by seafood matrix. Generally, DNA extraction protocols are used to minimize this problem. Another problem is the inability to distinguish between dead and viable cells. Nested PCR using 23S rRNA gene universal external primers and *V. vulnificus* specific internal primers had a sensitivity of detecting 120 cells of *V. vulnificus* in artificially inoculated samples without enrichment in 24 h. Nested PCR amplifying *vvhA* gene could detect as low as 1 cfu g^{-1} of seafood, when guanidinium isothiocyanate method is used for extraction of DNA. PCR can be used in conjunction with MPN technique for enumeration of *V. vulnificus*. Multiplex PCR for detection of *V. vulnificus* with other pathogens such as *Salmonella* Typhimurium, *V. cholerae*, *Vibrio parahaemolyticus*, and *E. coli*. In oyster homogenates seeded with pathogens, 10–100 cfu g^{-1} could be detected with two rounds of PCR. Combination of PCR and microtitre plate sandwich hybridization has been used to detect multiple pathogens like *V. vulnificus*, *V. cholerae*, *V. parahaemolyticus*, and *S.* Typhimurium. Amplified target DNA was hybridized with capture probes in microtitre plates and detection was achieved by hybridization with a biotinylated oligonucleotide probe internal to amplified DNA. In oyster homogenates seeded with *V. vulnificus*, detection limits were 100 cfu g^{-1}.

Recently, there have been several reports on the application of real-time PCR for quantification of pathogens associated with foods. Real-time PCR assay based on TaqMan probe as well as SYBR green dye have been used for detection and quantification of *V. vulnificus*. Sensitivity of the assay based on *vvhA* gene fragment amplification was 100 cells per g in oyster homogenates or seawater. Enrichment for 5 h increased the sensitivity of detection to one cell. Results of enumeration of *V. vulnificus* by real-time PCR performed on MPN tubes after 6 h enrichment showed 98% agreement with that obtained by plating the MPN enrichments followed by confirmation of colonies by colony hybridization but real-time PCR gave faster results. Loop mediated isothermal amplification (LAMP) is another technology that is gaining popularity in food safety testing laboratories, because this can be performed and the results read without expensive equipment. LAMP assay using primers binding to *vvhA* of *V. vulnificus*, had a detection limit of 10^7 cfu g^{-1} with oysters and 7 cfu g^{-1} after 5 h enrichment.

Risk Assessment

The FAO/WHO risk assessment for *V. vulnificus* in raw oysters modified the US FDA *V. parahaemolyticus* risk assessment model to assess the risk of *V. vulnificus* primary septicemia in the USA, because quantitative data for *V. vulnificus* levels in oysters, at the point of consumption and for the susceptible population available for the USA. This risk assessment used data obtained by weekly analysis of *V. vulnificus* levels in oysters from four Gulf States conducted during 1994–95. Since presently, it is not possible to specifically identify pathogenic strains, all strains were considered equally virulent. Postharvest practices (duration oysters in harvest vessel in water, time to first refrigeration) used in the model were based on surveys conducted in Gulf Coast. *Vibrio vulnificus* growth in oysters, survival during refrigeration, and levels at consumption were estimated based on data from studies in the US Gulf Coast. The model predicted that the mean *V. vulnificus* levels in oysters would be 5.7×10^4 per g in summer and 8.0×10^1 per g in winter. At a serving size of 196 g, the ingested dose would be 1.1×10^7 *V. vulnificus* in summer and 1.6×10^4 in winter. US FDA data on prevalence of risk factors in US population and oyster consumption data from surveys was used in the model. The dose response relationship was modeled by estimating the exposure per eating occasion and number of eating occasions for oyster associated *V. vulnificus* cases reported to US CDC during 1995–2001. The model predicted 0.5, 11.5, 12.2, and 8 illnesses for winter (January–March), spring (April–June), summer (July–September), and autumn (October–December) seasons, respectively. When compared with epidemiological data, the number of reported cases (average for 1995–2001 was 0.6 in winter, 9.6 in spring, 13.5 in summer, and 7.4 in autumn) were within the 90% confidence limit predicted by the model.

The risk assessment also predicted the reductions in illness that could be achieved by postharvest treatments to reduce *V. vulnificus* levels to target values such as 3, 30, or 300 per g. In the USA, there are three validated methods to achieve endpoint criterion of <3 MPN g^{-1} *V. vulnificus* and these include mild heat treatment (50 °C), freezing with extended frozen

storage, and high hydrostatic pressure. If all oysters are treated to achieve target level of 3 per g, the model predicted that the number of cases could be reduced from current 32 reported cases per year to one case every six years. If the target is shifted to 30 or 300 per g, then the predicted cases would increase to 1.2 and 7.7 cases per year, respectively. At a time to refrigeration range of 0–20 h, the predicted illness ranged from 17.7 to 59.3 cases, suggesting that immediate cooling of oysters alone is not adequate to achieve substantial reduction in the number of *V. vulnificus* illnesses. As *V. vulnificus* levels in oysters harvested from waters with a salinity of >30‰ is greatly reduced, it is predicted that if all oysters are harvested from waters at salinity of >30‰, irrespective of the water temperature, *V. vulnificus* illness would be <1 case per year. Relaying oysters to high-salinity waters (>32‰) has been shown to reduce *V. vulnificus* levels by 3–4 log units (<10 per g) within 2 weeks.

Control Measures

Cooling of oysters after harvest is very important for preventing multiplication of *V. vulnificus*. Multiplication of *V. vulnificus* does not occur at temperatures below 13 °C, hence this is the target temperature for cooling oysters for control of this pathogen. Levels of this pathogen in shellstock oysters held without refrigeration for 3.5, 7.0, 10.5, and 14 h increased 0.75, 1.3, 1.74, and 1.94 log units, respectively. According to the US regulations, when water temperature exceeds 27 °C, commercial shellfish should be refrigerated within 10 h of harvest. There are additional control plans for shellstock associated with two or more *V. vulnificus* illnesses. Temperature control should be applied within 14 h when water temperature is between 18 and 23 °C; within 12 h if water temperature is 23–28 °C; within 6 h if water temperature exceeds 28 °C.

In the USA, freezing combined with frozen storage is accepted as a control measure for *V. vulnificus*, but the process should be validated and hazard analysis critical control point (HACCP) compliant. High hydrostatic pressure is another technology that is permitted in the USA for postharvest treatment of oysters. To obtain a 5 $\log_{10}$ reduction of *V. vulnificus* levels, a treatment of 250 megapascal (MPa) for 120 s is required.

Commercial heat shock process is used in some parts of the USA as a processing aid for oysters. The process involves submerging chilled oysters in potable water at a temperature of 67 °C for approximately 5 min depending on oyster size and condition. Heat shocked oysters are cooled by spraying with potable water for 1 min before shucking and washing. 2–4 $\log_{10}$ reduction in *V. vulnificus* counts can be achieved by heat shock process. Low temperature pasteurization (50 °C for 10 min) reduced *V. vulnificus* counts from 10^5 MPN g^{-1} to undetectable levels in inoculated shellstock oysters.

Based on FAO/WHO risk assessment, Codex Committee on Food Hygiene developed a Code of Hygienic Practice for control of *Vibrio* spp. in seafood with an annex on control measures for *V. parahaemolyticus* and *V. vulnificus* in bivalve molluscs. This Code recommends assessment of the need for control measures based on (1) number of sporadic illness associated with bivalve molluscs in the area, (2) water temperature at harvest, air temperature, and harvest and postharvest practices, and (3) water salinity at harvest. Because there is a wide geographical variation in prevalence and levels of *V. vulnificus* in bivalves, control measures that have been validated and appropriate for the region may be adopted by the competent authority having jurisdiction and implemented under HACCP system. Validation of control measure should be carried out in accordance with the Codex Guidelines for the validation of food safety control measures (CAC/GL 69-2008).

Because only a certain section of population is susceptible to *V. vulnificus*, health education could be a useful tool for preventing infections. The US FDA has a health education kit. The Interstate Shellfish Sanitation Program has developed education materials and fact sheets to inform public about the link between *V. vulnificus* infections and diabetes, liver disease, and other immunocompromised conditions.

Glossary

AIDS Acquired immunodeficiency syndrome is a disease of the human immune system caused by the human immunodeficiency virus (HIV), which causes severe damage to the immune system.
Bacteremia The presence of viable bacteria in the circulating blood.
Cholecystitis Acute cholecystitis is a sudden inflammation of the gallbladder that causes severe abdominal pain.
Cytolysin The substance or antibody elaborated by microorganisms, plants, or animals that is specifically toxic to individual cells, in many cases causing their dissolution through lysis.
DNAse A deoxyribonuclease (DNAse) is a type of nuclease enzyme that catalyses the hydrolytic cleavage of phosphodiester linkages in the DNA backbone. DNases either can cleave only residues at the ends of DNA molecules or cleave anywhere along the DNA chain.
Fulminant Any event or process that occurs suddenly and quickly, and is intense and severe to the point of lethality.
Microbiome The totality of microbes, their genetic elements (genomes), and environmental interactions in a defined environment, for example, the gut.
QPCR-MPN Quantitative real-time polymerase chain reaction (QPCR) is a laboratory technique based on the polymerase chain reaction, which is used to amplify and simultaneously quantify a targeted DNA molecule. For one or more specific sequences in a DNA sample, QPCR enables quantification, which facilitates the determination of most probable number (MPN) enumeration.
rRNA Ribosomal ribonucleic acid, the RNA component of the ribosome, performs critical functions in the ribosome that allows protein synthesis to occur. The genes that encode rRNAs evolve (i.e. change sequence over time) in a very unique manner that makes them excellent 'markers' to trace evolutionary history and powerful tools to identifying species from sequence data.
Vibrovax Vaccine is used for the prevention of infertility and abortion in cattle caused by vibriosis.

Background

Noncholera *Vibrio* infections are caused by Gram-negative bacteria belonging to the same family, Vibrionaceae as those that cause cholera. Different species of *Vibrio* (except *Vibrio cholerae* O1 and O139) along with *V. cholerae* non-O1–non-O139 are collectively grouped as 'other vibrios.' These salt-tolerant Gram-negative bacilli are commonly found in warm coastal waters and infection can result from direct contact with contaminated seawater or ingestion of contaminated seafood.

Vibrio species are part of the normal flora of marine habitats and many of them are serious pathogens in fish and shellfish in marine aquaculture worldwide. Members of the genus *Vibrio* are autochthonous bacterial flora in the aquatic ecosystem and quite a few of them are associated with infections in humans and aquatic animals. Human infection follows either direct contact with aquatic environment or indirectly through contaminated food and water. While transmission of *Vibrio* infections in developing countries is by and large water- and foodborne *Vibrio* infections tend to occur more frequently in developed countries. Further, the magnitude of foodborne infections in developing countries is still incompletely understood due to lack of robust scientific information.

Characteristics of the Organism

The family Vibrionaceae currently consists of seven genera, namely, *Enterovibrio*, *Salinivibrio*, *Enhydrobacter*, *Listonella*, *Allomonas*, *Photobacterium*, and *Vibrio*.

At present, the genus *Vibrio* has 48 species that share the following characteristics: they are Gram negative, curved or straight rod, oxidase positive (except *Vibrio metschnikovii*), reduce nitrate to nitrite, susceptible to vibriostatic compound O129, motile by polar flagella, and facultatively anaerobic. Vibrios reach high densities in marine waters especially during the summer months. Although found primarily in marine ecosystems, some species (*V. cholerae* non-O1 and *Vibrio mimicus*) can live in fresh water. Halophilic vibrios require Na^+ for growth. Different abiotic factors like temperature, salinity, and pH of the water bodies are considered to be the factors that regulate their abundance and diversity. Among the currently described *Vibrio* species, 12 are known to be associated with infections in humans. *Vibrio parahaemolyticus* is the most common noncholera *Vibrio* associated with human infections, whereas *Vibrio vulnificus* is less common but more lethal. Other *Vibrio* species that occasionally cause human infections include: *Vibrio fluvialis*,

 doi:10.1016/B978-0-12-378612-8.00120-7

Vibrio furnissii, *Vibrio hollisae*, *Vibrio alginolyticus*, and *Vibrio cincinnatiensis*.

Different types of relationships like mutualistic association between *Vibrio fischeri* and fish; symbiotic association of *V. fischeri* with sepiolid squids, chitinous shellfish; and parasitic relationships of some vibrios typically affecting fish, frogs, and eels are known. In temperate climates, abundance of *Vibrio* vary seasonally as in the summer, vibrios can easily be isolated from water, suspended particulate matter, plankton, algae, sediment, fish, shellfish, and benthic marine environment while during winter months, they decline markedly in number and are found overwintering in sediments. Many of the *Vibrio* species have the capacity to produce biofilm, or surface-associated communities, which helps in the attachment of bacterial cells to host or environmental surfaces and in bacterial survival. Through the formation of biofilms, vibrios enter into a viable but noncultivable state.

Clinical Manifestation

Noncholera *Vibrio* infections are largely classified into two distinct groups: halophilic or nonhalophilic, depending on their requirement of sodium chloride for growth. Some species of noncholera vibrios are usually associated with foodborne gastroenteritis, soft-tissue infections or systemic infections such as meningitis, septicemia, cholecystitis, cellulitis, ear infection, and a variety of other wound infections.

Soft-tissue infections may result from direct inoculation or from localization after sepsis. Intense swelling and compromised blood supply necessitate a combined medical and surgical approach for treatment.

Gastroenteritis is the most common syndrome and is characterized by the acute onset of watery stools and crampy abdominal pain. Approximately half of those afflicted will have low-grade fever, headache, and chills; approximately 30% will have vomiting. Spontaneous recovery follows in 2–5 days. Wound infection is especially severe in people with liver disease or who are immune compromised.

Vibrio causes primary bacteremia, skin, and soft-tissue infections. The mortality can be up to 50% in septic patients. Sometimes, *V. vulnificus* can be isolated from the sputum without obvious signs of pneumonia, with the manifestations like erythema and painful swelling to hemorrhagic and necrotizing fasciitis.

Pathogenesis

Vibrio vulnificus is capable of causing severe and often fatal infections in susceptible individuals. It causes two distinct disease syndromes, a primary septicemia and necrotizing wound infections.

The presence of thermostable direct hemolysin (TDH) and TDH-related hemolysin (TRH) in *V. parahaemolyticus* remains closely associated with the severity of diarrheal illness. TDH and TRH have various biological activities including hemolytic activity, cardiotoxicity, and enterotoxicity. Type-III secretion system (TTSS) has been implicated to be involved in cytotoxicity to host cells and is instrumental for multifaceted host cell infection by induction of autophagy, cell rounding, and cell lysis.

Vibrio necrotizing soft-tissue infection is characterized by rapid progressing soft-tissue necrosis and fulminant septicemia in the at-risk host. Fulminant disease may quickly follow ingestion of raw oysters or clams in patients with hepatic cirrhosis, even when the liver disease is fully compensated. Different species like *V. vulnificus*, *V. hollisae*, *Vibrio carchariae*, *V. alginolyticus*, and *Vibrio damsela* cause serious wound infections. They can cross the intestinal mucosa barrier and produce different types of infections. Apart from enteric and wound infections, vibrios, along with other bacteria such as *Shewanella putrefaciens*, *Photobacterium phosphoreum*, and *Pseudomonas spp.* are likely sources of tetrodotoxin in pufferfish poisonings and probably other sources of tetrodotoxin in poisonous marine animals like the blue-ringed octopus and some sea snails.

Virulence Factor

Serogroups like *V. cholerae* non-O1, non-O139, O141, O75, O37, O10, O12, O6, and O14 have been reported to cause outbreaks of cholera-like illness. The variation in virulence of *V. cholerae* non-O1 and non-O139 isolates or host resistance factors potentially allow some strains to cause mild to severe gastroenteritis, whereas others may be involved in bloodstream invasion or deeper body sites.

Vibrio parahaemolyticus and *V. vulnificus* are serious human pathogens. *Vibrio parahaemolyticus* causes gastroenteritis in which the hemolysins, TDH and/or TRH, play a crucial role. Along with TDH/TRH, two TTSS of *V. parahaemolyticus* also plays a role in the pathogenicity of the bacterium. Other toxins, proteases, cytolysins, and pili may also play a role as virulence factors in both *V. parahaemolyticus* and *V. vulnificus*. The virulence of environmental strains of *V. vulnificus* appears to be indistinguishable from that of clinical isolates. A capsular polysaccharide is the primary virulence factor in *V. vulnificus* pathogenesis. *Vibrio vulnificus* secretes a cytotoxin RtxA which enables them to make their pathogenicity. Other vibrios (Table 1) have been sporadically found to be associated with human infections.

Few recent studies revealed that virulence genes could also be present among strains in the environment and acquisition of such genes might have taken place in the aquatic environment. Most of the pathogenic genes acquired by *Vibrio* spp. are either due to acquisition of mobile genetic elements or by phage infection.

Other Infections

In marine and estuarine environments, fish fauna are infected with species belonging to the genus *Vibrio*. *Vibrio* species that have been associated with disease in fish are *Vibrio anguillarum*, *Vibrio ordalii*, *V. damsela*, *V. carchariae*, *V. vulnificus*, *V. alginolyticus*, and *Vibrio salmonicida*. *Vibrio shiloi* and *Vibrio coralliilyticus* are pathogens implicated to bleach corals, with an extent of pathogenicity through adhesion, penetration, and

Table 1 Human infections caused by other *Vibrio* species

Vibrio *species*	*Clinical manifestation*	*Source of infection*	*Virulence factor*
V. cholerae non-O1 and non-O139	Gastroenteritis	Water and food	Hemolysin
V. parahaemolyticus	Gastroenteritis, wound infection, and bacteraemia	Shellfish and seawater	Cytotoxin and hemolysin
V. vulnificus	Wound infection, bacteraemia, and cellulites	Shellfish and seawater	Cytotoxin, hemolysin, lipopolysaccharide, capsular lipopolysaccharide, metalloprotease, and siderophore.
V. fluvialis	Gastroenteritis, fever, wound infection, and bacteraemia	Seafood	Cytotoxin
V. furnissii	Gastroenteritis	Seawater and seafood	Protease and hemolytic
V. mimicus	Gastroenteritis, wound infection, bacteraemia, and ear infections	Fresh water and seafood	Hemolysin (homologous to El Tor)
V. hollisae	Gastroenteritis, wound infection, bacteraemia, and septicemia	Shellfish and seafood	Hemolysin
V. alginolyticus	Wound infection, otitis, ear infection, diarrhea in AIDS patients, conjunctivitis, and posttraumatic intracranial infection	Seawater	Elastases, collagenases, DNAses, chondroitinases, gelatinases, lechitinases, and keratinases
V. damsela	Wound infection	Seawater	Cytolysin
V. metschnikovii	Bacteraemia	–	Cytolysin
V. cincinnatiensis	Bacteraemia and meningitis	–	Hemolysin
V. carchariae	Wound (shark bite)	Seawater	Hemolysin and cytotoxin

AIDS, Acquired immunodeficiency syndrome; DNAse, deoxyribonuclease.

multiplication within the coral tissues. *Vibrio fortis*, *Vibrio campbellii*, *Vibrio harveyi* are responsible in coral bleaching. *Vibrio harveyi* is a primary opportunistic pathogen of marine animal viz. oysters, lobsters, the common snook, prawns, turbot, barramundi, milkfish, and seahorses. *Vibrio fetus* causes abortion and/or infertility in sheep. Bacterial diseases have been reported in penaeid shrimp culture caused by 14 species of *Vibrio*.

Epidemiology

Although most *Vibrio* infections are reported from coastal areas, reports of gastrointestinal and wound infections in humans have also been documented from inland areas far from the sea coasts of Asia, Africa, Europe, Australia, and North and South America because of travel and shipment of contaminated food. Most of these infections are caused either by *V. cholerae* non-O1 or by *V. vulnificus*. Gastroenteritis caused by the noncholera *Vibrio* occurs in sporadic or common infection after consumption of raw, improperly prepared, or recontaminated seafood. All types of seafood products may be involved including oysters, mussels, clams, shrimp, and crabs, all of which are available almost universally. The risk of infection with *Vibrio* spp. is highest in filter-feeding bivalves as they concentrate bacteria in nature from the surrounding water. Contact with contaminated water is a risk factor mainly for wound infections and may involve the direct immersion or splashing of water in or onto open wounds or mucous membranes or entry through fish hook wounds, as well as less obvious routes such as cuts by broken shells or shark and other fish bites. Most pathogenic vibrios isolated from the environment exhibit wide strain-to-strain variation in virulence, except *V. vulnificus* (virulence of environmental strains are indistinguishable from clinical isolates). Animal-associated *Vibrio* microbiomes are increasingly documented as an influential source of *Vibrio* infection. In temperate and subtropic waters, *Vibrio* spp. show their greater consistency in the formation of different microbiomes with zooplankton, crabs, and mussels with higher variation among individuals, which suggests the evolution of a greater degree of host specificity. On the contrary, in planktonic (micro) habitats the microbiome seems to be an open system for vibrios in which high rates of immigration can take place.

Analytical Methods

Detection of pathogens either in sources (transmission vehicle) or at the site of infection is essential for ensuring the safety of different risk-prone groups. Advances in biotechnology have resulted in the development of rapid methods reducing the analysis time. Two major categories of rapid methods include immunological or antibody-based assays and genetic-based assays such as the polymerase chain reaction (PCR). Immunological identification and confirmation tests include enzyme immunoassay and enzyme-linked immunosorbent assay for pathogenic vibrios. Most of the genetic identifications are based on species-specific genes or 16S ribosomal ribonucleic

acid (rRNA). Recently QPCR-MPN (quantitative multiplex PCR) technique has been developed to minimize the work load of bacterial quantification through conventional MPN method. Molecular methods for identification and confirmation include simplex PCR, multiplex PCR, and loop-mediated amplification. PCR technique is widely used for efficient detection of foodborne as well as waterborne pathogens because of speed and specificity. However, PCR methods have focused mostly on species-specific detection. Different advanced approaches like multiple-locus variable-number tandem-repeat analysis, direct genome restriction enzyme analysis, matrix-assisted laser desorption ionization-time of flight mass spectrometry (MS), PCR-electrospray ionization-MS, capillary electrophoresis (resulting in a high-resolution and high-throughput), etc., genotyping methods help to understand the clonal relationship between the clinical as well as environmental *Vibrio* isolates. Light Upon eXtension real-time PCR assays are in use to observe the species-specific polymorphisms and rapid differentiation of the major pathogenic *Vibrio* species.

Control/Preventive Measures

People, both healthy and ill, including immunocompromised individuals, should be informed about the risk of eating raw seafood like oysters or clams and should be instructed not to eat them in a raw state. Consumption of well-cooked oysters and clams should be encouraged.

Knowledge about the resistance and growth characteristic of *Vibrio* species is more important to enable food manufacturers and consumers to avoid people getting contaminated by this foodborne pathogen in different parts of world. A set of regulations covering both foods in general and specific food stuffs also ensure that food has not been rendered injurious to health. Although foodborne infections are usually encountered in smaller numbers in tropical countries, pathogenic foodborne vibrios have been recognized as a reportable disease in the temperate countries wherein the practice of consumption of seafood is quite common.

As it is well known that most of the *Vibrio* species are naturally occurring, sanitation or other public health controls cannot delimit the contamination of oysters. As a result of which, California, Florida, and Louisiana in the USA enacted regulations in 1990 requiring restaurants and other establishments that serve or sell oysters to warn prospective purchasers about possible ill effects by using tagging, labeling, records retention, etc., which will help in rapid identification of the event of disease episodes.

Vaccination Research Needs

Vibrio is a major cause of many infectious diseases and a global threat to human health, aquaculture, and animal. Prevention by vaccination is the most efficient and economical way of preventing such infections, but one of the persistent challenges to prevent *Vibrio* infections and transmissions is the existence of closely related species and genera and the lack of efficient polyvalent vaccines against them. To date no such vaccination program has been initiated. Different studies targeting eels, fishes, and mice, showed a good immune response after vaccination. Moreover, Vibrovax has been used to vaccinate the cattle against vibriosis. A detailed study is required for generating the effective vaccine against other *Vibrio* infections.

BACTERIA

Yersinia enterocolitica and *Yersinia pseudotuberculosis*

ECD Todd, Ewen Todd Consulting LLC, Okemos, MI, USA

Glossary

Chitterlings (chitlins) Intestines of a pig, although cattle and other animals' intestines are similarly used, that have been prepared as food. In various countries across the world, such food is prepared and eaten either as part of a daily diet or at special events, holidays, or religious festivities. In the US, chitlins are an African American culinary tradition and a Southern culinary tradition sometimes called 'soul food' cooking.

Cirrhosis A chronic degenerative disease in which normal liver cells are damaged and are then replaced by scar tissue.

Diabetes mellitus A condition in which the pancreas no longer produces enough insulin or cells stop responding to the insulin that is produced, so that glucose in the blood cannot be absorbed into the cells of the body. Symptoms include frequent urination, lethargy, excessive thirst, and hunger.

Endocarditis Inflammation of the lining of the heart and its valves.

Erythema nodosum A skin disorder characterized by painful red nodules appearing mostly on the shins, and occasionally on the arms and face.

Eukaryotic Pertaining to a single celled or multicellular organism whose cells contain a distinct membrane bound nucleus. Eukaryotes include protoctists, fungi, plants, and animals.

Facultative anaerobe A microorganism that is capable of aerobic respiration in the presence of oxygen or fermentation in the absence of oxygen.

Fecal–oral route A means of spreading pathogenic microorganisms from feces produced by an infected host, usually via contaminated hands, objects, food, or water to the mouth of a recipient host.

Foci Origin or center of a disseminated disease. A small group of cells occurring in an organ and distinguishable, either in appearance or histochemically, from the surrounding tissue.

Glomerulonephritis Acute glomerulonephritis is an inflammatory disease of both kidneys, predominantly affecting children from age 2–12. Chronic glomerulonephritis can develop over a period of 10–20 years and is most often associated with other systemic disease including diabetes, malaria, hepatitis, or systemic lupus erythematosus.

Hemochromatosis An inherited blood disorder that causes the body to retain excessive amounts of iron, which can lead to serious health consequences, most notably cirrhosis of the liver.

Hypoacidity Decreased acidity (in the stomach).

Kawasaki disease An autoimmune disease in which the medium-sized blood vessels throughout the body become inflamed and affects the skin, mouth, and lymph nodes. It is most common among children less than five years of age of Japanese and Korean descent.

Lymphadenitis Inflammation of a lymph node. It is often a complication of a bacterial infection of a wound, although it can also be caused by viruses or other disease agents.

Modulate The functional and morphological fluctuation of cells in response to changing environmental conditions.

Multiple locus variable number tandem repeat analysis A laboratory tool designed to recognize tandem repeats and other qualities in a genome (in this case bacterial) to provide a high-resolution deoxyribonucleic acid (DNA) fingerprint for the purpose of identification.

Plasmid A circular, double stranded unit of DNA that replicates within a cell independently of the chromosomal DNA. Plasmids are most often found in bacteria and are used in recombinant DNA research to transfer genes between cells.

Polymerase chain reaction (PCR) primer A strand of nucleic acid that serves as a starting point for DNA synthesis. In PCR, primers are used to determine the DNA fragment to be amplified by the PCR process.

Pulsed field gel electrophoresis An electrophoretic technique in which the gel is subjected to electrical fields alternating between different angles, allowing very large DNA fragments to pass through the gel, and hence permitting efficient separation of mixtures of such large fragments.

Reactive arthritis An autoimmune condition that develops in response to an infection in another part of the body (cross-reactivity). A bacterial infection causes the arthritis, but by the time the patient presents with symptoms, the causative agent is no longer present.

Uveitis Serious form of eye inflammation.

Voges–Proskauer A diagnostic test to help identify bacterial species. Specifically, it is used to detect acetoin in a bacterial broth culture. The test is performed by adding alpha-naphthol and potassium hydroxide

 doi:10.1016/B978-0-12-378612-8.00121-9

to the Voges–Proskauer broth which has been inoculated with bacteria. A cherry red color indicates a positive result, whereas a yellow–brown color indicates a negative result.

Background

The genus *Yersinia* belongs to the Enterobacteriaceae family, and of the 11 species, only 3 are known to be pathogenic to humans, the plague bacillus, *Yersinia pestis*, and two that cause gastroenteritis: *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. Actually, *Y. pestis* is more genetically related to *Y. pseudotuberculosis* and less so to *Y. enterocolitica*. Genetic analysis of *Y. pestis* revealed it to be a clone of *Y. pseudotuberculosis*, which evolved sometime between 1500 and 20 000 years ago. *Yersinia enterocolitica* has between 10% and 30% DNA homology with the Enterobacteriaceae family and is only 50% related to *Y. pseudotuberculosis* and *Y. pestis*. *Yersinia enterocolitica* was first reported in 1934 and the first recognized description of five human isolates occurred in 1939. The causative bacillus of pseudotuberculosis was earlier described in 1883 as Bacille de Malassez et Vignal and was later renamed twice, i.e., as *Bordetella* and *Pasteurella pseudotuberculosis* before the current name *Y. pseudotuberculosis* was established in the 1960s. *Yersinia pseudotuberculosis* is the least common of the three main *Yersinia* species that cause infections in humans. *Yersinia pseudotuberculosis* primarily causes zoonotic infections in various hosts, including domestic and sylvatic animals and birds but has been associated with foodborne infection in humans, and a few outbreaks of *Y. pseudotuberculosis* infections in humans have been reported (see Section 'Examples of Outbreaks'). The most susceptible populations for these diseases and potential complications are the very young (<10 years), the debilitated, the very old, and people undergoing immunosuppressive therapy. Those most susceptible to postenteritis arthritis are people with human leukocyte antigen (HLA)-B27 (or related antigens such as B7). Because *Y. pestis* is not a foodborne pathogen, it will not be further discussed.

Characteristics of *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*

Yersinia spp. are small, rod-shaped, facultatively anaerobic, intracellular Gram-negative bacteria that tend to be motile at room temperature but nonmotile at 37 °C. Members of this species usually range from 0.5 to 0.8 μm by 1–3 μm in size. *Yersinia enterocolitica* and *Y. pseudotuberculosis* can grow over a pH range of 4–10, generally with an optimum pH of 7.6. They tolerate alkaline conditions very well, compared with acidic conditions (although that depends on the kind of acid used, environmental temperature, composition of the medium, and growth phase of the bacteria). Both of these are psychrotrophic with the ability to grow at temperatures <4 °C, but their optimum growth temperature is 28–30 °C. The generation time varies by incubation temperature: 34 min at 30 °C, 60 min at 22 °C, and 5 h at 7 °C.

Yersinia enterocolitica has six biogroups that may be present in feces, sputum, and mesenteric lymph nodes and infected wounds. For *Y. enterocolitica* there are 54 serogroups, but O:3, O:5, O:8, O:9, and O:27 are usually the most prevalent for human infections. More specifically, the pathogenic *Y. enterocolitica* serotypes/biotypes are O:3/4 and 3 variant Voges–Proskauer (VP) negative, O:5, 27/2, O:8/1b, and O:9/2 have been reported worldwide. In Japan, O:3/3 variant VP negative is the most frequent cause of human yersiniosis. In the US, despite declining incidences of serotype O:8/1b infections, O:3/4 and O:5, 27/2 infections are on the increase. In Europe, Serotype O:3 and O:9 infections account for more than 90% of *Y. enterocolitica* isolates from patients. For *Y. pseudotuberculosis*, there are 15 serogroups; serogroups O:1 and O:2 are each divided into subtypes a, b, and c, and serotypes O:4 and O:5 are each divided into subtypes a and b, for a total of 21 serotypes.

Virulence and Pathogenesis

Both pathogens harbor virulence genes that affect pathogenesis. High pathogenicity *Y. enterocolitica* biotype 1A and *Y. pseudotuberculosis* 1 (III) have the virulence plasmid (pYV) and high pathogenicity island (HPI). These include an outer membrane protein, *Yersinia* adhesion A (YadA), and the genetic suite comprising the type III secretory system. This process usually is facilitated by *Yersinia* outer proteins (Yops) proteins, which contribute to the ability of the cells to resist phagocytosis by causing disruption of the phagocytes. Pathogenicity of *Y. pseudotuberculosis* is determined by the HPI and the *Y. pseudotuberculosis*-derived mitogen, a superantigen. The presence of the three virulence factors varies among *Y. pseudotuberculosis* isolates.

Although *Y. pestis* is considered a bioterrorism agent, this does not apply to *Y. enterocolitica* or *pseudotuberculosis*. Nevertheless, because of the similarity between *Y. pestis* and *Y. pseudotuberculosis*, anyone isolating and working with this genus should be meticulous about the proper culturing, labeling, and transporting of these organisms.

Clinical Manifestations

The clinical manifestations may be similar for both species. These are enteroinvasive and/or destructive strains which typically invade the colon and terminal ileum, multiply within the mucous cells, neutralize the macrophages, and colonize the Peyerian glands or patches. They also elaborate enterotoxins responsible for the gastroenteritis symptoms. The infective dose for humans is high, estimated to be in a wide range of 10^4–10^9 organisms for both pathogens. However, the infective dose may be lower depending on the type of infecting strain and certain host factors, for example, in people with gastric hypoacidity.

Infection with *Y. enterocolitica* can cause a variety of symptoms depending on the age of the person infected. Infection with *Y. enterocolitica* occurs most often in young children, and the infection is more common in the winter.

Common symptoms in children are fever, abdominal pain, and diarrhea, which is often bloody. Diarrhea occurs in approximately 80% of cases; abdominal pain and fever are the most reliable symptoms. Symptoms typically develop 4–7 days (reported 1–11 days range) after exposure and may last 1–3 weeks or longer, even up to several months. In older children and adults, right sided abdominal pain and fever may be the predominant symptoms and may be confused with appendicitis. Yersiniosis usually resolves itself without antibiotic treatment unless the disease is unusually severe or there are ongoing complications. In a small proportion of cases, bacteremia can occur. However, fatal cases are rare. If septicemia or other invasive diseases occur, antibiotic therapy, typically with gentamicin or cefotaxime (doxycycline and ciprofloxacin), is administered. Complications can occur in a small proportion of cases because of the infecting strain type and/or the presence of the specific human immunologic leukocyte antigen, HLA-B27. Sequelae include reactive arthritis, glomerulonephritis, endocarditis, erythema nodosum (which occurs predominantly in women), uveitis, and thyroid disorders. The frequency of the arthritic conditions is approximately 2–3%, and these may occur even in the absence of obvious gastrointestinal symptoms. Performance of unnecessary appendectomies also may be considered a major complication of yersiniosis, as one of the main symptoms of the disease is abdominal pain in the lower right quadrant. However, it has been argued that both *Y. enterocolitica* and *Y. pseudotuberculosis* are important causes of granulomatous appendicitis, and *Yersinia* infections may mimic Crohn's disease.

Yersinia pseudotuberculosis infection in humans usually leads to a gastroenteritis (although diarrhea is less frequent than in yersiniosis) characterized by a selflimited mesenteric lymphadenitis that mimics appendicitis. *Yersinia pseudotuberculosis* infects the intestinal tract, liver, spleen, and lymph nodes and causes these tissues to become inflamed. In Japan, *Y. pseudotuberculosis* was implicated in the etiology of Kawasaki disease. *Yersinia pseudotuberculosis* invades mammalian cells and survives intracellularly; the primary virulence factor is a plasmid-encoded protein that causes increased invasiveness. Postinfectious complications include erythema nodosum and reactive arthritis (particularly the O:3 strain). The arthritic phase of the disease can last up to six months. Thus, a major triad for *Y pseudotuberculosis* infection includes fever, abdominal pain, and rash, and later joint or back pain. *Yersinia pseudotuberculosis* infects eukaryotic hosts through a type III secretion system which involves the transport of proteins through the bacterial envelope and past the host cell plasma membrane. The secretion is part of a highly regulated system that is indirectly modulated by temperature changes and by a calcium dependency. The secretion system, regulatory pathways, and toxic proteins are all encoded on the virulence plasmid. It is relatively resistant to the nonspecific human immune response. Blood infections caused by *Y. pseudotuberculosis* may be rare but Kaasch *et al*. (2012) documented 72 of them since 1911,with 29 occurring in the past decade (2001–2011), and found that the most frequently described predisposing factors were diabetes mellitus in 21 patients (30%), cirrhosis in 16 patients (22%), and hemochromatosis in 6 patients (8%). Foci at distant sites were reported in 15 cases (21%). Overall, 26 patients (36%) died from the bloodstream infection. Thus, the mortality of invasive *Y. pseudotuberculosis* infection is comparable to other bloodstream infections.

Analytical Methods

As yersiniosis or pseudotuberculosis are diseases that are not routinely looked for in gastrointestinal cases, analysis of stool specimens must be requested by the epidemiologist or other investigators for the respective *Yersinia* species when either of these two are suspected as causes of these cases. The organism can also be recovered from other sites including the throat, lymph nodes, joint fluid, urine, bile, and blood. Yersiniosis may be misdiagnosed as Crohn's disease (regional enteritis) or appendicitis. Diagnosis of yersiniosis begins with isolation of the organism from the human host's feces, blood, or vomit, and sometimes at the time of appendectomy. Confirmation of a foodborne infection occurs with the isolation of *Y. enterocolitica* or *Y. pseudotuberculosis* from both the human host and the ingested food, followed by biochemical and serological identification. Molecular subtyping may also be useful for determining the source of the pathogen.

Yersinia enterocolitica or *Y. pseudotuberculosis* in patients with acute gastroenteritis can be readily isolated via conventional bacteriological media designed to isolate *Yersinia*. It is much more challenging to isolate these pathogens in asymptomatic carriers or from foods. Because *Yersinia* is able to resist weak alkaline treatment, potassium hydroxide (KOH) is used to select the organism while suppressing background flora such as *Pseudomonas, Proteus,* and *Serratia*. It is reported that *Y. enterocolitica* serotypes O:3, O:5, 27, O:8, and O:9 and *Y. pseudotuberculosis* serotype 5a strains in the artificially contaminated pork samples showed comparatively high resistance to KOH, and all *Yersinia* strains were recovered from the pork samples contaminated with more than 10^2 CFU g^{-1} after direct KOH treatment, without enrichment. However, food samples with lower contamination levels require an enrichment procedure for successful recovery of *Yersinia*. For these, cold and selective enrichment methods based on phosphate buffered saline and possibly mannitol, sorbitol, or bile salts, have been successful, for example, 25 g sample of the food mixed with 225 ml of peptone sorbitol bile broth for 10 days at 10 °C. Generally, cold enrichment yields higher recovery rates of pathogenic *Y. enterocolitica* than selective enrichment containing antibiotics, and an effective selective enrichment system for *Y. pseudotuberculosis* has yet to be developed. *Yersinia enterocolitica* can be presumptively identified in 36–48 h using biochemical testing or API 20E or Vitek GNI. Because many *Y. enterocolitica* isolated from nonhuman sources are not considered pathogenic, it is important to distinguish these isolates from pathogenic *Yersinia* species. Serology is used to identify the biotype (based on biochemical analysis) and serogroup (O antigen). Sera from acute or convalescent patients can also be titered against the suspect serotype of *Yersinia* spp. Polymerase chain reaction (PCR) based assays have been developed to target virulence genes on both the chromosome and plasmid and can be used to rapidly confirm the pathogenicity of the isolate. Several PCR primer sets are directed to either the plasmid-borne genes, for example, virF or yadA or the chromosomally located loci such as ail.

Because these pathogens are not normally looked for in stools or other clinical specimens in most countries, clinicians should consider both *Y. pseudotuberculosis* and *Y. enterocolitica* as a cause of gastroenteritis and pseudoappendicitis and request appropriate microbiological testing for patients with suspected cases.

Epidemiology

Both yersiniosis and pseudotuberculosis can be spread from animals to humans by contact with infected animals and their feces; human-to-human transmission also can occur (pathogens can be present in stool weeks after the clinical symptoms have ceased, and the bacterium is passed from the stools or soiled fingers of one person to the mouth of another person). However, consumption of contaminated foods is the most frequent means of infection. Because pigs are the principal reservoir for virulent strains of *Y. enterocolitica*, pork products are most at risk of causing yersiniosis, such as home slaughtered pork and chitterlings. In these cases, contact with the raw meat or organs contaminated with pathogen plus lack of hand hygiene has led to infections. For instance, an outbreak associated with chocolate milk occurred after chocolate was hand mixed in an open vat with bare hands at a school cafeteria. Bulk milk tanks and untreated water sources have been found to be contaminated with *Y. enterocolitica*. This explains why milk and tofu packed in unchlorinated spring water have been vehicles of outbreaks of yersiniosis in the US. Yersiniosis is far more common in Scandinavia and Japan than it is in the US. Different biotypes of *Y. enterocolitica* have been associated with infections around the world, with the most common biotype being 4/O:3.

The EFSA Panel on Biological Hazards (BIOHAZ) (2007) concluded that the best and most reliable indicator of *Y. enterocolitica* pathogenicity is the biotype as the various biotypes are either pathogenic or nonpathogenic. The serotype is not a reliable marker of *Y. enterocolitica* pathogenicity because several serotypes are common to both pathogenic and nonpathogenic strains. Strains of biotype 4 (serotype O:3) and biotype 2 (serotypes O:9) are commonly associated with human infections in Europe. Biotype 4 predominates in most Member States. However, biotype 2 might predominate in a few other Member States. These biotypes are seldom reported to be isolated from the environment. Animals (pigs and cattle) are the main reservoir and human cases are typically sporadic. Even though the number of reported human cases of yersiniosis in the EU has been decreasing since 2005, yersiniosis was the third most common zoonoses reported in the EU in 2009. A total of 12 647 single samples and batch based samples were included in the present analysis of *Yersinia* in food from 2004 to 2009 in Member States. Pathogenic biotype 2 (serotype O:9, O:5, 27) was reported from pig meat in Germany, Portugal, and the UK, and serotype O:3 was reported from pig meat in Germany. This O:3 serotype might belong to biotype 4, which is the most common human pathogenic biotype in the EU. Serotype O:5, belonging to nonpathogenic biotype A1, was reported from raw cow's milk, bovine meat, and sheep meat (UK).

Although *Y. pseudotuberculosis* infections are distributed worldwide, particularly in northern Europe, epidemiological information on this pathogen is not as well defined, and cases of *Y. pseudotuberculosis* are reported less frequently than infections from *Y. enterocolitica*. For instance, little is known about the incidence and epidemiology of *Y. pseudotuberculosis* in the US. It was first recognized in that country in 1938 and has rarely been identified since then. During 1996–2007, 1903 *Yersinia* infections were reported in the US FoodNet sites. Of these, 1471 (77%) had species information available. Most of the isolates were *Y. enterocolitica* (1355; 92%); compared with 18 (1%) *Y. pseudotuberculosis*. The average annual incidence of *Y. pseudotuberculosis* infections was 0.04 cases per 1 000 000 persons, with most cases reported from California and Oregon.

Both pathogens have a history of causing a higher incidence of disease in cooler months and in temperate climates. In many cases and even epidemics, the source of infection remains unknown, and there may be more reservoirs and implicated food sources yet to be determined. One example of this is an outbreak in Turku, Finland in winter 1981–1982 with 19 cases of infection caused by *Y. pseudotuberculosis* serotype 3. Postinfection complications developed in 10 of 19 patients, but the presence of antigen HLA-B27 was not a determining factor. In spite of active screening of the respective families and environments of the patients, no transmitting factor was found, and the precise source of the infection was never identified. However, vegetables including carrots were the most likely common source because they were grown, sold, or eaten by the 19 cases. From succeeding outbreaks in Finland, where carrots and lettuce were implicated, raw vegetables could have been the vehicle for the pathogen (see Section 'Examples of Outbreaks'). In a later study in France, *Y. pseudotuberculosis* infections increased in that country during the winter of 2004–2005 in the absence of epidemiologic links between patients or strains. This increase represents transient amplification of a pathogen endemic to the area and may be related to increased prevalence of the pathogen in rodent reservoirs.

Because both of these species cause gastroenteritis, they are transmitted through the fecal–oral route and have been found in the gut of a variety of wild and domestic animals. The major reservoir for *Y. enterocolitica* strains that cause human illness is the tonsils of pigs. Rodents that inhabit pig abattoir may also be carriers of virulent types of *Yersinia*. Other, mostly nonpathogenic, strains of these species are found in many other animals including rodents, rabbits, beaver, sheep, cattle, horses, dogs, and cats. Nonpathogenic strains of *Y. enterocolitica* have also been found in surveys of a wide variety of environmental sources, such as frogs, fleas, flies, soil, ponds, lakes, meats (other than pork), oysters, fish, crabs, and raw milk. Although the prevalence of this organism in soil, water, and animals offers many opportunities for nonpathogenic strains of *Yersinia* to enter the food supply, raw or undercooked pork products have drawn the greatest attention as a source of the pathogenic strains of *Y. enterocolitica*. *Yersinia enterocolitica* can grow easily at refrigeration temperature in contaminated vacuum-packed meat, boiled eggs, boiled fish, oysters, raw shrimp, cooked crab meat, pasteurized liquid eggs, pasteurized whole milk,

cottage cheese, and tofu. It persists longer in cooked foods than in raw foods due to increased nutrient availability. The risk of contracting an infection from these pathogens would be most likely from poor sanitation by food handlers, handling of raw pork, and inadequate cooking. Prolonged refrigerated storage of contaminated foods may be a contributing factor in cases of foodborne disease. Hunters may be at risk by eviscerating and dressing carcasses, because sudden death of nine deer in a deer farm were caused by *Y. pseudotuberculosis* serotype O:3 found with virulence factors for invasion and colonization of host intestine and lung.

Examples of Outbreaks

Yersinia enterocolitica

Yersinia enterocolitica foodborne outbreaks have occurred in Australia, Finland, Japan, Norway, the US, and Brazil. There were two foodborne outbreaks in China in 1980s; one was caused by beef contamination in Lanzhou of Gansu Province in 1986 with 109 patients with diarrhea caused by *Y. enterocolitica* O:3 infection. The second occurred in a school in Shenyang, Liaoning Province, with 352 students having diarrhea caused by *Y. enterocolitica* O:8 infection. *Yersinia enterocolitica* is a concern worldwide with foodborne infections having been reported in hundreds of countries. The incidence of yersiniosis is lower than the better known foodborne pathogens partly because yersiniosis is of rare occurrence in nontemperate regions, and routine surveillance for *Yersinia* spp. in patients and foods is limited or nonexistent in many countries. Vehicles either confirmed or suspected have included liquid milk, both pasteurized and unpasteurized, powdered milk, pork products, and tofu and bean sprouts contaminated through spring or well water. Mishandling of the vehicles was often cited in reports, such as infected workers contaminating reconstituted powdered milk and chocolate milk.

1. 50 persons were infected with *Y. enterocolitica* after eating contaminated tofu (soybean curd) in Washington State in the winter of 1981–1982. The majority had gastroenteritis; two had appendectomies and one had a partial colectomy. *Yersinia enterocolitica* serotype O:8 was isolated from the patients and the tofu. Two of thirteen workers were culture positive for the *Yersinia*, although they denied illness. The plant had no hand washing facilities; only pit privies were available and a badly contaminated, untreated surface water source (so-called spring water) that was positive for the *Yersinia*. The workers packed the tofu in this water with their bare hands before shipment.
2. In July 1981, an outbreak of gastroenteritis occurred at a summer diet camp. Of the 455 campers and staff, 35% developed an illness characterized by abdominal pain, fever, diarrhea, and/or nausea and vomiting. Seven persons were hospitalized, five of whom had appendectomies. *Yersinia enterocolitica* serogroup 0:8 was isolated from 37 (54%) of 69 persons examined, including the camp cook and three assistants. An epidemiologic investigation demonstrated that illness was associated with consumption of reconstituted powdered milk and/or chow mein. The epidemic strain was subsequently isolated from milk, the milk dispenser, and leftover chow mein. Information obtained during the investigation suggested that the *Yersinia* had been introduced by a food handler during food preparation procedures.
3. Yersiniosis, a notifiable disease in Norway, is the fourth most common cause of acute bacterial enteritis registered by the Norwegian Surveillance System for Communicable Diseases. Approximately 30 domestic cases are reported annually, and fecal specimens from patients who have acute gastroenteritis are routinely tested for the presence of *Y. enterocolitica*. Presumptive *Y. enterocolitica* O:3 and O:9 isolates are sent by primary laboratories to the National Reference Laboratory (NRL) at the Norwegian Institute of Public Health, where they are routinely verified, serotyped against a range of O antisera, biotyped if relevant, and tested for *Yersinia* virulence plasmid (pYV). If the strains are pathogenic, they are typed by use of multiple locus variable number tandem repeat analysis (MLVA). In March 2011, a multidisciplinary investigation was initiated after the NRL received five isolates of *Y. enterocolitica* O:9 from humans in disparate areas of the country. All had an identical MLVA profile, which had not been previously seen in Norway. The identified 21 case patients, mostly ill between 7 February and 20 March, resided in 10 geographically dispersed municipalities throughout the country. Therefore, a widely distributed product was probably the vehicle of infection, and the cases were epidemiologically associated with ingestion of ready-to-eat commercially prepared salad mix. The likely source of contamination for the outbreak, radicchio rosso, was imported from another European country. Few European countries regularly type *Y. enterocolitica*, which might explain why international requests for information produced no similar reports from other countries. The Norwegian company voluntarily withdrew all salad mixes containing radicchio rosso from the market, and since then no new outbreak cases were reported.

Yersinia pseudotuberculosis

Outbreaks of *Y. pseudotuberculosis* have been reported in the Northern Hemisphere, including Canada, Japan, Finland, and Russia. However, only in a few of the outbreaks has the vector or source of the infection been identified, and most published reports have originated from Finland. Milk and fresh produce, such as iceberg lettuce and carrots, have been implicated by epidemiologic investigations and some laboratory analysis as a source of infection, but mechanisms of contamination of such produce are as yet unclear. To date, no foodborne outbreaks caused by *Y. pseudotuberculosis* have been reported in the US, but it may be a matter of misdiagnosis that this has not yet happened.

1. Three outbreaks of *Y. pseudotuberculosis* infection were documented from 1982 to 1984 in Okayama Prefecture, Japan, and in two of these, untreated water seemed to be vehicle. In outbreak A, *Y. pseudotuberculosis*, a causal organism, was detected in 16 patients (serotype 5A). The incubation period of the infection was long (2–20 days).

Outbreak B and C occurred in remote mountain areas. In outbreak B, *Y. pseudotuberculosis* was detected in the feces of 35 out of 276 people (serotype 4B in 34 stools, 2C and 4B in one stool). In outbreak C, 12 children became sick; one of the 4 patients whose stools were examined showed an organism belonging to serotype 4B. The inhabitants in the area of outbreak B and C took unchlorinated mountain stream and well water for drinking. *Yersinia pseudotuberculosis* was detected in 3 out of 51 water samples (serotype 4A in one, 6 in 2 samples) and 2 out of 57 wild animal fecal samples (serotype 2C in 2 samples) in B area, and 4 out of 33 water samples (serotype 4A in 2, 4B in 2 samples) in C area.

2. In Finland, in October 1998, the number of *Y. pseudotuberculosis* serotype O:3 infections increased markedly. A case-control study revealed 47 case patients. One of these with bacteremia died, and five underwent appendectomies. Iceberg lettuce was implicated as the vehicle of a widespread outbreak. Four lunch cafeterias that had served iceberg lettuce were associated with clusters of case patients. The lettuce was traced back to originating farms. Without laboratory-based surveillance and serotype analysis this outbreak would not have been recognized and brought to a halt. Cases of yersiniosis, which appear to be sporadic, may be part of unrecognized outbreaks caused by contaminated fresh produce.
3. A single brand of homogenized milk was associated with an outbreak of *Y. pseudotuberculosis*, serotype O:1B, in British Columbia. The case-control study identified the same brand of homogenized milk, pork, and fruit juice as possible risk factors for illness. All case-patient stool isolates were genetic matches. A consumer sample of the brand of homogenized milk implicated by case patients was found to be contaminated with the outbreak strain of the *Yersinia*. An assessment of the consumer's home could not exclude the possibility of cross-contamination of the milk within the consumer's home. The traceback investigation found that this milk originated from a single plant; milk obtained from the plant showed no contamination. The precise cause of this outbreak was never determined. The incidence of postinfectious complications and the effect of antibiotic use on the clinical course were followed up for four months after the outbreak. The most common postinfectious symptoms were rash (8/59) and joint pain (7/59). Microbiological analysis, at follow-up, revealed 0/36 stools positive for *Y. pseudotuberculosis*. There was no significant difference in the frequency of postinfectious symptoms between cases who had or had not taken antibiotics. The postinfectious pathogenicity of *Y. pseudotuberculosis* serotype lb is lower than that documented for other serotypes.
4. In Finland, in 2004, 53 school children suffered from a *Y. pseudotuberculosis* outbreak case after they ate in a school cafeteria in March in which carrots were the suspected food vehicle. The kitchen had received all vegetables from a fresh food processing plant with produce supplied from two farms. Samples were taken from the carrot peeling line, carrot peeling leftovers, grated carrots, and other vegetable processing lines at the plant. Carrots originated from only two farms, which were inspected, and samples were obtained for bacteriological examination. Small mammals at the farms were caught in carrot fields and investigated microbiologically to identify the reservoir of *Y. pseudotuberculosis*. This pathogen was isolated from the carrot peeling line in the fresh food processing plant, from spoiled carrots, fluid draining from spoiled carrots, and a pooled sample of common shrew (*Sorex araneus*) intestines from one of the farms. The serotype was subtype O:1b and all 22 isolates from human and environmental samples had an identical or similar pulsed field gel electrophoresis pattern. The shrews may have been picked up with carrots by harvesting machinery and ended up dead in wooden storage frames with the carrots. If carrots become contaminated from the shrews, long storage at cold temperatures would favor growth of *Y. pseudotuberculosis*. After the outbreak, the Finnish Food Safety Authority recommended controlling contamination at the farm level by removing spoiled carrots and paying attention to any subsequent spoilage during handling procedures. Wild animals have been suspected as the reservoir of *Y. pseudotuberculosis*. The vole population had a cyclical peak in western Finland in 2001–2002 and declined until the spring 2003. Two field voles (*Microtus agrestis*) and two common shrews (*Sorex araneus*) were caught in the surrounding fields of the implicated farm in June 2004. The pooled intestinal sample of the shrews was positive for *Y. pseudotuberculosis* but not the pooled intestinal sample of the voles. This small study seems to implicate carnivorous shrews rather than typically herbivorous voles, but their link to carrots was not determined.

A second large outbreak of *Y. pseudotuberculosis* involving carrots occurred in 2006. *Yersinia pseudotuberculosis* O:1 infection affected more than 400 children from 23 schools and 5 day-care centers in two municipalities in southern Finland in August–September, 2006. A retrospective cohort study conducted in a large school center showed that the outbreak was strongly associated with the consumption of grated carrots served at a school lunch. The risk of illness increased with the amount of carrots eaten. Poor quality carrots grown the previous year had been delivered to the school kitchens in the two municipalities affected. In the patients' and the environmental samples collected from the carrot distributor's storage facility, identical serotypes and genotypes of *Y. pseudotuberculosis* were found, but the original source and the mechanism of the contamination of the carrots remained unclear. Domestic carrots for human consumption are usually consumed by the end of March next year, but some large farms have been able to provide carrots even up to July of the following year after harvesting, and during this long storage time, some carrots become spoiled and liquefied. In the current investigation, *Y. pseudotuberculosis* was detected in the fluid from spoiled carrots after one week's enrichment, indicating there were high levels of bacteria in the fluid. Outbreaks of *Y. pseudotuberculosis* linked to fresh produce have been detected repeatedly in Finland. To prevent future outbreaks, instructions in improved hygiene practices on the handling of raw carrots have been issued to farmers, vegetable processing plants, and institutional kitchens.

Unless epidemiologists and physicians are aware that *Y. pseudotuberculosis* could be a cause of gastroenteritis and

know which diagnostic test to order, *Y. pseudotuberculosis* infections will continue to go largely undiagnosed.

Control and Preventive Measures

To prevent yersiniosis and pseudotuberculosis, consumers should be educated to:

1. Avoid eating raw or undercooked pork or drinking unpasteurized milk or nonpotable water. Those at the highest risk of infection (very young and < 10 years, the very old, persons undergoing immunosuppressive therapy, and persons most susceptible to postenteritis arthritis) should be particularly vigilant about drinks and foods consumed and exposure to raw pork.
2. Wash hands with soap and water before eating and preparing food, after contact with animals, carcasses, and after handling raw pork. Because wild animals may be carriers of *Yersinia* spp., those dressing game meat should be especially careful after contact with intestinal contents and be meticulous about subsequent hygiene.
3. Clean hands and fingernails scrupulously with soap and water after handling raw chitterlings, or any raw pork product, before touching infants or their toys, bottles, or pacifiers. Someone other than the food handler should care for children while these foods are being prepared.
4. Prevent cross-contamination in the kitchen, for example, use separate cutting boards for meat and other foods, and carefully clean all cutting boards, countertops, and utensils with soap and hot water, especially after preparing raw meat.
5. Dispose of hog feces and offal in a sanitary manner.

PREFACE

Why an Encyclopedia on Food Safety?

With the world's growing population, the provision of a safe, nutritious, and wholesome food supply has become a major challenge. To achieve this, effective risk management based on sound science and unbiased information is required by all stakeholders, including the food industry, governments, and consumers themselves. In addition, the globalization of the food supply requires the harmonization of policies and standards based on a common understanding of food safety among authorities in countries around the world.

Furthermore, reports of food safety incidents and foodborne disease outbreaks in one country are disseminated almost instantaneously through the 24/7 news cycle to consumers in other countries all over the world. Consequently, food safety managers in government and industry are sometimes called on to respond to queries from politicians, the media, and the general public even before they may be aware of the problem. Taking effective intervention measures and communicating the basis of their decisions and actions are essential for maintaining confidence in the safety of the food supply.

In all the above circumstances, sound scientific information is the key to effectively and efficiently assess, manage, and communicate on food safety risks. Yet, professionals and other specialists working in this multidisciplinary field are finding it increasingly difficult to keep up with developments outside their immediate areas of expertise. The time and staff needed to provide this information are beyond the resources of most individuals and organizations. Therefore, a single source of concise, reliable, and authoritative information on food safety has, more than ever, become a necessity.

This is the role that the Encyclopedia on Food Safety sought to fulfill by gathering all of the world's knowledge and expertise covering the entire spectrum of food safety topics into one comprehensive reference work. This was done with the objective of facilitating the work of those working in the field of food safety and related fields, such as nutrition, food science and technology, and environment. The Encyclopedia also provides a platform for experts to share their state-of-the art expertise and experience with the rest of the food safety community. Furthermore, the Encyclopedia's online feature is designed for rapid search and retrieval of relevant information.

Who Will Benefit from the Food Safety Encyclopedia?

The Encyclopedia will be useful for professionals and other specialists working in, but not limited to, the following institutions:

- Regulatory and enforcement agencies.
- Food industry.
- Trade and industry organizations.
- Audit and certification bodies.
- Academic institutions.
- Private and governmental scientific and research institutions.
- International and nongovernmental organizations with an interest in food.

What Does the Encyclopedia of Food Safety Contain?

With some 280 articles, the Encyclopedia provides comprehensive coverage a broad range of food safety topics, which may be grouped under the following general categories:

- History and basic sciences that support food safety.
- Foodborne diseases, including surveillance and investigation.
- Foodborne hazards, including microbiological and chemical agents.
- Substances added to food, both directly and indirectly.
- Food technologies, including the latest developments.
- Food commodities, including their potential hazards and controls.
- Food safety management systems, including their elements and the roles of stakeholders.

In developing the Encyclopedia, the editors and members of the Editorial Advisory Board have aimed to ensure that the Encyclopedia provides:

- Contributions by the foremost authorities in their fields.
- Unbiased and concise overviews on a multitude of food safety subjects.
- References for further information
- Specialized and general definitions for food safety terminology.

While the editors have made every effort to ensure that the Encyclopedia reflects the most complete and up-to-date information available, new scientific findings, and advances in food safety occur continuously. In undertaking a project of this scale and with the inevitably delays that occur during production, the editors acknowledge that some topics may have been omitted or insufficiently addressed. Therefore, the feedback of readers to point out any such errors or oversights will be greatly appreciated and will facilitate the development of future editions.

Acknowledgments

The lead editors would like to thank the Editorial Advisory Board members, section editors, and particularly, the authors who have generously contributed their time and talent to the development of this Encyclopedia. We are indebted to the Elsevier secretariat, which has assisted in the production of this work since its inception. Finally, a special note of thanks goes to our families whose patience and support are greatly appreciated.

DEDICATION

This Encyclopedia is dedicated to our children, our grandchildren, and all the world's future generations who we hope will enjoy the benefits of a safe and nutritious food supply, produced with fair management of people working in industry and ethical treatment of animals.

FOREWORD I

Today's food system is one of the humanity's great achievements. It includes millions of commercial actors all over the world who produce, process, transport, store, market, and serve food that feeds billions of people daily. The complexity, diversity, and scope of the food system are almost beyond comprehension – ranging from small producers and processors serving local communities to vast global enterprises producing food for millions and managing extended international supply chains – all aimed at meeting high consumer expectations for safe, nutritious, and affordable food.

For all of its successes, the food system is full of challenges. Food insecurity and hunger remain major problems worldwide, and, for those with ready access to the foods of their choice, it is too easy to choose products high in salt, fat, and added sugar. Food safety – the task of avoiding chemical and microbiological contamination of food that can make people sick – is another persistent and dynamic challenge. In fact, new products in the marketplace, new patterns of production and supply, new consumer behaviors and new bacterial and chemical hazards – coupled with high consumer expectations – conspire to make food safety one of the central challenges of today's food system.

People working in the food system know this. Prominent illness outbreaks and contamination incidents take a toll on the public's health and cause a loss of confidence that can steer consumers away from healthy foods, like fresh fruits and vegetables, and impose big economic losses on food producers and processors. And the food system is responding with a heightened awareness of food safety at all levels of the food system and tremendous effort across the system to improve food safety. Much progress is being made.

One of the most important food safety developments of the last quarter century has been the emergence of a widely shared, science-based understanding of foodborne illness, its causes, and how it can be prevented. This begins with the understanding that the current burden of foodborne illness is unacceptable because it is largely preventable. It is preventable if we see food safety as a food system issue and recognize that microbiological and chemical hazards can enter the food supply at any point in the system along the pathway from the farm through processing, transport, storage, and retail sale. Likewise, opportunities to minimize hazards and help prevent food safety problems exist throughout the system, which means that everyone in the system shares responsibility for the safety of the food we eat.

Fulfilling this responsibility requires that we understand as much as we can about food safety hazards and their causes, devise the appropriate, science-based preventive controls for particular hazards and food production settings, monitor their effectiveness, and adjust the controls as needed based on experience. In short, progress on food safety depends fundamentally on a strong base of knowledge and continuous learning to systematically prevent food safety problems. And participants across the global food safety community are actively seeking and applying the knowledge needed to produce safe food and meet high consumer expectations.

This food safety encyclopedia provides a comprehensive overview of what we know about food safety hazards and control measures. We have more to learn, but the knowledge compiled in this encyclopedia demonstrates that we know a lot and that what we know can help empower participants in today's food system to fulfill their food safety responsibility. Although the food safety challenge is global and continuing, and may seem daunting, it can be met if all who share responsibility for food safety take advantage of the knowledge we have, participate in continuous learning, and place first priority every day on protecting the safety of food. That will be good for the food system – and for the consumers it serves.

Michael R Taylor
Deputy Commissioner for Foods and Veterinary Medicine, US Food and Drug Administration (FDA), Silver Spring, MD, USA

FOREWORD II

Food is one of the most basic requirements to sustain life. However, the safety of food and water cannot be taken for granted. Owing to both manmade and natural processes, an array of chemical and microbiological disease-causing agents find their way into food through multiple routes. When contaminated, such food can endanger or even destroy life. Therefore, from time immemorial, humankind has waged a constant battle against foodborne disease. Over many centuries of human development, people invented technologies that helped them fighting this battle, such as cooking, smoking, sun drying, canning, and freezing, to mention but a few. But like any scientific advance, some of these technologies presented their own food safety issues.

In a number of holy books, religious proscriptions for handling food contributed to food safety. In addition, many centuries ago, some governments already recognized that they had responsibilities in this domain and many laws were enacted to ensure the purity of certain foods. But it was only at the end of the nineteenth century, following scientific developments in the field microbiology and other areas of food science, that 'modern' food regulatory activities started.

In 1948, the availability, accessibility, and affordability of food were recognized as a basic human right by the United Nations in its Universal Declaration of Human Rights (Article 25, 1948). Implicit in this concept is the assumption that the food is first and foremost safe to consume, i.e., absence of health damaging properties. It is therefore not surprising that in the same year, the World Health Organization (WHO) was established as a specialized agency of the United Nations with a broad health mandate that included the specific responsibility to "develop, establish and promote international standards with respect to food…". Subsequently in 1963, WHO together with the Food and Agriculture Organization of the United Nations established an intergovernmental body to develop international standards for food – the Codex Alimentarius Commission. Today Codex stands as a major achievement in the promotion of food safety worldwide with an extensive collection of health and safety recommendations for food that are international recognized and referenced by the World Trade Organization and its member countries.

Thirty years ago, in 1983, WHO, again jointly with FAO, convened an Expert Committee on Food Safety to review the global food safety situation and provide guidance for governments, the food industry and consumers on how to cope with the inherent hazards and risks of our food supply. Based on available data and evidence at the time, the committee concluded that "illness due to contaminated food is perhaps the most widespread health problem in the contemporary world and an important cause of reduced economic productivity."

Unfortunately, this rather alarming statement appears to be still true today. Recent studies examining the morbidity and mortality of foodborne diseases have confirmed the significant public health burden posed by these diseases. In developed countries, one-quarter to one-third of the population are made ill each year because of foodborne diseases. In the developing world, the burden is much more severe. For example, diarrheal diseases are now estimated to cause 2.43 million deaths a year. According to WHO statistics, this is the second leading cause of mortality in low-income countries and kills more people than human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS), malaria, or tuberculosis.

In addition, the large number of food safety crises, which occur with increasing frequency, is contributing to the growing public demand for better health protection from contaminated food. This has prompted governments to strengthen their food safety legislation, improve capacities and infrastructure, and tighten control measures. Examples of governmental measures include the creation of European Food Safety Agency by the European Union in 2002, the Food Safety Modernization Act in the USA of 2011 and, most recently, 2013, the commitment of the Premier of the People's Republic of China, Mr. Li Keqiang, to act with an 'iron fist' to improve food safety.

These positive developments are, unfortunately, contrasted by the fact that in many other countries, mostly developing countries, food safety does not receive the attention it deserves. In this regard, the medical profession and public health community appear to be slow in accepting the role that contaminated food plays in the epidemiology of diarrhea, particularly in infants and young children. The treatment of hospitalized cases and outpatients is rarely seen as an opportunity for educating patients and their families on why foodborne diseases occur and how they can be prevented. Two publications published in WHO's Bulletin in 1993 and 2003 urged the health sector to take steps to correct this oversight. Yet even today progress has been disappointing. For example, in the 2009, United Nations Children's Fund (UNICEF) and WHO published a document entitled 'Diarrhea: Why children are still dying and what can be done,' that again overlooked food safety as one of the most important interventions for these diseases. Consequently, in a recent publication in a prestigious *Medical Journal of Gastroenterology*, the issue had to be raised again and omission corrected. It can only be hoped that the public health and donor communities will eventually adopt a more holistic approach for the prevention of diarrheal diseases, which includes essential food safety interventions.

It is for this and many other reasons that I enthusiastically welcome the initiative of Elsevier to publish this Encyclopedia of Food Safety under the editorial leadership of Drs. Yasmine Motarjemi and Gerald Moy (my former WHO colleagues) as well as Dr Ewen Todd, a world renowned expert in food safety. The laudable collaboration and support of the Editorial Advisory Board, Section Coordinators, and the many authors who have freely devoted their time to advance the cause of food safety through the development of this Encyclopedia is also acknowledged.

With such a collection of information, whoever needs first-hand, reliable, and authoritative information on food safety does not need to consult various books, periodicals, or

websites. All of what is presently known in this domain can be found in this comprehensive work. In particular, the Encyclopedia will be useful for decision-makers, managers, officials, and scientists working in government, the food industry, academia, and nongovernmental organizations.

This Encyclopedia may be particularly important for colleagues in developing countries to not only improve food safety for their people but also convince politicians and other policy makers of the pivotal role of food safety in health and development. Without this awareness, the ultimate goal of safe food for all cannot be achieved.

F Käferstein
Former Director, Food Safety and Food Aid Programme (1980–98), World Health Organization, Wiesbaden, Germany

EDITOR-IN-CHIEF

Yasmine Motarjemi holds a Masters degree in Food Science and Technology from the University of Languedoc, Montpellier, France (1978) and a Doctoral degree in Food Engineering from the University of Lund, Sweden (1988).

After her research and academic career at the University of Lund, in 1990, she joined the World Health Organization in Geneva as Senior Scientist. In WHO, she was responsible for the surveillance and prevention of foodborne illnesses (including education of professional food handlers and consumers), the development of the food safety assurance systems (e.g., Hazard Analysis and Critical Control Point system), and for assistance to the WHO Member States in strengthening their national food safety programme. She also contributed to the development of the risk analysis process. She has served in the Secretariat of various sessions of the Codex Alimentarius Commission and its Committees.

From 2000 to 2011, she held the position of Assistant Vice President in Nestlé where she worked as the Corporate Food Safety Manager. In this capacity, she has, among others, developed the Nestlé Food Safety Management system and managed various emerging food safety issues and crises.

She is the author, co-author, or editor of numerous peer-reviewed articles, books, training manuals, and other publications. Her latest books are Food Safety Management: A Practical Guide for the Food Industry (Elsevier 2014) and Invisible Things (original in French under the title: Les Invisibles), a book on food safety for children.

CO-EDITORS BIOGRAPHY

Dr Gerald G Moy, since his retirement from the World Health Organization in 2008, is a scientific adviser with Food Safety Consultants International working with numerous governments and international organizations. His expertise includes assessment of national food safety programs, risk assessment of chemical hazards in food, total diet studies, food safety during mass gatherings, and food defense. Dr Moy is the editor-in-chief for recently published book Total Diet Studies (Springer) and is currently preparing a chapter on food and water protection for a book on key public health considerations during mass gatherings. He serves on the International Scientific Advisory Committee of the China National Center for Food Safety Risk Assessment, the Technical Advisory Group of the World Food Program Technical Advisory Group, and the WHO International Virtual Advisory Group on Mass Gatherings. He is the author of numerous book chapters, articles, and publications and serves on the editorial boards for several food safety journals.

He received his BS in chemistry from the University of Wisconsin and his PhD in physical organic chemistry from Oregon State University, followed by a post-doctoral fellowship in biophysics at the University of New Mexico. He is a Fellow in International Academy of Food Science and Technology and a recipient of the 2009 Great Wall Friendship Award for his contributions to food safety during the Beijing Olympics.

Ewen CD Todd is the President of Ewen Todd Consulting and the former Professor in the Department of Advertising, Public Relations and Retailing, and he is also the Adjunct Professor in the Departments of Food Science and Human Nutrition and Large Animal Clinical Sciences at Michigan State University (MSU). He was former directors of the Food Safety Policy Center and the National Food Safety and Toxicology Center at MSU. At both these centers, Dr. Todd coordinated research in microbiology, toxicology, epidemiology, risk assessment, social science, and policy in the area of food safety, distance education programs, and outreach in the community. Previously, he was in the Bureau of Microbial Hazards, Health Products and Food Branch, Health Canada, Ottawa where he was a research scientist for 33 years working on methods development for pathogens in foods, foodborne disease investigation and reporting, costs and surveillance of disease, illnesses caused by seafood toxins, and risk assessment of foodborne pathogens. He also helped develop risk management strategies for the Department including producing videos and pamphlets on food safety education. Some of his recent research has been working on *Listeria* and *E. coli* O157 transfer coefficient and modeling projects, hygiene in child care centers, schools, and elder care facilities. He has also collaborated with government agencies and academia in Spain, Kuwait, Saudi Arabia, Lebanon, Cambodia, Korea, Japan, and China on food safety issues, and is an expert witness in legal suits involving food safety. He has published extensively on many different aspects of food safety, including 11 recent papers on food workers and hand hygiene. He is active in the International Association for Food Protection (IAFP) and other organizations, and speaks and organizes symposia at national and international meetings. He is the associate editor for the Journal of Food Science and is a frequent reviewer of manuscripts submitted to several different scientific journals.

He has received the Government of Canada Distinctive Service Award for extraordinary teamwork and support to the Science and Technology Community; Recipient of the Excellence in Science Award for 1998 by Health Canada; Deputy Minister's Award of Team Excellence for the work done in promoting the Fight BAC! Campaign in Canada; the Professional Institute of the Public Service of Canada Gold Medal for Pure and Applied Science; and he is Fellow of the American Association for the Advancement of Science, the IAFP, and the MSU University Outreach and Engagement. He is also an honorary life member of the IAFP. He is a graduate of Glasgow University with a BSc in Bacteriology and a PhD in bacterial systematics.

CONTENTS

VOLUME 2 Hazards and Diseases

Prions and Agents of TSEs

Protozoa

Organisms of Concern but not Foodborne or Confirmed Foodborne

Natural Toxicants

Mycotoxins

Environmental Contaminants

Toxic Metals

Foods, Materials and Risks

Safety of Food and Beverages

VOLUME 4 Food Safety Management

Food Safety Management

Public Health Measures

Food Safety Assurance Systems

Institutions Involved in Food Safety

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into five broad sections, presented in four volumes. The sections consist of:

1. **History, science, and methods**: this section includes papers which help in the understanding of basic sciences underpinning food safety and foodborne diseases and their historical development.
2. **Hazards and diseases**: this section addresses the features of major foodborne hazards be they chemical, microbial, parasitical or physical and their health consequence.
3. **Food technologies**: this section explains the various food technologies and aspects related to their safety, or risks in their application.
4. **Foods, materials, and risks**: similarly, in this section, various groups of food products are described in terms of their risks and measures needed to ensure their safety.
5. **Food safety management**: finally, in this part, the building blocks of food safety management in the private and public sector are explained. The role of major international organizations is also reported.

To help realize the full potential of the material in the Encyclopedia the authors have provided five features to help you find the topic of your choice: a preface giving an overview of the encyclopedia and its objectives, a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1 Contents List by Subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2 Alphabetical Contents List

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the alphabetical order. This list provides both the volume number and the page number of each entry. On the opening page of an entry a contents list is provided so that the full details of any articles within the entry are immediately available.

3 Cross-references

All of the entries in the Encyclopedia have been extensively cross-references. The cross-references, which appear at the end of the entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other entries.
iii. To indicate the material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry Characteristics of Foodborne Hazard and Diseases | Drug Resistant Pathogens.

> *See also*: Bacteria: *Listeria monocytogenes*; *Salmonella* Non-Typhi; *Salmonella* Typhi and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli* and Other Pathogenic *Escherichia coli*; *Shigella*; *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. Characteristics of Foodborne Hazard and Diseases: Cost of Foodborne Diseases. Food Safety Assurance Systems: Cleaning and Disinfection. Public Health Measures: Food Safety in Hospitals and Other Healthcare Settings; Surveillance of Foodborne Diseases

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., *Listeria monocytogenes*; *Salmonella* Non-Typhi; *Salmonella* Typhi, and *Salmonella* Paratyphi; Shiga Toxin-Producing *Escherichia coli*), parallel discussion in other entries (e.g., Other Pathogenic *Escherichia coli*), and reference to entries that broaden the discussion (e.g., Food Safety Assurance Systems: Cleaning and Disinfection. Public Health Measures: Food Safety in Hospitals and Other Healthcare Settings).

4 Index

The index provides you with the page number where the material is located. The index entries differentiate between materials that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5 Contributors

A full list of contributors is listed at the beginning of each volume.

GLOSSARY OF SELECTED TERMS

This Glossary of Selected Terms is a partial list of definitions for terms commonly used in the area of food safety. The terms selected are those that are important for communication among the various disciplines or are often subject to misunderstanding. Most of the definitions are taken from those recommended by international organizations or given by the authors contributing to this Encyclopedia. In cases where there are different definitions for a term, the Glossary presents the definition that is most consistent with usage by the majority of authors. Note that in some instances, slight differences between general definitions in this Glossary and those appearing in the individual articles may occur as the result of the specific context of the articles.

Acceptable daily intake The estimate of the amount of a substance in food or drinking water, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk to the consumer.

Acute reference dose The estimate of the amount of a substance in food or drinking water, expressed on a body mass basis, that can be ingested in a period of 24 h or less without appreciable health risk to the consumer.

Adulteration (economic) A fraudulent action which is intended to omit a valuable constituent or substitute another substance, in whole or in part, for a valuable constituent; conceal damage or inferiority in any manner; or add any substance to increase its bulk or weight, reduce its quality or strength, or make it appear bigger or of greater value than it is (Note that in the US, adulterated food is generally defined as impure, unsafe, or unwholesome food.).

Antiseptic A substance that inhibits the growth and development of microorganisms. For practical purposes, antiseptics are routinely thought of as topical agents, for application to skin, mucous membranes, and inanimate objects, although a formal definition includes agents which are used internally, such as the urinary tract antiseptics.

As low as reasonably achievable A risk management approach that aims to keep exposure to a substance at the lowest level that is realistically achievable.

Asymptomatic shedder A person who does not exhibit the symptoms of an illness but excrete the pathogen (*see also* carrier).

Benchmark Reference point or standard against which performance or achievements can be assessed. A benchmark refers to the performance that has been achieved in the recent past by other comparable organizations, or what can be reasonably inferred to have been achieved in the circumstances.

Biomarkers Indicators of changes or events in human biological systems. Biomarkers of exposure refer to cellular, biochemical, or molecular measures that are obtained from biological media such as human tissues, cells or fluids, and are indicative of exposure to a substance. Biomarkers of effect refer to biological changes that represent an alteration in endogenous body constituents (e.g., depression of cholinesterase levels as an indicator of exposure to pesticides).

Carrier A person or animal that harbors a specific infectious agent without discernible clinical disease and serves as a potential source of infection. The carrier state may exist in an individual with an infection that is unapparent throughout its course (commonly known as healthy or asymptomatic carrier), or during the incubation period, convalescence and postconvalescence of an individual with a clinically recognizable disease (commonly known as an incubatory or convalescent carrier). Under either circumstance the carrier state may be of short or long duration (temporary or transient carrier, or chronic carrier) (*see also* asymptomatic shedder).

Case-fatality rate Usually expressed as the percentage of persons diagnosed as having a specified disease who die as a result of that illness within a given period. This term is most frequently applied to a specific outbreak of acute disease in which all patients have been followed for an adequate period of time to include all attributable deaths. The case-fatality rate must be clearly differentiated from the mortality rate (Compare with mortality rate).

Colony-forming unit A measure of viable bacterial or fungal cells in which a colony represents an aggregate of cells derived from a single progenitor cell.

Contaminant Any biological, chemical, or physical agent not intentionally added to food, which is present in food as a result of the production, manufacture, processing, preparation, transport, or holding of such food (Compare with hazard).

Control (noun) The state wherein correct procedures are being followed and critical criteria are being met.

Control (verb) To take all necessary actions to ensure and maintain compliance with criteria established in the Hazard analysis and critical control point system (HACCP) plan.

Control measure Any action and activity that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Corrective action Any action to be taken when the results of monitoring at the Critical Control Point (CCP) indicate a loss of control.

Crisis A predicted or unpredicted event which represents an immediate or future significant threat to an organization, its employees, consumers, and the public at large.

Critical control point A step at which control can be applied and is essential to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Critical limit (CL) A criterion which separates acceptability from unacceptability.

Detergent A chemical used to remove grease, dirt and food, such as washing-up liquid.

Disability adjusted life year (DALY) A metric used to express a health gap that extends the concept of potential years of life lost due to premature death to include equivalent years of 'healthy' life lost by virtue of being in states of poor health or disability. The DALY combines in one measure the time lived with disability and the time lost due to premature mortality. One DALY can be thought of as one lost year of 'healthy' life and the burden of disease as a measurement of

the gap between current health status and an ideal situation where everyone lives into old age free of disease and disability.

Disinfectant A chemical agent or a process that destroys, neutralizes, or inhibits the growth of pathogenic microorganisms (*see also* sanitizer).

Dose–response assessment The determination of the relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response) in the exposed organism, system, or (sub) population in reaction to the agent.

Endotoxin A toxin present in intact bacterial cells and released when bacteria die or the cells are disrupted. A notable endotoxin is lipopolysaccharide, which is a major constituent of the outer cell membrane of Gram-negative bacteria and can cause toxic effect on lysis of bacteria. The term 'endotoxin' is to be differentiated from 'exotoxin', which is a toxin secreted in the surrounding medium and environment of the bacterial cell.

Enterotoxin A cytotoxin produced by bacteria that is specific for the mucous membrane of the intestine and causes diarrhea and/or vomiting associated with foodborne disease. Many infectious microorganisms produce enterotoxins in the gut, but some are produced external to the host (*see also* exotoxin and endotoxin).

Exotoxin A toxin that is secreted by bacteria. There are many different types of exotoxins. They can be released into the susceptible host (after infection and growth) or into the environment, including food (after contamination and growth). Those released into the intestines are typically heat labile (but some *E. coli* strains can produce both heat labile (HL) and heat stable (HS) toxins). *Clostridium perfringens* produces a HL enterotoxin after completion of sporulation in the host's intestines. *Staphyloccocus aureus* and *Bacillus cereus* enterotoxins produced in food are HS and cause vomiting and diarrhea, whereas toxins of *Clostridium botulinum* toxin, also produced in food, are HL and cause systemic neurological symptoms (*see also* exotoxin and endotoxin).

Epidemic The occurrence in a community or region of a group of illnesses which are similar in nature and clearly in excess of normal expectancy, and derived from a common or from a propagated source (Compare with pandemic).

Equivalence The situation where the application of two different food safety management measures lead to the same, or equivalent, public health outcomes.

Equivalence of sanitary measures (import–export of food) Equivalence is the state wherein sanitary measures applied in an exporting country, though different from the measures applied in an importing country, achieve, as demonstrated by the exporting country, the importing country's appropriate level of sanitary protection.

Exposure assessment The qualitative and/or quantitative evaluation of the likely ingestion of a biological, chemical, or physical agent in food as well as exposures from other sources if relevant.

Fecal–oral route A means of spreading pathogenic microorganisms from feces produced by an infected host to another host, usually via the mouth; for example, contact between contaminated hands or objects and the mouth.

Flow diagram A systematic representation of the sequence of steps or operations used in the production or manufacture of a particular food item.

Food Any substance, whether processed, semiprocessed, or raw, which is intended for human consumption, and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation or treatment of 'food' but does not include cosmetics or tobacco or substances used only as drugs.

Food additive Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport, or holding of such food results, or may be reasonably expected to result, (directly or indirectly) in it or its byproducts becoming a component of or otherwise affecting the characteristics of such foods.

Food allergy A form of food intolerance in which there is evidence of an abnormal immunological reaction to the food (Compare with food intolerance).

Food establishment Any building or area in which food is handled and the surroundings under the control of the same management.

Food handler Any person who handles, prepares, or serves food, be they domestic food handlers, such as preparing family food, or professional food handlers, such as those working in food service establishments (cooks and waiters), retail stores, supermarkets, etc. (*see also* food worker).

Food hygiene All conditions and measures necessary to ensure the safety and suitability of food at all stages of the food chain.

Food industry The term includes primary manufacturing and processing industry as well as some other establishments involved in the food chain.

Food intolerance A reproducible, unpleasant reaction to a food or food ingredient, including reactions due to immunological effects, biochemical factors, such as enzyme deficiencies and anaphylactic reactions that often include histamine release (Compare with food allergy).

Food poisoning (or acute foodborne intoxication) A disease caused by a toxin or a chemical in food with symptoms usually appearing within 24 h after ingesting the agent. This term is commonly misused as a synonym for foodborne disease, which covers both infections and intoxications.

Food safety Assurance that food will not cause harm to the consumer, when it is prepared and/or eaten according to its intended use (Compare with food suitability and food hygiene).

Food safety hazard A biological, chemical, or physical agent in, or condition* of, food with the potential to cause an adverse health effect (Compare with contaminant). *Refers also to property of a food.

Food safety objective (FSO) The maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP) (Compare with Performance objective).

Food suitability Assurance that food is acceptable for human consumption according to its intended use (Compare with food safety and food hygiene).
Food worker Individuals who harvest, process, prepare and serve food, i.e., across the whole food chain to retail/foodservice; it is broader than that of a food handler, who typically works in foodservice establishments typically foodservice; however, the two terms are used interchangeably in the literature (*see also* food handler).
Foodborne disease Any disease of an infectious or toxic nature caused by or thought to be caused by consumption of contaminated food, including drink.
Foodborne pathogens Disease-causing microorganisms that are transmitted to humans via foods.
Generally recognized as safe Status of a substance that is generally recognized, among qualified experts, as having been adequately shown to be safe under the conditions of its intended use (used mainly in the USA).
Genomics The study of an organism via decoding the entire genetic sequence of the organism.
Genetic modification A process of altering the genetic makeup of an organism by techniques of modern biotechnology.
Genetically modified organism (GMO) AGMO or genetically engineered organism is an organism whose genetic material has been altered using genetic engineering techniques.
Good animal husbandry practice A system of management controls that need to be adopted at the level of primary producers to ensure production of food of animal origin that is safe for human consumption and acceptable for trade in the world market.
Good hygienic practice A system of management controls that need to be adopted at production, processing, storage, distribution, and preparation to ensure safety and suitability of products of consumption.
Good laboratory practice A system of management controls for laboratories and research organizations to ensure the quality, integrity, consistency, and reliability of results.
HACCP plan A document prepared in accordance with the principles of HACCP to ensure control of hazards which are significant for food safety in the segment of the food chain under consideration (see also HACCP).
Hazard A biological, chemical, or physical agent in, or condition*; of, food with the potential to cause an adverse health effect (Compare with contaminant). *Refers also to a property of a food.
Hazard analysis The process of collecting and evaluating information on hazards and conditions leading to their presence to decide which are significant for food safety and therefore should be addressed in the HACCP plan.
Hazard analysis and critical control point system A preventive system which identifies, evaluates, and controls hazards which are significant for food safety.
Hazard characterization The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with a biological, chemical, or physical agent which may be present in food. For a chemical agent, a dose–response assessment should be performed. For a biological or physical agent, a dose–response assessment should be performed if the data are obtainable.
Hazard identification The identification of the type and nature of adverse effects that a biological, chemical, or physical agent in food is capable of causing in an exposed population.
Incidence rate The number of new cases of a condition arising in a defined group within a given period or the number of new infections per unit of person–time at risk (Compare with prevalence).
In vitro In an artificial environment outside the living organism.
In vivo Within a living organism.
Lethal dose 50% The dose of a substance that would be expected to kill half of a population of exposed organisms.
Margin of exposure Ratio of the no-observed-adverse-effect level or benchmark dose lower confidence limit for the critical effect to the theoretical, predicted, or estimated exposure dose or concentration.
Maximum residue limit The maximum concentration of residues resulting from the use of a pesticide or veterinary drug that is acceptable in or on a food.
Minimum infective dose The lowest number of microorganisms required to cause an infection in the host.
Monitoring (CCP) The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a CCP is under control.
Monitoring (general) Continuous or repeated observation, measurement and evaluation of health, and/or environmental or technical data for defined purposes, according to prearranged schedules in space and time, using comparable methods for sensing and data collection.
Morbidity rate An expression of the number of illnesses in a population at risk over a given period of time (usually one year).
Mortality rate An expression of the number of deaths in a population at risk over a given period of time (usually one year).
Nanomaterials Materials engineered at the nanoscale to have novel functionality or properties. Such properties will typically, but not exclusively, be demonstrated in the size range 1–100 nm, but this size range should be considered approximate.
Nanoparticles Particles with one or more external dimensions in the range 1–100 nm, but this size range should be considered approximate.
Nanotechnology The manipulation or materials at the nano level.
Notifiable disease A disease that must, by law or by ministerial decree, be reported to a government authority.
Outbreak A group of at least two cases of a single illness that are demonstrated by epidemiological investigation to have a single common exposure or source.
Pandemic Epidemic occurring over a very wide area, crossing international boundaries (often more than one continent) and usually affecting a large number of people.
Pasteurization A process involving heat treatment at a prescribed time–temperature combination to kill vegetative forms of pathogens that may be present, while causing minimal changes in the composition, flavor, and nutritive value of food. However, with advances and the development

of new food technologies, the term is sometimes used for nonthermal technologies leading to the same effect.

Pathogen An organism capable of causing disease.

Pathogenesis The course of a disease from its origin to its manifestation; more specifically it refers to the cellular events and reactions, and other pathologic mechanisms occurring in the development of the disease.

Pathogenicity Ability of a microorganism to cause disease in a host (Compare with virulence).

Performance criterion The effect in frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a performance objective (PO) or an FSO.

Performance objective The maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable (Compare with Food Safety Objective).

Pesticide Any substance intended for preventing, destroying, attracting, repelling, or controlling any pest including unwanted species of plants or animals during the production; storage; transport; and distribution and processing of food, agricultural commodities, or animal feeds or which may be administered to animals for the control of ectoparasites. The term includes insecticides, herbicides, fungicides, rodenticides and algicides as well as plant growth regulators, defoliants, desiccants, and agents for thinning fruit or preventing the premature fall of fruit.

Prerequisite program Practices and conditions needed prior to and during the implementation of HACCP and which are essential to food safety.

Prevalence The number of persons in a population who have a disease at a specified point in time or over a specified period of time (Compare with incidence rate).

Primary production Those initial steps in the food chain up to and including, for example, harvesting, slaughter, milking, and fishing.

Processing aid Any substance or material, not including apparatus or utensils, and not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods, or its ingredients, to fulfill a certain technological purpose during treatment or processing and which may result in the nonintentional but unavoidable presence of residues or derivatives in the final product.

Processing contaminant Undesirable contaminants that are formed during the treatment of food as a result of the interaction of their natural components or their ingredients.

Provisional maximum tolerable daily intake (PMTDI) The health-based reference value used for contaminants with no cumulative properties. Its value represents permissible human exposure as a result of the natural occurrence of the substance in food and in drinking water. In the case of trace elements that are both essential nutrients and unavoidable constituents of food, a range is expressed, the lower value representing the level of essentiality and the upper value the PMTDI.

Provisional tolerable monthly intake The health-based reference value used for a food contaminant with cumulative properties that has a very long half-life in the human body. Its value represents permissible human monthly exposure to a contaminant unavoidably associated with otherwise wholesome and nutritious foods.

Provisional tolerable weekly intake The health-based reference value used for food contaminants such as heavy metals with cumulative properties. Its value represents permissible human weekly exposure to those contaminants unavoidably associated with the consumption of otherwise wholesome and nutritious foods.

Quality management Quality management includes all the activities that organization use to direct, control, and coordinate quality. These activities include formulating a quality policy and setting quality objectives. They also include quality planning, quality control, quality assurance, and quality improvements.

Recommended dietary allowance The average daily dietary nutrient intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy subjects in a particular life stage and gender group.

Reservoir An animal species that specifically harbors an infectious agent over long periods, often without harm to the host.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Risk analysis A process of decision making (usually government) for managing food safety, consisting of three components: risk assessment, risk management, and risk communication.

Risk assessment A scientifically based process for evaluating risks associated with foodborne hazards, consisting of the following steps: (i) hazard identification, (ii) hazard characterization, (iii) exposure assessment, and (iv) risk characterization.

Risk assessment policy Documented guidelines on the choice of options and associated judgments for their application at appropriate decision points in the risk assessment such that the scientific integrity of the process is maintained.

Risk characterization The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors, and risk perceptions, among risk assessors, risk managers, consumers, industry, the academic community, and other interested parties, including the explanation of risk assessment findings and the basis of risk management decisions.

Risk estimate The quantitative estimation of risk resulting from risk characterization.

Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of consumers and for the promotion of fair trade practices, and, if needed, selecting appropriate prevention and control options.

Risk manager A person or an organization (usually government) with the authority to decide on the acceptability of risk and, if necessary, measures needed for their management.

Risk profile The description of the food safety problem and its context.

Safe (food) A level of risk that is deemed to be acceptable by some standard. The question of safety always involves the question of to whom the risk is acceptable, and by what criteria that party judges it so.

Sanitizer Type of antimicrobial (disinfectant) that kills or irreversibly inactivates microorganisms present on a surface, especially designed for use on food-processing equipment. The US Environmental Protection Agency further defines a sanitizer as providing at least 99.9% reductions of all microorganisms on a surface (*see also* disinfectant).

Shelf-life The predicted time at which a product will change from acceptable to unacceptable quality. It is influenced by factors such as raw ingredient quality, processing conditions, packaging practices, and storage conditions. Typically, shelf-life is determined by a combination of microbial, sensory, and chemical methods. 'Shelf-life' can be expressed on food labels by a variety of dates, including 'expiry', 'use by', 'sell by', 'best before', and 'consume by', depending on the applicable legislation.

Step (HACCP) A point, procedure, operation, or stage in the food chain including raw materials, from primary production to final consumption.

Strain An isolate of the same type of microorganism possessing different properties.

Surveillance The systematic, ongoing collection, collation, and analysis of data on specific diseases in a defined population, to guide public health decisions.

Surveillance (active) Public health surveillance that regularly reaches out to diagnostic laboratories or to clinicians to actively collect reports of specific diagnoses of infections.

Surveillance (passive) Public health surveillance that collects reports of specific diagnoses from clinicians or diagnostic laboratories, which they are required or requested to submit because of notifiable diseases regulations.

Time–temperature abuse A situation where food has not been cooked for long enough or at a sufficient high temperature to reduce contaminants to safe levels, or food has been stored for a time or at a temperature that permits bacteria to proliferate.

Traceability/product tracing The ability to follow, forward as well as backward, the movement of a food through specified stage(s) of production, processing, and distribution.

Uncertainty In risk assessment, imperfect knowledge concerning the present or future state of an organism, system, or (sub) population under consideration.

Validation (analytical methods) Practice undertaken to substantiate or confirm methods or procedures perform as expected and in a reliable manner and consistently meet expectations.

Validation (control measures) Obtaining evidence that a control measure or combination of control measures, if properly implemented, is capable of controlling the hazard to a specified outcome.

Validation (HACCP) Obtaining evidence that the elements of the HACCP plan are effective.

Variability Heterogeneity of values over time, space, or different members of a population. Variability implies real differences among members of that population.

Verification (general) The application of methods, procedures, tests, and other evaluations, in addition to monitoring and to determine whether a control measure is or has been operating as intended.

Verification (HACCP) The application of methods, procedures, tests, and other evaluations, in addition to monitoring and to determine compliance with the HACCP plan.

Veterinary drug Any substance applied or administered to any food-producing animal, such as meat or milk producing animals, poultry, fish, or bees, whether used for therapeutic, prophylactic, or diagnostic purposes, or for modification of physiological functions or behavior.

Virulence The degree of pathogenicity of a microorganism as indicated by case-fatality rates and/or its ability to invade the tissues of the host; the competence of any infectious agent to produce pathologic effects. The virulence of a microorganism is a measure of the severity of the disease it causes (Compare with pathogenicity).

Waterborne disease A disease resulting from the contamination of water either by pathogenic viruses, bacteria or protozoa, or by chemical substances. These agents are directly transmitted to people when the water is used for drinking, preparing food, recreation, or other domestic purposes.

Withdrawal period (veterinary drugs) The interval between the time of the last administration of a veterinary drug and the time of the collection of edible tissue or products from a treated animal that ensures the concentration of residues in food comply with the maximum residue limit for the drug.

Zoonosis A disease that can be passed directly or indirectly from animals, whether wild or domesticated, to humans. Also called zoonotic disease.

ABBREVIATIONS OF TECHNICAL TERMS

This is a nonexhaustive list of commonly used abbreviations in the area of food safety.

ADI	Acceptable daily intake.
ADME	Absorption, distribution, metabolism, and excretion.
AI	Adequate intake.
ALARA	As low as reasonably achievable.
ALOP	Appropriate level of protection.
ARfD	Acute reference dose.
BMD	Benchmark dose.
BMDL	Benchmark dose at lower confidence limit.
CCP	Critical control point.
CFR	Case fatality rate.
CFU	Colony forming unit.
CIP	Cleaning in place.
DALY	Disability adjusted life year.
DGGE	Denaturing gradient gel electrophoresis.
DNA	Deoxyribonucleic acid.
EAR	Estimated average requirement.
ED_{50}	Effective dose 50%.
ELISA	Enzyme linked immunosorbent assay.
EMRL	Extraneous maximum residue limit.
FSO	Food safety objective.
GAHP	Good animal husbandry practice.
GAP	Good agricultural practice.
GHP	Good hygienic practice.
GAqP	Good aquacultural practice.
GC	Gas chromatography.
GC–MS	Gas chromatography–mass spectrometry.
GHP	Good hygienic practice.
GLP	Good laboratory practice.
GM	Genetically modified.
GMO	Genetically modified organism.
GMP	Good manufacturing practice.
GPVD	Good practice in the use of veterinary drugs.
GRAS	Generally recognized as safe.
HAB	Harmful algal bloom.
HACCP	Hazard analysis and critical control point.
HPLC	High performance liquid chromatography.
HPLC–MS	High performance liquid chromatography–mass spectrometry.
HPP	High pressure processing.
HTST	High temperature short time.
HUS	Hemolytic uremic syndrome.
IEDI	International estimated daily intake.
IESTI	International estimated short term Intake.
LD_{50}	Lethal dose 50%.
LOAEL	Lowest observed adverse effect level.
LOD	Limit of detection.
LOQ	Limit of quantitation.
MFFB	Moisture on a fat free bases.
ML	Maximum level.
MLST	Multilocus sequence typing.
MLVA	Multiple locus variable number tandem repeat analysis.
MOE	Margin of exposure.
MRL	Maximum residue limit.
mRNA	Messenger ribonucleic acid.
MS	Mass spectrometry.
NEDI	National estimated daily intake.
NOAEL	No observed adverse effect level.
NOEL	No observed effect level.
OPRP	Operational prerequisite programme.
PC	Performance criterion.
PCR	Polymerase chain reaction.
PDCA	Plan do check act.
PEF	Pulsed electric fields.
PFGE	Pulsed field gel electrophoresis.
PMTDI	Provisional maximum tolerable daily intake.
PO	Performance objective.
PRP	Prerequisite program.
PrP	Protease resistant protein.
PTMI	Provisional tolerable monthly intake.
PTWI	Provisional tolerable weekly intake.
QPS	Qualified presumption of safety.
RDA	Recommended dietary allowance.
RNA	Ribonucleic acid.
SMEs	Small- and medium-sized enterprises.
SOP	Standard operating procedure.
SPS Agreement	Agreement on the Application of Sanitary and Phytosanitary Measures.
TBT Agreement	Agreement on Technical Barriers to Trade.
TDI	Tolerable daily intake.
TDS	Total diet study.
TEF	Toxic equivalency factor.
TEQ	Toxic equivalence.
TMDI	Theoretical maximum daily intake.
TSE	Transmissible spongiform encephalopathy.
UHT	Ultra high temperature.
UL	Upper limit.
UV	Ultra violet.

PRIONS AND AGENTS OF TSES

Contents

Bovine Spongiform Encephalopathy in Cattle

D Matthews, United Kingdom

Glossary

Oral ID_{50} The infectious dose, administered by mouth, that is predicted to kill 50% of animals inoculated. Note that the figure quoted for bovine spongiform encephalopathy (BSE) is not an absolute, as it is dependent on the concentration of infectivity in the starting material. Nevertheless, it is sufficient to demonstrate that the amount would be undetectable in contaminated raw ingredients or finished feed and difficult to prevent unless extreme measures are adopted.

Peyer's patches Peyer's patches are nodules or collections of lymphoid tissue found within the wall of the intestine, especially in the young. They can become continuous and prominent, particularly within the lower small intestine (ileum). In ruminants, they are prominent before maturity but eventually regress in adulthood.

Phenotype The biological concept of phenotype is defined as the detectable characteristics displayed by an organism resulting from its interaction with the infected host and its environment or the sum of the observable characteristics embracing the entire physical, biochemical, and physiological make up of an organism. Disease phenotype can be defined as the characteristic clinical signs and pathological changes of a particular form of a disease entity or group, enabling it to be characterized and distinguished by such criteria from other forms of the disease. The frequent detection of infected, but clinically healthy, individuals through surveillance frequently prevents the inclusion of criteria such as clinical signs and pathology in consideration of phenotype. In such circumstances, the term is used more loosely in describing other characteristics, such as patterns of banding obtained by biochemical tests, or the secondary characteristics produced when laboratory rodents are inoculated.

Prion The term prion was originally coined to refer to an infectious protein, and at that time conflicted with those that believed that diseases previously known as transmissible spongiform encephalopathies (TSEs) were caused by viruses, or were at least associated with viruses. Although abnormal prion protein is still the only marker consistently associated with disease, it is still not possible to exclude the possibility that it does not act alone. The term is now accepted generically as a substitute for the infectious agent(s) that causes TSEs, acknowledges the role of prion protein in the transmissibility and pathogenesis of the diseases in which protease-resistant protein PrP^{Sc} is detected, but accepts that it is not yet possible to exclude a role for other molecules in conferring infectivity on prion protein.

PrP^{Sc} PrP stands for protease-resistant protein, the protein that is associated with prion diseases, and the product of the PrP gene (*PRNP*). It can be found in many tissues of healthy individuals although its function remains unclear. In a healthy individual, it is normally designated at PrP^{C}, where the C stands for cellular. PrP^{Sc} denotes the disease-specific isoform of PrP, that is folded differently, with a greater proportion of β sheet, and as a result is more resistant to digestion by proteases both within the body and in immunological tests. The Sc arises from its first identification in scrapie in sheep and rodent models, but it is often used generically to refer to the abnormal isoform of PrP^{C} in all affected species. At times, it is referred to as PrP^{res} to denote the protease-resistant property of the pathological protein, PrP^{d} for disease-specific PrP (particularly when detected by methods, such as immunohistochemistry, that do not rely on the use of proteases), or specifically in the case of BSE as PrP^{BSE}. In some instances, such as the World Health Organization (WHO) categorization of infectious tissues, the term PrP^{TSE} is used.

Strain Because it is not possible to isolate individual prions and to extract DNA or other agent/strain-specific molecules other than PrP (which is host-derived), science cannot categorize isolates into strains or species/subspecies by means of methods that are appropriate for bacteria or viruses. The characterization of isolates as different from each other relies, therefore, on a combination of approaches. At one time there was reliance on the inoculation of laboratory rodents, followed by a description

of the ensuing disease, or pathology, such as attack rate, incubation period, and lesion profile of vacuolation produced within the brain. More recently, molecular tools that measure and characterize prion protein extracted from host tissues are also used, but remain relatively crude. Most depend on the characterization of the products of enzyme digestion and their comparison with defined strains from either laboratory rodents or from naturally infected animals or humans. As a consequence, the process of confirming that two isolates are different, identical, or similar is slow and now involves both biochemical and bioassay approaches. Genetically modified rodents may also be used as they can speed up the process and sometimes facilitate infection that would otherwise fail in unmodified animals. Given the current state of knowledge and the logistical difficulties of processing many isolates, the categorization of isolates into strains remains relatively crude.

Transmissible spongiform encephalopathy (TSE) Before the adoption of prion for the categorization of diseases such as scrapie, BSE, chronic wasting disease, and Creutzfeldt–Jakob disease, they were grouped under the term TSEs. The term describes the pathology of the diseases in the brain of affected individuals, but acknowledges that each can be experimentally transmitted to laboratory rodents. The association of prion protein with these diseases has resulted in the more common reference to prion diseases, rather than TSEs, although the term remains both accurate and appropriate.

Introduction

Bovine spongiform encephalopathy (BSE) is a disease of domesticated cattle, first recorded in November 1986 in the United Kingdom (UK), but subsequently recognized in another 26 countries. It is a disease of the nervous system and is spread between cattle by the consumption of contaminated feed. The epidemic also spread to other countries via exported contaminated feed constituents and infected live cattle. Retrospective investigations suggest that clinical cases of BSE were first seen on British farms early in 1985, but modeling studies indicate a likely origin at least a decade earlier.

Although it was the subject of some international concern soon after its first recognition, a larger worldwide crisis of confidence in food safety was triggered almost 10 years later. This followed the recognition in 1996 that BSE had transmitted to humans, giving rise to a disease that was referred to as variant Creutzfeldt–Jakob disease (vCJD).

Where this article focuses on events in the UK, this is solely because the size of the epidemic in that country enabled the consequences of exposure of both cattle and humans to be studied more comprehensively than elsewhere. The principles described remain sound in all at-risk countries, although the degree of risk faced by cattle and humans will vary according to the extent of exposure of cattle and the nature of controls introduced.

Nature of the Agent

The first diagnosis of BSE was made after the detection of brain lesions similar to those described for a disease of sheep and goats called scrapie. The lesions include vacuolation of neurons identified by the histological examination of fixed tissue sections stained with hematoxylin and eosin. Subsequent studies demonstrated that BSE could be transmitted experimentally to laboratory rodents by inoculation of brain tissue from affected cattle. Consequently, BSE was classified alongside scrapie as a transmissible spongiform encephalopathy (TSE). Chronic wasting disease (CWD) of cervids in North America is another member of this group of disorders.

TSEs are now more commonly referred to as prion diseases. The 'prion hypothesis' is the favored hypothesis for the nature of the infectious agent and mechanisms of transmission. It has been proved difficult to demonstrate the involvement of alternative putative infectious agents, such as viruses or nonviral nucleic acid. Common to the various diseases is the presence in the central nervous system (CNS), and occasionally in other tissues, of an abnormal isoform (prion protein, PrP^{Sc}) of a host-encoded protein (PrP^{C}). When PrP, which is encoded by the PrP gene (*PRNP*), is viewed three-dimensionally, more than 40% of the molecule is organized into α-helix. It contains no β-sheets, but conversion to PrP^{Sc} involves refolding into an isoform that comprises both β-sheets and α-helices, with the former being predominant. PrP^{Sc} is prone to aggregation and accumulation in affected tissues. Prion diseases are part of a wider group of disorders in which abnormalities of protein folding occur, but natural transmissibility has so far only been demonstrated for the prion diseases.

The prion hypothesis ascribes infectivity to protein alone, with transmissibility between individuals being influenced by the degree of homology between their PrP gene sequences. Significant differences can prevent transmissibility, whereas small differences result in greater difficulty of transmission and longer incubation periods. This variability in susceptibility to transmission between species is normally referred to as the species barrier. Although PrP^{Sc} is the only protein that appears to be associated with infectivity, leading to its use as a marker for infection, there are instances where it is undetectable despite the presence of significant amounts of infectivity. This may simply reflect the lack of sensitivity of the tools used to detect PrP^{Sc}, but such instances fuel debate about the potential involvement of another factor in conferring the infectious state.

In the absence of a clearly defined pathogen, there are significant challenges in characterizing isolates of the infectious agent from animals or humans. Biological characteristics of disease produced by inoculation of experimental animals, mostly rodents, have been used to define different 'strains' of isolates. Molecular tools are overtaking these traditional bioassay approaches, which are too expensive and slow for routine use. Cell cultures remain of limited use at present, as no model can support replication of most natural

isolates. Available molecular diagnostics, involving western immunoblotting and enzyme-linked immunosorbent assay (ELISA) in particular, remain rather unsophisticated. Their dependence on the visualization or quantification of PrP after enzymatic degradation makes it difficult to standardize and control methods to facilitate comparison of results obtained in different laboratories. These tools cannot, in isolation, definitively identify a strain or subtype, or confirm an association between BSE in cattle and prion disease in other species. Nevertheless, with the introduction of immunoblotting into the diagnostic armory for surveillance, two additional phenotypes of BSE have been recognized in cattle. Commonly referred to as atypical BSE, they have been classified as H-type and L-type on the basis of their banding pattern on western blot. 'H' and 'L' denote high and low positions for the unglycosylated band relative to classical BSE, which is referred to as C-BSE for the sake of consistency. Such variants are however rare.

Irrespective of the components of the BSE pathogen, it is, along with other prions, relatively resistant to normal approaches to decontamination, disinfection, or sterilization. In the context of food safety, it is clearly not possible to rely on cooking to eliminate infectivity. Regulatory approaches rightly aim to exclude infectious tissues from the food chain.

Epidemiology

The visible face of BSE in the UK was a large epidemic of clinically affected animals. Almost 200 000 such animals were identified by the end of 2009. By 2003, however, it was estimated that more than 4 million cattle had actually been infected. The majority died or were slaughtered for human consumption, without being recognized as infected. Epidemics in all other countries have been significantly smaller. In some, the risk of a large long-term epidemic was small for a variety of reasons: exposure levels may have been low; factors required for the escalation of infectivity levels in feed were absent; or, based on British experience, it was possible to introduce control measures sooner than was possible in the UK.

Early epidemiological investigations identified one factor in common for all cases detected. They had all consumed commercial feed that contained meat-and-bone meal (MBM) derived from ruminants (cattle or sheep). This was a commonly used ingredient in feed for dairy cattle in the UK before 1988. In common with many countries, animals that died on farm were usually rendered (cooked), and the residual solid material, MBM, was considered to be a valuable source of protein. Waste material from animals slaughtered for human consumption also entered the rendering system. Before the recognition of BSE, the safety of MBM as an ingredient of animal feed had focused largely on potential contamination with salmonella species. With the benefit of hindsight, it is clear that rendering systems were at that time unable to inactivate BSE infectivity, and the absence of any species barrier between cattle meant that transmission was relatively easy. Although the exact origin of the first case of BSE still remains in doubt, it is clear that the majority of cattle that became infected did so when fed MBM derived from cattle.

Although sheep scrapie is known to transmit naturally from mother to lamb (maternal transmission) and from sheep to sheep (horizontal transmission), there remains no evidence that BSE transmits horizontally, and evidence of maternal transmission is slender and improbable. Also, there is no suggestion that the disease is transmitted via germ plasm (semen, ova, and embryos).

The cycle of infection, therefore, relied on infectious tissues from cattle being rendered and converted into MBM, followed by subsequent consumption by more cattle, especially in their first year of life (Figure 1). This cycle has not been demonstrated for atypical BSE, primarily because cases have been detected in insufficient numbers to enable detailed epidemiological investigations. It is postulated that they may represent a natural scenario of low prevalence spontaneous disease, which may indeed have become the origin of the C-BSE epidemic. If truly spontaneous, it is possible that the total removal of regulatory controls may enable BSE to return, or an escalation of atypical BSE, especially in countries where

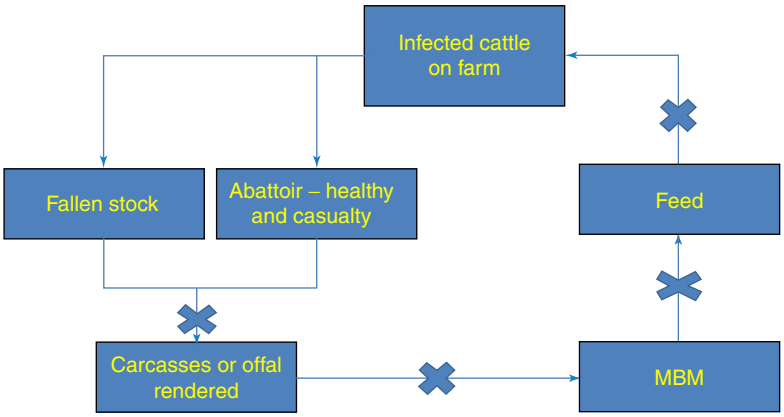

Figure 1 The epidemiology of BSE. Crosses denote points at which the cycle of re-infection needs to be broken. It is normally insufficient to rely on breaking the cycle at a single point, but this decision may be influenced by estimates of risk. It is essential to ensure that accidental cross-contamination does not perpetuate risk despite prohibition on the inclusion of raw material or by-product in products at the next stage of the cycle.

rendering standards have not been modified to inactivate the agent. It should however be stressed that at the time of writing, the oral transmission of atypical BSE to cattle has not been demonstrated. Research to investigate this possibility remains in progress.

The initial assumptions on which the control of BSE was based were, therefore, shown to be correct. The disease can be eradicated by breaking the cycle of infection via feed. With hindsight, however, it is clear that breaking the cycle is also difficult and requires the rigorous application of regulations and auditing of compliance. Failure to prevent cross-contamination of feed with traces of bovine-derived infectivity led to the infection of many cattle after the use of ruminant MBM was banned. The initial UK feed ban was still very successful, and it is clear that even the application of incomplete measures in many countries did significantly reduce the likelihood of infection. Although it has been demonstrated that calves can become infected by consuming as little as a milligram of BSE-infected brain tissue, the oral ID_{50} is now estimated to be 0.16 g. The significance of cross-contamination of feed with such a low infectious dose during the production, storage, and transportation of feed ingredients was not anticipated, and led to incomplete compliance with feed controls. Draconian risk-management measures are justified by the need to eliminate such feed-borne exposure sooner rather than later.

Exported MBM also proved to be the conduit by which BSE spread to many other countries, some before BSE was even recognized in the UK. Infected cattle were also exported. When infected imported or indigenous cattle died, they initiated epidemics in the importing countries. The timescales from the initiation of recycling of infectivity to the implementation of control measures were usually shorter than in the UK, thus preventing the weight of infectivity in cattle feed from reaching the levels experienced in the UK. Additionally, unlike the UK, in many countries MBM was only an infrequent component of cattle feed.

Early in the course of the epidemic in the UK, the recognition of TSEs in animal species in which such diseases had not previously been recorded strengthened concerns that BSE was capable of spreading to nonruminant species. In domestic cats, feline spongiform encephalopathy (FSE) was recognized in 1990, and also occurred in exotic Felidae, including cheetah, lion, tiger, ocelot, puma, Asian golden cat, and leopard cat. Additional ruminant species were also affected and included nyala, greater kudu, and three species of oryx, eland, ankole cattle, and bison. Most of the cases in ruminants and felids, other than domestic cats, were in zoological collections in the UK. Although the exotic felids would most probably have consumed raw infected tissues from cattle, domestic felids and all ruminants are more likely to have consumed MBM incorporated into their feed.

Pathogenesis

Because the infectious agent cannot be visualized, even by microscopic examination, the pathogenesis or course of the disease from infection to death has been proved difficult to study. Naturally infected animals were examined early in the British BSE epidemic, but the examination of tissues from animals killed at clinical end stage cannot determine the behavior and distribution of the agent in the body during the incubation period of several years. Quantification of risk associated with the consumption of tissues, therefore, relied on the examination of materials derived from experimentally infected calves, sequentially slaughtered during the incubation period.

The gold standard for determination of the presence of infectivity was the inoculation of inbred laboratory rodents. Bioassay in cattle, and in genetically modified mice, have more recently offered increased assay sensitivity. The timescales involved in awaiting incubation in cattle, followed by incubation to negative end points in the assay model, have been long (up to 14 years). The high cost of such studies has also limited the number of assays such that negative results must be interpreted with caution. At times, the categorization of a tissue as noninfectious may arise from the inoculation of a single sample from a single animal. This does not devalue the result, particularly if interpreted alongside the additional negative results from other tissues. Together, they build up a body of evidence that enables confident classification into risk categories, recognizing that negative transmissions cannot be guaranteed to represent the total absence of infectivity. All assay models have limits to their power to detect infectivity.

Once BSE infectivity is ingested, replication of the agent is first detectable, both by bioassay and by immunochemical detection of PrP, in the Peyer's patches (PPs) of the lower small intestine. Most cattle appear from epidemiological studies to become infected in calf-hood, which partly reflects early exposure through feed, but may also be dependent on the presence of prominent and numerous PPs in the ileum of the young animals. These regress naturally when mature.

The next organ in which significant infectivity can be detected is the CNS, appearing almost simultaneously in the brain stem and spinal cord. Thereafter, as infectivity levels rise exponentially and disperse within the CNS (including the eye), there also appears to be gradual retrograde spread into the peripheral nervous system (PNS), including the dorsal root ganglia (DRG), trigeminal ganglion, and peripheral nerve trunks (facial, optic, sciatic, phrenic). DRG lie within the vertebral column, close to the spinal cord, and form the interface between the CNS and motor and sensory peripheral nerve trunks.

The route by which infectivity migrates from the intestine to CNS remains uncertain, but most probably involves transport via the autonomic nerves (vagus and splanchnic) and their associated ganglia. These nerves are, therefore, infected early in the pathogenesis, during preclinical stages of disease. The adrenal gland with its rich sympathetic innervations contains infectivity at or close to clinical onset.

Although infectivity has not been detected in the thymus or spleen, two of the original tissues designated as potential risks to consumers, or indeed in lymph nodes, traces have been detected in palatine tonsils of experimentally infected cattle. Additionally, single equivocal results from sternal bone marrow collected close to the onset of clinical disease in experimentally infected cattle and from pooled nictitating membranes from naturally infected cattle have not been replicated. Consequently, although infectivity has been demonstrated to circulate in blood in scrapie-infected sheep, it is not

possible to conclusively demonstrate a role for hematogenous spread through the body in BSE-infected cattle. Indeed, blood is accepted as a safe commodity as long as there is no risk of contamination with brain tissue at slaughter.

The only additional tissue in which there is published evidence of transmission is muscle. This result, from a single naturally infected and clinically affected cow, was based on evidence of transmission to only one of 10 inoculated transgenic mice expressing the bovine PrP gene. This transgenic mouse, estimated to be even more susceptible than a calf to BSE, otherwise produced results that were consistent with all other bioassays of bovine tissues. Consequently, muscle is not considered to be infected, although the presence of peripheral nerves within muscle masses gives rise to potential risk if consumed after the onset of clinical disease.

Arising from the analysis of pathogenesis is a general theme that in the early stages of infection, the greatest risk is associated with the intestine and particularly the ileum. In the later stages of incubation, intestinal infectivity levels are exceeded by CNS infectivity, which reach maximal levels after onset of clinical disease. Bioassay results have demonstrated that infectivity can be present marginally before the CNS tests positive with a postmortem test. It is not possible to specify when the CNS will become infected in any individual animal. There is considerable variation in incubation period, with naturally infected and clinically affected cattle in the UK ranging from 20 months to 22 years of age when identified. Incubations will have been marginally shorter than lifespan. In experimentally infected cattle, incubation period is generally dose-related, but even within a single dose group it can be highly variable.

The assumption that risk is primarily associated with CNS from cattle aged 30 months or more, as used in defining regulations for the removal of specified risk materials (SRMs), derives from the pragmatic interpretation of epidemiological data, taking into account the decline of risk of infection in young calves by the time the rule was first adopted in the UK in 1996. It is however supported by subsequent evidence from

Table 1 Tissues in which infectivity is confirmed or presumed to be present

Tissue	*When infectious*	*Designated SRMs*
Higher levels of infectivity		
Brain and spinal cord	Late incubation – shortly before onset of clinical disease	Yes
Eye (retina) and optic nerve	After onset of clinical disease	Yes – may be incorporated into definition of skull
Trigeminal ganglion	After onset of clinical disease	Yes – may be incorporated into definition of skull
Spinal ganglia	After onset of clinical disease	Yes – removed with vertebral column
Lower levels of infectivity		
Ileum (lower small intestine)	Probably throughout incubation, but with infectivity levels greatest in first two years of incubation	Yes
Gastrointestinal tract excluding the ileum	Probably throughout incubation, but with infectivity levels greatest in first two years of life. Infectivity levels are much lower than detected in the ileum. Not yet classified by WHO as infectious	In EU, still assumed to be infected, and, partly for ease of risk management, entire intestine is defined as SRM. Other countries restrict definition to ileum
Peripheral nerve trunks Facial Sciatic Phrenic	After onset of clinical disease	No – but likely to be partially removed during carcass dressing/deboning and jointing of meat
Autonomic nerves and ganglia, vagus/splanchnic nerves	Probably from early stages of incubation, and up to clinical onset	No – partial removal likely during carcass dressing
Tonsil	Probably for significant part of incubation period, but only demonstrated in experimentally infected cattle	Yes
Bone marrow – equivocal result	Not clear, but possibly close to onset of clinical disease	No
Third eyelid (nictitating membrane) – equivocal result	Not clear – may be a rare event	No – but will be removed along with skull and eyes
Muscle (equivocal result)	Not clear – evidence is unconvincing, has not yet been repeated	No
Not detected but designated as SRMs		
Thymus	No infectivity detected	Yes originally, but now delisted
Spleen	No infectivity detected	Yes originally, but now delisted
Lymph nodes	No infectivity detected	No – but visible lymph nodes removed along with major peripheral nerves during deboning process

Note: Infectivity levels and risk levels are not synonymous. Many factors determine the degree of risk to consumers, and will include not only the quantity of tissue to which they are exposed, but also the stage of incubation of the source animal (early or late), and the route of exposure. For example, oral exposure is regarded as relatively inefficient in comparison with direct inoculation into the brain or blood stream.

calves experimentally exposed to low doses of infectivity, to simulate the most likely dose received naturally, and provides a considerable margin of safety to consumers.

Tissues in which infectivity or PrP^{Sc} have definitely been detected are summarized in Table 1, which is based on data collated and tabulated on behalf of the World Health Organization (WHO).

Controls

The principles of risk management for animals and humans were, and indeed still are, similar. They involve a precautionary approach, based on known science, but taking into account the need for feasible regulatory measures. The aim is to eliminate or minimize the risk of exposure by mouth, the only routes by which BSE is considered to be naturally transmitted to cattle and humans.

The initial steps were taken before there was any understanding of the pathogenesis of BSE, and were based on what was already known about sheep scrapie. With the benefit of hindsight, this proved to be appropriate. Measures were, however, tempered by the recognition of uncertainty regarding the science of BSE, necessitating a balance between the maintenance of viable food production and allied industries and reduction of putative risk. Excessive regulation, unsupported by scientific evidence, could have generated resistance to the implementation of controls, and put lives at risk.

Protection of Animal Health

Because cattle became infected through the consumption of ruminant-derived MBM, the key control was the prevention of the recycling of ruminant protein. Therefore, the first feed ban in the UK prohibited the feeding of ruminant-derived MBM to ruminants. The World Organisation for Animal Health (OIE) continues to retain this position, insisting that the mechanism of implementation and enforcement of such a prohibition is an issue for individual countries.

In time it became clear that some cattle were still becoming infected in the UK even if born after the introduction of the ruminant-to-ruminant feed ban. In part, this arose because ruminant-derived MBM still contained some infectivity (not all infected tissue had been identified and excluded at that time), and the use of such material in feed for pigs and poultry was still permitted. Rendering standards had not been changed at this point to maximize the inactivation of infectivity in source tissues. These changes are described below.

The presence of contaminated MBM in facilities and equipment that produced or stored feed for ruminants led to a real risk of cross-contamination. Furthermore, it was not possible to test the feed for evidence of random contamination, and uncertainty remained with respect to verification of the species of origin of feed ingredients. No tests introduced to audit feed production systems actually attempt to identify infectivity. They simply aim to detect the presence of tissues derived from prohibited species.

As a result, from 1994 the use of any mammalian-derived MBM (MMBM – to include porcine protein) in ruminant feed was prohibited in the European Union (EU). The continuing evidence for the role of cross-contamination in premises manufacturing animal feed led to an even wider prohibition in the UK in 1996. From this point, MMBM was excluded from all feed for farmed animals, including fish and horses, and indeed also for pets where there was a risk of contamination of feed intended for ruminants. Feed prohibitions were similarly extended in the EU at the beginning of 2001, although the prohibition referred to processed animal protein rather than MMBM. Minor exclusions are permitted, such as the feeding of milk or blood meal.

Three additional measures reinforce the protection of cattle, namely the slaughter and destruction of clinically affected cases, a prohibition on the use of high-risk tissues (SRMs) for animal feed (although now encompassed in rules for their segregation and destruction) and improved rendering standards. Because clinically affected cattle represent the greatest source of infectivity, in particular within the CNS, their exclusion from the rendering system will have reduced the infectious load entering the process.

SRMs were originally defined for the protection of human health, and were removed from healthy animals at slaughter. Their removal from animal feed, including animals that die on farm from which SRMs are not removed, protects animal health by also reducing the infectious load entering the rendering and animal feed chains. Although retrospective audits and advancement of the underlying science confirmed that some infectivity continued to enter the rendering plants in the UK in the early 1990s, the absence of cases of FSE in cats born in the UK after the first exclusion of SRMs from animal feed demonstrates the effectiveness of the measure.

Research conducted in the EU into the effectiveness of rendering processes in inactivating BSE, and scrapie demonstrated that most could not guarantee the elimination of infectivity. This led to changes in EU regulations, both in terms of processing standards (e.g., higher temperatures) and the segregation of raw materials into risk categories. The end result, a regulation that prescribes processes for the handling of all wastes, demands the most rigorous standards for tissues and carcasses that potentially carry a risk of transmitting TSEs. Animal by-products, other than SRMs, arising from animals that are healthy and fit for human consumption are subject to less rigorous processing standards. In non-EU countries, rendering processing standards have not necessarily been adjusted, however, particularly where risk is perceived as being low.

In summary, the removal, segregation, and processing of SRMs, or carcasses containing SRMs, reinforce the wider feed prohibition in order to minimize the risk of continued exposures and infection of cattle through the cross-contamination of feed. Protection of animal health inevitably delivers a reduction in risk for humans, albeit over a longer time frame. With the incubation period averaging 5 years in the UK, and frequently much longer elsewhere, it is usually necessary to wait many years before controls visibly reduce the prevalence of disease. Subtle effects may be seen sooner, but a decline in case numbers is likely to take 5–6 years. This is why it is recommended that preventive measures are implemented before an epidemic is detected in countries classified as being at risk. The consequences of the introduction of controls, in the

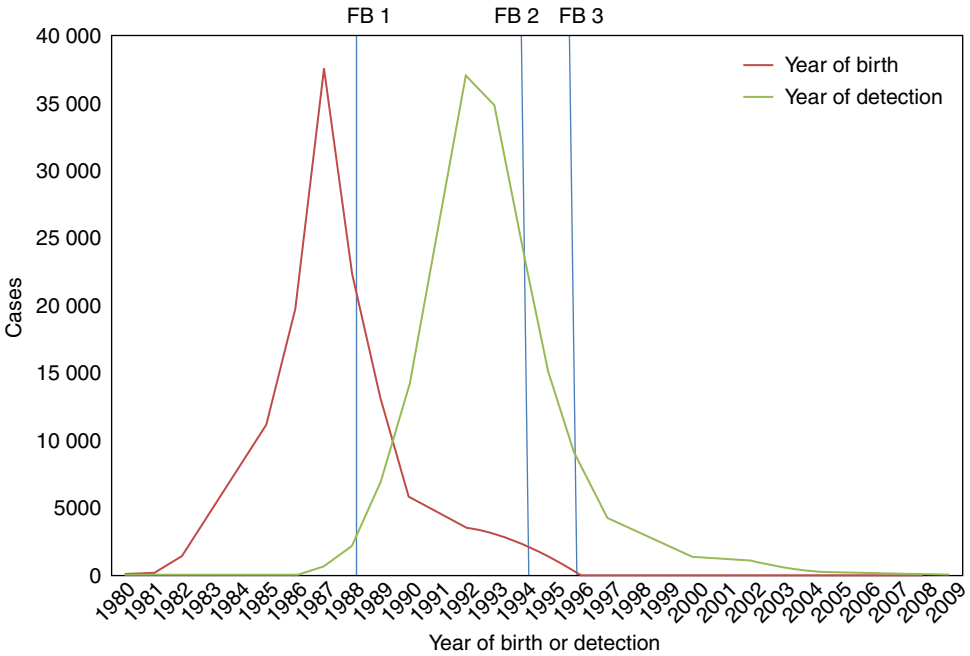

Figure 2 Graphic of British epidemic, showing by date of birth and date of confirmation – with feed bans superimposed, based upon data supplied by the Veterinary Laboratories Agency, United Kingdom. The two lines represent all cases detected, predominantly as clinical cases, the first plotted by date of birth (infection will have occurred shortly afterwards), the second by date of detection. The second peak includes animals for which no accurate date of birth was available, and therefore represents more animals than in the first peak, but this does not detract from the trends depicted, and their relationship to feed bans. The interval between peaks represents the mean incubation period of 5 years. FB1: first feed ban – ruminant protein to ruminants; FB2: second feed ban – mammalian MBM to ruminants; FB3: third feed ban – MMBM to all livestock.

form of graphic representation of the UK epidemic, on which the different feed bans are superimposed, are provided in Figure 2.

Protection of Human Health

The eradication of BSE offers the greatest protection to consumers, but interim measures are necessary to mitigate risk of exposure until this is achieved.

The most obvious protective measure is the exclusion of clinically affected cases of BSE from the human food chain. These represent the greatest risk because infectivity levels in the brain and spinal cord are at maximal levels. It is important, however, to appreciate that the clinical signs of BSE can be very subtle in their early stages, and will not always guarantee detection and exclusion of the affected animal from the food chain.

By late 1989, it proved possible to define and introduce additional controls in the UK that recognized the fact that infected cattle, destined to be consumed by humans, remained alive but undetectable on British farms. They could not be tested while alive to determine whether they were infected, and this remains unchanged at the time of writing. Based on knowledge of the pathogenesis of sheep scrapie, a short list of tissues was identified that appeared to represent the greatest risk to consumers if eaten. At the time, there were no data about the actual risk associated with these tissues in cattle, nor evidence that humans were susceptible to BSE, but they were excluded from the human food chain on a precautionary basis.

With time, research into BSE has confirmed the potentially infectious status of some of these tissues (brain, spinal cord, intestine), but did not confirm the categorization of others (thymus, spleen). Additional tissues have been added to the list of SRMs on the basis of new research findings, but it is interesting that results arising late in the EU epidemic, when prevalence of infection was low, and consumer concerns reduced, did not trigger the extension of the list of SRMs. For example, peripheral nerves have never been classified as SRMs, but are thought only to become infectious at about the time of clinical onset. With respect to the likely impact of such tissues on human exposure levels, it is necessary to appreciate that the amounts of infectivity estimated to be present in nerves are substantially less than in the brain and spinal cord.

There continues to be some international disagreement in the definition of SRMs, with the EU adopting a more precautionary approach than elsewhere. This is primarily because of the scale of the crisis in consumer confidence that occurred in Europe in 1996. Consumer risk was inevitably greater in the EU by virtue of the large number of infected cattle present, but relaxation of regulations is anticipated as risk falls to acceptable levels. It is, however, more difficult to relax regulations than to introduce them, because the relaxation inevitably increases risk to consumers even though the residual risk may still be extremely low. SRM measures in Europe, North America, and Japan as at January 2009 are summarized in Table 2. Some SRMs, such as skull and vertebral column,

Table 2 A summary of bovine-derived SRMs in Europe, North America, and Japan as at January 2009

	European Union and Switzerland
Cattle	
Skull (including brain and eyes)	>12 months
Tonsils	All ages
Spinal cord	>12 months
Vertebral column (including dorsal root ganglia – DRG – but excluding vertebrae of the tail and the transverse processes of lumbar and thoracic vertebrae)	>30 months
Intestines and mesentery	All ages
	USA
Cattle	
Skull (including brain, eyes, and trigeminal ganglia)	>30 months
Tonsils	All ages
Spinal cord	>30 months
Vertebral column (including dorsal root ganglia – DRG – but excluding vertebrae of the tail and the transverse processes of lumbar and thoracic vertebrae, and wings of sacrum)	>30 months
Distal ileum	All ages
	Canada
Cattle	
Skull (including brain, eyes, and trigeminal ganglia)	>30 months
Tonsils	>30 months
Spinal cord	>30 months
Dorsal Root Ganglia (Vertebral column, excluding vertebrae of the tail and the transverse processes of lumbar and thoracic vertebrae, and wings of sacrum, is not defined in law as SRM, but removal from the human food chain is ensured by administrative action through meat hygiene controls.)	>30 months
Distal ileum	All ages
	Japan
Cattle	
Head (including brain, eyes, and tonsils, but excluding tongue and cheek meat)	All ages
Spinal cord	All ages
Vertebral column (including dorsal root ganglia)	All ages
Distal ileum	All ages

are not inherently infected. They are designated as SRMs because they are closely associated with the brain and spinal cord, and it is assumed that they are either contaminated during the slaughter and carcass dressing process or that it is impossible to completely separate the CNS tissues from the bones encasing them.

There were two further examples of protective measures that were driven by potential contamination of raw materials during the process of slaughter and meat production, rather than the inherent presence of infectivity. These affected procedures for the stunning of cattle and the production of mechanically separated meat. When cattle were stunned before slaughter with a mechanism that injected air into the skull, particles of brain tissue were subsequently detected in the blood stream. This meant that any tissues exposed to that blood could potentially be contaminated. Blood itself has not been shown to be infectious. The prohibition of the use of such methods minimized the risk of accidental contamination of muscle and other organs.

Mechanically separated meat, however, was a process by which the vertebral column and some other bones were subjected to further treatment after the primary dressing of the carcass. This process mechanically stripped residual meat from the bone. Any residual infectivity attached to the vertebral column after carcass splitting, via retained DRG, incomplete removal of spinal cord, or contamination of the cut surface caused by the splitting saw, presented a risk that the stripped meat could be contaminated. Controls were, therefore, necessary to prohibit the use of bovine bones in the manufacture of such products.

It is interesting that no cases of vCJD have been identified in the UK in individuals that were born after the introduction of the first SRM prohibition. Although with hindsight it is now known that this measure did not remove all infectivity from the food chain, it appears to have had a significant effect in reducing human exposures and likelihood of infection.

Two further measures were perceived to have possible additional protective effect for humans. First, milk from clinically affected cattle was excluded from the human food chain (UK only). Although infectivity has not been detected in milk from BSE-affected cattle, it has been demonstrated in sheep with scrapie. Second, the identification of birth or feed cohorts of affected cattle, and their exclusion from the food chain, was adopted internationally. Birth or feed cohorts represent animals that were born or reared at about the same time as an infected animal, on the same farm, and were potentially exposed to the same feed source. They clearly represent a greater risk than the population at large, but with the exception of cattle born in the UK before the first feed ban came into force in 1988, the numbers of infected animals actually detected in cohorts has been extremely low.

A final protective measure, not specifically introduced to reduce the risk for BSE, now included in international BSE-related guidelines for trade in beef includes the removal of visible lymph nodes and nerves during the process of dressing carcasses following slaughter. This applies particularly to deboned beef, where preparation of the meat for sale, storage, and transit has involved the removal of such tissues for many years. Infectivity has never been detected in bovine regional carcass lymph nodes, or in bones, but such a measure provides the final level of protection should clinically affected cattle be inadvertently slaughtered.

The introduction of postmortem testing of healthy cattle of more than 30 months of age in Europe, and later in Japan even in younger cattle, was frequently portrayed and perceived as a risk reduction measure. There is no doubt that it increased consumer confidence, but in reality, SRM removal ensured that the vast majority of infectivity was removed from the food chain anyway. Furthermore, SRM removal protected consumers from instances where infectivity was present in the brain, but the postmortem test result was negative. Following research into the time-course of detection of PrP^{Sc} by

postmortem tests on experimentally infected cattle, it has been estimated that postmortem testing would only detect approximately 50% of infected animals at 1.7 months before onset of clinical signs. Detection would fall close to zero at 3 months before onset of disease, or 97% of the incubation period. In most countries, where epidemics are likely to be small and infectivity levels in cattle feed low, incubation periods are likely to be very long. Therefore, infected cattle that are slaughtered while still healthy are most unlikely to be detected by postmortem testing.

At the time of writing, investigations into cases of vCJD have not identified any route of infection directly from cattle to humans other than through contaminated food produced before the introduction of regulatory controls.

Specific Food Products

To the consumer, the relationship between a food product and a specific source tissue may not always be obvious. This is particularly so where a manufacturing process is involved. Additionally, the pooling of materials from different animals and regions compromises traceability. Regulatory authorities have used the evolving knowledge of the pathogenesis of BSE to ensure that food, whether processed or unprocessed, is safe by excluding certain tissues from the food chain, but their impact on certain commodities may not be obvious. In view of their widespread use, it is appropriate to discuss certain commodities and their safety in a little more detail.

It is important to remember that safety is assured by two measures: the exclusion of infectivity by the removal of tissues in which the presence of infectivity is suspected or confirmed and the prevention of contamination with infected tissues during the manufacturing process. At no time have authorities accepted the principle that food can be made safe solely by the application of specific processing standards. Heating, or cooking, has never been accepted as sufficient to remove infectivity, and even in the production of animal feed, it is only expected to reduce infectivity levels rather than guarantee elimination.

The most obvious commodity that receives minimal processing before consumption is milk. The initial exclusion of milk from clinically affected cows from the human food chain in the UK was precautionary. It presumed that because sheep scrapie appeared to transmit from ewe to lamb, this may have been via milk. There is now sound scientific support for such transmission in sheep, but none for transmission of BSE via bovine milk. For this reason the OIE, supported by the WHO, lists bovine milk as a commodity that can be traded safely irrespective of the BSE status of the country of origin.

Gelatine is an animal by-product that is incorporated into a wide range of food and pharmaceutical products. It is derived from two source tissues, hides or bones, and the extraction of gelatine involves rigorous chemical processes. Infectivity has not been detected in hides. Gelatine derived from skin or hide is, therefore, considered to be free of risk. Although infectivity has not been detected in bone, the close association of the skull and spinal (vertebral) column with the brain and spinal cord means that the bones are inevitably contaminated with CNS tissue during the process of carcass dressing. Despite the rigor of the process for extracting gelatine from bones, it has not been possible to conclusively demonstrate that it is free of infectivity when derived experimentally from raw materials that contained BSE infectivity. In part, this is because of the limitations of sensitivity of the assay methods. The outcome of extensive consideration by expert committees is a requirement to exclude bovine skull and vertebral column from the manufacturing process in BSE-affected countries.

Tallow is a product that most consumers are unaware of, but is an essential ingredient of much processed food and of pharmaceuticals. It is produced by rendering tissues resulting in three by-products, namely water, fat, and protein. The water is driven off as steam, the fat is separated from the protein, and the latter is further processed into MBM. The separated fat is processed further to produce a range of end products or derivatives. There are several categories of tallow determined in part by the nature of the raw materials and by the type of rendering process used. Tallow intended for use in food products would be derived from animals and raw materials already inspected and passed fit for human consumption. Although there is no published evidence that infectivity is found in tallow after rendering, there is both unpublished data and scientific opinion that suggest that such a risk cannot be totally ignored. As for gelatine, this subject has been debated extensively, concluding that any residual infectivity is likely to be associated with traces of protein that may remain in the tallow. Consequently, trade rules focus on establishing maximal levels for insoluble impurities in tallow if it is allowed to be traded freely. Levels of contamination above this maximum require the application of additional conditions to the production process, which may include the exclusion of certain SRMs.

It is worth stressing, however, that the residual risks estimated to be associated with gelatine and tallow are extremely low. Furthermore, these commodities are not inherently risky. If there is no BSE in the cattle from which source tissues are derived, then there will be no scope for infectivity to be present in the end product unless contaminated from another source after production.

Diagnosis

At the time of writing, there is no live animal test for BSE. Claims that tests can detect BSE *in vivo* must be treated with caution unless accompanied by evidence of thorough evaluation by a third party.

Clinical signs alone are insufficient to enable detection of the majority of infected animals. In most countries that have experienced BSE, such cases are too rare to reinforce diagnostic skills, and only the most extreme clinical signs are recognized.

In accordance with rules established by the OIE, BSE should be legally notifiable. This ensures that suspicion of disease is reported to national authorities, and that tests used to confirm a diagnosis are appropriate. The accepted approaches for postmortem diagnosis are established in the OIE Manual of Diagnostic Tests and Vaccines for Terrestrial animals, and accommodate the likely range of technical facilities that may be present in member countries.

BSE Risk – Categorization of Countries

Traditional approaches to international trade in animals and animal products require the declaration of health status of source countries, zones, farms, or animals. This may involve the testing of individual animals or herds. Because of the difficulties encountered in identifying BSE-infected animals while still alive, national and international organizations have adopted alternative approaches to define BSE-related risk. Additionally, it is accepted that the risk mitigation measures that need to be introduced in a country should be driven by the estimated risk within it, as determined by independent scrutiny of national data. In other words, countries that represent a low BSE risk require fewer control measures and smaller surveillance programs than those with significant risk. A proportionate response to risk is considered appropriate.

Although with other diseases the incidence of disease is normally an appropriate indicator of risk, the recognition that clinically affected cases of BSE are difficult to detect and that they represent only a small proportion of infected animals challenges this traditional approach to categorization. The European Commission was advised by its former Scientific Steering Committee (SSC) to apply a comprehensive qualitative risk-assessment approach, based initially on likelihood of exposure from the UK through the importation of MBM, and potential for further amplification of infectivity after importation. This approach proved to be very successful, and was reinforced by the later results of active surveillance. Infected cattle were detected in several countries that previously claimed freedom from disease, and which may have exported BSE-infected cattle or contaminated products before indigenous cases were identified.

The SSC methodology was eventually updated by the European Food Safety Authority (EFSA), and took into account changes adopted in the OIE rules for categorization and surveillance. It is important to recognize the fact that statements of BSE-related risk are most robust where countries have been categorized as being of negligible risk or controlled risk. Remaining countries, which are of undetermined risk, may not have been exposed to BSE. It would be wrong, therefore, to presume that their inclusion within this broad category is an indicator of risk, but the absence of external evaluation of risk means that statements of safety must be interpreted with caution.

Future categorization will take into account the establishment of surveillance programs that target the most appropriate population of cattle (potential clinical cases in particular), but also recognize the infrastructure in individual countries. A one-size-fits-all program is not possible, other than in the establishment of a target for each to achieve in order to facilitate categorization. Such programs are intended to detect trends in prevalence of infection, as a means of monitoring the effectiveness of controls.

Conclusions

There are two reasons for anticipating that BSE will eventually assume a more appropriate position in the spectrum of foodborne zoonoses to which consumers are exposed. First, however incomplete, the research conducted over the past 20 or more years indicates that irrespective of disease incidence in a source country, the distribution of infectivity within the body of infected cattle lends itself to practical approaches to risk reduction. Second, the natural experiment conducted in the UK before the introduction of control measures, when exposure levels were high, demonstrates that exposure of both animals and humans can be controlled.

The steep and continued decline in prevalence of BSE in cattle following the introduction of the feed ban illustrates this statement, albeit with a time lag that is determined by the long incubation period. In addition, the absence of vCJD cases in humans born after the first ban on consumption of SRM in 1989 will, if sustained, confirm the effectiveness of excluding targeted high-risk tissues in protecting consumers. Although the consequences of infection are fatal, the likelihood of infection after the initial SRM regulation was low relative to the quantity of infectivity that entered the food chain beforehand. Evidence for transmission between humans, for example via blood transfusions, does not undermine such a statement.

The first announcement of the likely transmission of BSE to humans prompted unprecedented concerns about human safety. Uncertainty prompted prognostications of doomsday scenarios, with millions of human deaths. They also failed to recognize the fact that the human cases arose from historical exposure, before the introduction of protective measures. Global events drove the establishment of international protective measures to unprecedented levels, but the process of relaxation has begun and may conclude with residual, but focused, measures that may remain in place in perpetuity. Countries that have taken the trouble to determine their status *vis-à-vis* BSE risk should be congratulated, and others encouraged to transparently eliminate any uncertainty surrounding the status of their national herds.

PRIONS AND AGENTS OF TSES

Creutzfeldt–Jakob Disease

RG Will, University of Edinburgh, Edinburgh, UK

Glossary

Creutzfeldt–Jakob disease The most important human prion disease.

Mechanically recovered meat A material derived by a pressure system applied to portions of the carcass of animals which is used as an additive in food products.

Prion diseases Diseases caused by an infectious form of a misfolded host protein.

Sporadic Creutzfeldt–Jakob disease The commonest form of human prion disease which is of unknown etiology and occurs worldwide.

Variant Creutzfeldt–Jakob disease A form of Creutzfeldt–Jakob disease causally linked to bovine spongiform encephalopathy in cattle.

Characteristics

Creutzfeldt–Jakob disease (CJD) is the most important human form of transmissible spongiform encephalopathy or prion disease and is unique biologically as it may occur as a sporadic, hereditary, or transmissible disease. There are a number of subtypes of CJD, classified in part according to etiology (Table 1), but all forms of CJD are progressive and fatal neurological diseases, with no effective treatment for the underlying disease process. Prion diseases, including CJD, pose particular challenges to public health because the causal agents are relatively resistant to decontamination or sterilization, and infectivity is present, asymptomatically, in peripheral tissues as well as the central nervous system (CNS). Human prion diseases are associated with extended incubation periods, measured in years or even decades, and there is no available *in vivo* test to identify individuals who are incubating the disease. The identification of variant CJD (vCJD) as a zoonosis, causally linked to bovine spongiform encephalopathy (BSE), has had significant implications for the food industry because of the hypothesis that the transmission from cattle to humans was through dietary exposure to BSE infectivity in the food chain.

Epidemiology

Sporadic CJD (sCJD) occurs worldwide with a relatively standard mortality rate of 1–1.5 cases per million per annum and the temporal and geographical distribution of cases within countries appears random, with no localized aggregation of cases. This evidence, together with the failure to identify any consistent risk factor for the development of disease, has led to the hypothesis that sCJD is not related to acquired environmental infection, but develops following the chance, spontaneous transformation of prion protein in the brain to the disease-associated self-replicating form. This hypothesis is now widely accepted and is compatible with the occurrence of sCJD in countries, such as Australia, in which animal prion diseases have not been identified. The implication is that sCJD is not a zoonosis and therefore has no implications for food safety.

Hereditary forms of human prion disease, including genetic CJD, Gerstmann–Straussler syndrome (GSS), and fatal familial insomnia (FFI), are dominantly inherited and associated with point or insertional mutations of the human prion protein gene (*PRNP*). The frequency of these disorders varies by country, for reasons that are unclear, except that in Libyan-born Israelis and localized areas of Slovakia there may be relative genetic isolation. The occurrence of a genetic disease that is nevertheless infectious, as confirmed by laboratory transmission studies, is a paradox, but the occurrence of cases within branches of pedigrees that are separate in time and space argues against genetic susceptibility to an acquired infection. The favored hypothesis is that the *PRNP* mutations lead to instability in the brain prion protein, which is more likely to adopt the disease-associated form and eventually result in disease.

Iatrogenic CJD is caused by the transmission of infection from person to person in the course of medical or surgical treatment. Although such transmission has rarely occurred through contaminated neurosurgical instruments or corneal grafts, the numerically most significant mechanism of transmission has been through human pituitary derived hormones, in particular human growth hormone (hGH), and human dura mater grafts, with more than 400 cases in total worldwide. Pituitary glands or dura mater obtained at postmortem from sCJD patients must presumptively have been included in the production process and cross-contamination resulted in dissemination of infection. Importantly, these transmissions

Table 1 Human prion diseases

Disease	*Geographical distribution*	*Etiology*
sCJD	Worldwide	Unknown
vCJD	Predominantly UK, smaller numbers in France, Ireland, Italy, Netherlands, Portugal, Spain, USA, Canada, Saudi Arabia, Japan	BSE
Genetic CJD/GSS/FFI	Worldwide but higher incidence in Slovakia, Italy, Israel	Mutation in *PRNP* gene
Iatrogenic CJD	Variable; hGH cases most frequent in France and UK. Dura mater most frequent in Japan. Four cases of transfusion transmission of vCJD in the UK	CJD-infected pituitary hormones, dura mater grafts, neurosurgical instruments, stereotactic EEG, corneal grafts, blood

have involved CNS tissues with high levels of infectivity and there is no evidence, to date, of transmission of sporadic (or hereditary) CJD through general surgical instruments or peripheral tissue transfer. In vCJD, there are higher levels of infectivity in peripheral tissue, including the lymphoreticular system, and there have been four instances of transmission of infection from person to person through blood transfusion, including three clinical cases and one pre- or subclinical infection, in which abnormal prion protein was identified in the spleen of an individual who died of a nonneurological disease.

vCJD was first identified in 1996 in the UK and was thought to be a novel human prion disease as the clinical and pathological phenotype had not been observed previously. It was suggested that this disease might be a zoonosis owing to the occurrence of this disease in a country with a potentially novel risk factor for prion disease, BSE, and the absence, at that time, of cases with a similar phenotype in some other European countries which had established systematic surveillance systems for CJD, namely France, Germany, Italy, the Netherlands, and Slovakia. The hypothesis that BSE infection had been transmitted to humans through infectivity in the human food chain raised concerns that there might be a large epidemic of vCJD as the human population had potentially been exposed to large quantities of BSE-infected material. However, the number of observed cases of variant CJD in the UK has been relatively limited (**Figure 1**) and the epidemic curve peaked in 2000 and has subsequently declined.

Since 1996, cases of vCJD have been identified in a number of other countries ($n = 10$), mainly in Europe. There is an international agreement that cases of vCJD will be attributed to the country of residence at the time of disease onset, even if the causal exposure may have taken place in another country at a time of prior residence. **Table 2** provides data on the number of cases of vCJD by country and includes the number of cases linked to blood transfusion and the number of cases by country, with a history of residence in the UK for a period of at least 6 months. These cases are presumed to have been exposed to BSE infection in the UK and to have later developed clinical disease in the country of residence. There is some evidence that the vCJD cases outside the UK, with no history of having lived in the UK, may have been infected through exposure to infection through BSE-implicated exports from the UK, rather than indigenous BSE. The source of infection in the cases from Saudi Arabia is unknown as BSE has not been identified in Saudi Arabia, and UK imports were limited. The overall trend in the number of vCJD cases outside

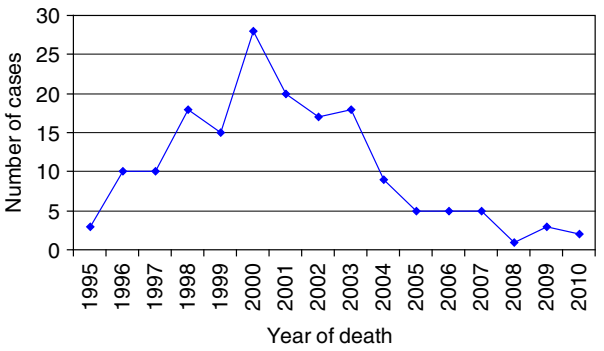

Figure 1 Deaths from vCJD in the UK.

the UK is in decline, most notably in France, which has the second largest number of cases ($n = 25$), but it is still possible that further countries exposed to indigenous BSE or with a history of UK imports will identify cases of vCJD.

The incubation period in vCJD is unknown because the timing of the causal exposure cannot be identified in any individual case. However, mathematical modeling of the epidemic suggests that the mean incubation period is approximately 15 years and this is consistent with estimates of the incubation period derived from the known periods of residence in the UK and the timing of disease onset in non-UK cases. The infectious dose and the route of exposure are important determinants of incubation periods in prion disease and the interval between blood transfusion and disease onset in transfusion transmitted cases is between 5 and 8 years, shorter than by oral exposure, probably because the intravenous route of exposure to infection is more efficient.

One characteristic that distinguishes vCJD from sCJD is a significantly earlier age at death with mean ages at death of 29 and 66 years, respectively. The reason for this disparity is unknown but hypotheses include age-related susceptibility to infection and variation in dietary exposure to the BSE agent by age cohort. Fitting the vCJD epidemic curve to estimated BSE exposure patterns requires an age-related susceptibility factor, but variation in exposure to BSE by age is likely to be a codeterminant of age at onset of the disease. The incidence of vCJD in the UK is approximately double in the north of the UK in comparison with the south and one analysis showed a relationship between the regional incidence of vCJD and regional differences in past intake of foodstuffs potentially contaminated with high levels of BSE infectivity, including food containing bovine-derived mechanically recovered meat (MRM).

Table 2 Variant CJD cases worldwide (July 2010)

Country	*Total number of primary cases (number alive)*	*Total number of secondary cases: blood transfusion (number alive)*	*Residence in UK more than 6 months during the period 1980–96*
UK	170 (4)	3 (0)	173
France	25 (0)	–	1
Republic of Ireland	4 (0)	–	2
Italy	2 (1)	–	0
USA	3 (0)[a]	–	2
Canada	1 (0)	–	1
Saudi Arabia	1 (0)	–	0
Japan	1 (0)[b]	–	0
Netherlands	3 (0)	–	0
Portugal	2 (0)	–	0
Spain	5 (0)	–	0

[a]The third US patient with vCJD was born and raised in Saudi Arabia and has lived permanently in the US since late 2005. According to the US case-report, the patient was most likely infected as a child when living in Saudi Arabia.
[b]The case from Japan had resided in the UK for 24 days in the period 1980–96.

The main risk factors for developing vCJD are young age, a history of residence in the UK and a specific genotype, methionine homozygous at codon 129 of the human prion protein gene (*PRNP*). Codon 129 of *PRNP* is a polymorphic region, with genotypes at this locus varying in the normal population between methionine homozygous (MM), valine homozygous (VV), and heterozygous (MV) (Figure 2). Variation at this site is known to influence susceptibility to sporadic and iatrogenic CJD, but in vCJD to date, all definite and probable cases with available genetic analysis have been MM homozygous. The biological mechanism underlying this observation is uncertain, but homology of the prion protein gene may facilitate prion conversion and all bovines are MM at the equivalent site in the bovine prion protein gene.

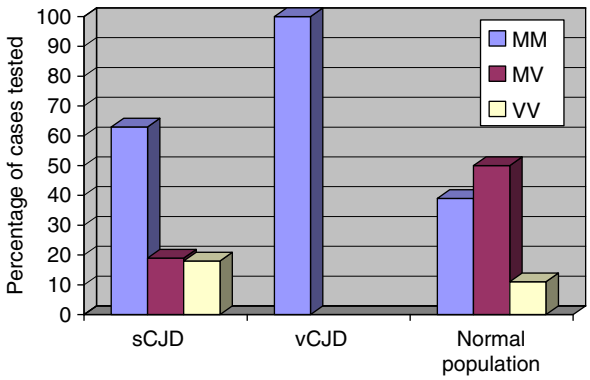

Figure 2 Codon 129 distribution in sporadic CJD, variant CJD, and the general Caucasian population.

Evidence of a Link Between BSE and vCJD

The first indication of a causal link between BSE and vCJD was the occurrence of a new human prion disease in the UK, where the human population had been exposed to a potential novel risk for prion disease in the form of BSE. Although cases of vCJD have subsequently been identified in a number of other countries, the highest incidence of vCJD is in the UK, the country with the highest incidence of BSE, and other countries with cases of vCJD have either indigenous BSE epidemics or a history of importing bovines or bovine products from the UK. As indicated above, there are also a small number of cases that were exposed to BSE in the UK and developed vCJD years later in their country of residence. The possibility that vCJD was identified as a result of improved ascertainment of an already existing disease is unlikely, as no previous case with a similar pathology has been identified despite rigorous review of pathology archives in the UK and other European countries. Furthermore, only small numbers of cases have been identified outside the UK despite systematic surveillance in many countries, including a coordinated surveillance program for CJD in Europe. It would be a remarkable coincidence if vCJD was a rare indigenous disease and the isolated cases identified in countries such as the USA and Canada had a history of residence in the UK as a matter of chance. Recent laboratory transmission studies have demonstrated that the agent characteristics in terms of incubation periods and anatomical distribution of brain lesions are virtually identical in cases of vCJD from the Netherlands, France, Italy, the USA, and the UK.

The hypothesis that the infectious agent or prion in vCJD is derived from BSE infection has been supported by a number of laboratory studies. The biochemical properties of the prion protein on Western blot analysis are identical in BSE and vCJD, and distinct from other forms of human prion disease. The characteristic florid plaques that are deposited in the brain in vCJD are also present in a primate model after intracerebral inoculation of BSE. Most compelling are the results of transmission studies in laboratory rodent models, including wild-type and transgenic mice. In these studies, the incubation periods and neuropathological lesions are remarkably similar following intracerebral inoculation of BSE and vCJD, whereas the results following inoculation of sCJD are clearly distinct. The conclusion of these studies is that the agent causing vCJD is the same as the agent causing BSE.

If BSE is the cause of vCJD, a critical question is the mechanism of transmission of infection from cattle to humans. Human exposure to the BSE agent could potentially occur through a range of mechanisms, for example, through dietary contamination, bovine-sourced medications, or through occupation, such as working in an abattoir. Searching for a potential causal exposure is complicated by the long incubation period and the necessity to obtain information on relevant risk factors from the relatives of patients, because the nature of the neurological illness often precludes direct interview with cases. Additional information has been sought from medical and general practitioner records, which contain details of past surgical procedures and medical treatments, including vaccination history. A case-control study of risk factors for vCJD, including 136 cases from the UK, found that frequent consumption of beef and beef products were thought likely to contain mechanically recovered or head meat, or both, including burgers and meat pies, and was associated with increased risk for vCJD. No other risk factors were identified and there was no link with prior occupation or animal exposure, or with medical or surgical exposures. This is consistent with dietary exposure to BSE as the mechanism of human exposure to BSE, but the results are compromised by the potential for reporting bias. However, no other plausible mechanism of exposure has been identified and the UK population was exposed to large quantities of BSE infection in the human food chain during the 1980s and to a lesser extent during the early 1990s.

The possibility of secondary transmission of vCJD through organ or tissue transplant, or through the reuse of contaminated surgical instruments, has been an important concern for public health. To date, there is no evidence of this form of transmission, but the potential protracted incubation periods following relatively low-dose exposure by a peripheral route indicate that it may be many years before this type of transmission can be excluded.

Clinical Features and Diagnosis of CJD

All forms of CJD present with a progressive neurological disorder, but the clinical and investigative features vary by subtype. Diagnostic criteria for the various forms of human prion disease have been formulated and partially validated.

sCJD characteristically presents with a rapidly evolving dementing illness, often associated with cerebellar ataxia and myoclonic involuntary movements of the limbs and trunk. The mean survival from symptom onset to death is only 4 months, which distinguishes sCJD from other, more common, forms of dementia. The mean age at death is 65 years, but there is a wide range in age at onset of symptoms and sCJD has been identified in individuals in their teens and in their nineties. Age alone cannot distinguish sCJD from other forms of human prion disease. The clinical and pathological phenotype varies according to the codon 129 genotype and the biochemical form of prion protein deposited in the brain, of which there are two main forms, Type 1 and Type 2, distinguished by their mobility on Western blot analysis. The typical, rapidly progressive, form of sCJD is associated with an MM or MV genotype and Type 1 prion protein, whereas atypical forms of sCJD with a relatively prolonged survival, atypical neuropathological features, or a younger age at onset of symptoms are associated with the other combinations of genotype and protein type, MM2, MV2, VV1, or VV2. The typical MM1 or MV1 cases account for approximately 80% of sCJD cases and the other forms are rare.

Hereditary forms of human prion disease vary in clinical and neuropathological features according to the underlying mutation. Some forms of hereditary CJD have a phenotype that is very similar to sCJD, for example, cases associated with the mutation at codon 200 of *PRNP*, but other forms of hereditary human prion disease have distinctive features, including cases of GSS, which present with cerebellar ataxia and FFI which presents with insomnia and autonomic disturbance. The genotype at codon 129 influences the clinical presentation, notably with the codon 178 mutation in which an MM genotype is associated with FFI and a VV genotype with an illness similar to sCJD. However, there is marked variation in clinical phenotype both between and within families which is unexplained and not determined solely by genetic influences. Overall, patients with hereditary forms of human prion disease develop symptoms approximately 5 years earlier than sCJD and the duration of illness is also longer.

In iatrogenic CJD, the clinical features are determined in part by the route of exposure to infection. Iatrogenic CJD with a peripheral route of exposure to infection, for example, cases related to prior treatment with human pituitary growth hormone, which was given by injection, present with a cerebellar syndrome and there may be little evidence of cognitive impairment. Cases caused by the introduction of infection directly in to the CNS, for example, through contaminated neurosurgical instruments, present with features akin to sCJD. In cases related to human dura mater grafts there is variation in clinical presentation, although many of these cases have features similar to sCJD. Homozygosity at codon 129 of *PRNP* is a risk factor for the development of iatrogenic CJD.

vCJD has a clinical presentation which is different from other forms of human prion disease, consistent with the hypothesis that this condition is caused by a distinct strain of infectious agent. In addition to the relatively early age of disease onset mentioned above (mean 29 years), the first symptoms are psychiatric rather than neurological, with early depression , anxiety, and sometimes delusions for a mean of 6 months before the development of ataxia, involuntary movements including chorea or myoclonus, and progressive cognitive impairment. The terminal stages are similar to sCJD and the mean survival is 14 months from symptom onset. The nonspecific initial psychiatric features make early diagnosis very difficult and indicators include persistent painful sensory symptoms, gait ataxia, or frank cognitive decline. All tested definite or probable cases of vCJD internationally have been MM homozygous at codon 129 of *PRNP*.

Diagnosis of CJD

A number of specialist investigations are useful in supporting the diagnosis of CJD, but their utility varies according to the disease subtype. As with other neurological disorders, diagnosis depends on suspecting the relevant condition and

arranging and interpreting the results of investigations in the clinical context.

In sCJD, the most useful investigations are the electroencephalogram (EEG), which shows periodic complexes at a frequency of approximately $1\,s^{-1}$ in approximately 50% of cases and immunoassay for 14-3-3 protein in the cerebrospinal fluid (CSF) which is positive in approximately 80% of cases. Recently high signal in the caudate or putamen on MRI brain scan has been found to have a relatively high sensitivity (75%) and specificity for the diagnosis of sCJD, and has been included in the diagnostic criteria for case classification. These criteria include a combination of suggestive clinical features and the results of EEG, CSF, and MRI brain scan to allow classification of cases as definite, probable, or possible. A definite diagnosis requires the identification of the cardinal neuropathological features of sCJD (spongiform change, neuronal loss, and astrocytic gliosis) at postmortem or rarely brain biopsy. Most authorities report definite and probable cases of sCJD as there is significant diagnostic uncertainty in cases classified as possible sCJD.

The diagnosis in hereditary forms of human prion disease depends on either obtaining a family history of CJD or other human prion disease in a relative or relatives of the index patient or on identifying a disease-associated mutation on sequencing of *PRNP*. Only approximately one-third of mutation-associated cases have a positive family history and *PRNP* sequencing is essential for an accurate diagnosis if hereditary CJD is suspected, although routine genetic analysis in all cases of CJD may be necessary to avoid missing genetic cases. Specialist investigations, including EEG, CSF 14-3-3, and MRI brain scan, may be positive in genetic forms of human prion disease, but in many cases these investigations may not be diagnostic.

Iatrogenic cases of CJD are recognized on the basis of identifying a relevant risk factor in a patient with a suggestive neurological presentation. A history of exposure to human pituitary hormones, human dura mater graft, or corneal graft should be sought in all suspected cases of CJD as the clinical phenotype in iatrogenic CJD may be similar to sCJD. Iatrogenic transmission through contaminated neurosurgical instruments has not been recognized for decades, but any potential exposure through this mechanism requires specific epidemiological investigation. Specialist investigations are less likely to be helpful in diagnosis of iatrogenic CJD, but should be carried out in all cases of suspected CJD.

In vCJD, the suspicion of the diagnosis is raised by the occurrence of a progressive neuropsychiatric syndrome in an individual in a younger age range than expected for sCJD. The EEG is usually normal or exhibits nonspecific slowing in the great majority of cases, although periodic complexes at $1\,s^{-1}$ have been found in two cases in the terminal stages of the illness. The 14-3-3 CSF immunoassay is positive in approximately half the cases and is of limited diagnostic value. The MRI brain scan is the most useful investigation, showing high signal in the posterior thalamus, the pulvinar sign, in more than 90% of cases. These appearances are virtually pathognomonic for vCJD in the appropriate clinical context. Tonsil biopsy, showing positivity for disease-associated prion protein, is also a highly reliable diagnostic aid, but this investigation is invasive and has risks, including hemorrhage. A definite diagnosis requires the identification of the specific neuropathological features of vCJD, including widespread deposition of florid plaques of abnormal prion protein in a number of cortical regions, usually at postmortem. Diagnostic criteria for vCJD have been formulated and validated and provide a reliable framework for case classification. As with sCJD, most authorities report definite and probable cases of vCJD because of the diagnostic uncertainty in cases classified as possible vCJD.

CJD and Public Health

Following the identification of BSE in 1986, the possible public health implications were considered by a number of agencies in the UK and Europe, and the consensus was that BSE was unlikely to pose a significant risk to the human population owing to the fact that BSE was likely caused by transmission of sheep scrapie to cattle and there was no evidence that this condition was transmissible to humans. However the origin of BSE was, and remains, uncertain and it was known that prions can change their characteristics, including species specificity, after transmission across a species barrier. A range of measures were introduced in the UK in order to control the BSE epidemic, but the critical measure aimed at minimizing human exposure to BSE in the food chain was the specified bovine offals (SBO) ban, which was introduced in 1989. The tissue distribution of infectivity in BSE was not known and a range of bovine tissues from all cattle were excluded from the human food chain, although this measure was not fully enforced. Subsequently the tissues designated as SBOs were extended, bovine-sourced MRM was banned in 1995 and in 1996, following the identification of vCJD, and the Over Thirty Months Rule was introduced, which excluded cattle aged more than 30 months from the human food chain. Other countries in the European Union introduced a ban of specified risk materials (SRMs) in 2000 and a compulsory testing of all animals for human consumption over the age of 30 months in 2001, following the development of rapid tests for the presence of BSE, which could be utilized in abattoirs.

The impact of these measures on reducing the risk of vCJD is difficult to estimate because of the long mean incubation period in vCJD and the fact that human exposure to BSE was significant in the UK before these measures were introduced and probably before BSE was first identified. It has been estimated from a mathematical model that between 1 and 3 million infected cattle may have entered the human food chain before the introduction of the SBO ban in 1989 and infected cattle are also likely to have been consumed in other European countries before the introduction of measures to minimize human exposure to BSE, although in much lower numbers than in the UK.

An important question is why the epidemic of vCJD has been relatively limited in the UK and other European countries despite the extent of human exposure to BSE. The most parsimonious explanation is that there is a significant barrier to the transmission of bovine prions to humans, and the so-called species-barriers to transmission are well recognized in experimental prion disease. The possibility that there may be cofactors necessary for transmission in the form of concurrent

conditions, for example, inflammatory bowel disease, easing the spread of infected prions across the gut wall, or occupational exposure to BSE have been largely excluded by detailed analysis of the vCJD patient characteristics. Genetic factors other than variation in *PRNP* are potential determinants of susceptibility to BSE, but no such genetic factors have been identified. A crucial issue for public health is the prevalence of infection in the general population, and studies of routine appendix and tonsil specimens in the UK suggest that there may be a population of individuals who are infected with BSE, with an estimated prevalence of 237 per million. The mismatch between the observed incidence of vCJD and the estimated number of individuals who are infected may be explained by subclinical infection in which disease does not develop in lifespan.

The identification of transfusion transmission of vCJD has raised concerns regarding the possibility of the spread of infection in the population through transmission of vCJD from person to person, a concern that has been heightened by the estimated prevalence of infection in the general population. Measures to reduce the risk of secondary transmission of vCJD have included the sourcing of plasma for plasma product manufacture from outside the UK and the deferral of transfusion recipients as blood donors. As with the SBO ban and other measures to reduce the risk of BSE, most of the policies to minimize the risk of secondary transmission of vCJD were introduced well before the demonstration of an actual risk, underlining the importance of precautionary action in relation to potential public health consequences of prion diseases.

Future Prospects

The epidemics of BSE and vCJD are in decline and there will be an increasing pressure to review the current measures in place to control BSE, not least because of the costs involved in the active testing program and the SRM ban. This has to be balanced against the risks to the human population from BSE, and the decisions about relaxing the protective measures are essentially political rather than scientific. However, the identification of atypical forms of BSE and scrapie in recent years indicates that there are continuing uncertainties about the extent and nature of animal prion diseases.

There are also uncertainties about the future of vCJD. A possible case of vCJD in an individual with an MV codon 129 genotype has been described, raising the possibility of further outbreaks of vCJD in individuals with MV and perhaps VV genotypes. Mathematical predictions of the likely numbers of cases in these genotypes suggest that these will be no greater than the primary outbreak in the MM population, but these analyses make a range of assumptions that cannot be verified. The identification of abnormal prion protein in the spleen of an individual with hemophilia A has raised the possibility of a further outbreak of vCJD cases in the population treated with plasma products. There may be further cases of transfusion transmission of vCJD, and individuals who donated blood and later developed vCJD have been identified in Ireland, France, Saudi Arabia, as well as the UK. There are concerns about the potential for secondary transmission of vCJD through contaminated surgical instruments and perhaps vertically from mother to child.

Prion diseases have had a major impact on the general population, policy makers, and industry, and the difficulties in managing diseases with long incubation periods, a fatal outcome, and no means of identifying those that are infected suggest the need for continuing caution.

PROTOZOA

Contents

Cryptosporidium spp.

BR Dixon, Health Canada, Ottawa, ON, Canada

Glossary

Genotype A genetically distinct group of organisms within a species.
Immunocompetent Having the ability to develop an effective immune response following exposure to an antigen.
Immunocompromised Having impaired immune response due to a disease or condition, or as a result of medical treatment.
Oocyst The infectious environmental stage of *Cryptosporidium* and other apicomplexan parasites, which is produced following the sexual stage of the life cycle.
Zoonotic An infectious disease transmissible from animals to humans.

Background

Cryptosporidium spp. is a protozoan parasite of the phylum Apicomplexa. It is found worldwide in a large number of different hosts, including humans. There are currently more than 20 valid species of *Cryptosporidium*, and more than 40 distinct genotypes. Some species, such as *Cryptosporidium hominis*, have very narrow host ranges, whereas others, such as *Cryptosporidium parvum*, have a wide range of hosts. A growing number of *Cryptosporidium* sp. have been reported to infect humans (Table 1), and several genotypes have also been identified. However, approximately 90% of reported human infections involve *C. hominis*, which is found primarily in humans, and *C. parvum*, which is an important zoonotic species. *Cryptosporidium hominis* accounts for more human cases than *C. parvum* in North America, Australia, Asia, and Sub-Saharan Africa, whereas *C. parvum* is more common in Europe and the UK. Generally speaking, *C. parvum* is more prevalent in rural or agricultural regions, a likely result of zoonotic transmission.

Cryptosporidium was regarded as a benign commensal until the early 1970s when it was recognized as an important cause of diarrhea in animals. It was only recognized as a pathogen in humans in 1976. In recent years, human infection with *Cryptosporidium* has emerged as a global public health problem and this parasite is now considered to be a common cause of gastroenteritis in immunocompetent individuals, and of severe illness in immunocompromised individuals. Prevalence rates based on oocyst excretion vary from approximately 1–3% in industrialized countries, up to 10% or higher in developing

Table 1 *Cryptosporidium* species reported in humans

Cryptosporidium sp.	*Major hosts*
Cryptosporidium hominis	Humans
Cryptosporidium parvum	Humans, cattle, pigs, sheep, and mice
Cryptosporidium meleagridis	Turkeys
Cryptosporidium cuniculus	Rabbits
Cryptosporidium canis	Dogs
Cryptosporidium felis	Cats
Cryptosporidium suis	Pigs
Cryptosporidium muris	Mice
Cryptosporidium baileyi	Chickens
Cryptosporidium andersoni	Cattle

countries. The higher prevalence in developing countries is likely due to a lack of clean water and poor sanitation, crowded housing conditions, and closer contact with domestic animals. Those people at greatest risk of infection include young children, people in contact with young animals or children, international travelers, recreational water users, and consumers of poor quality drinking water. *Cryptosporidium* oocysts are found in the stools of 10–20% of patients with acquired immunodeficiency syndrome (AIDS)-associated diarrhea, and chronic intestinal cryptosporidiosis is currently listed as an AIDS-defining disease.

Cryptosporidium are intracellular parasites, which generally inhabit epithelial cells of the small intestine but have been detected throughout the gastrointestinal tract, and even in the respiratory tract. These parasites undergo asexual multiplication, followed by sexual stages leading to fertilization and formation of oocysts, which are then shed with the feces of the host and transmit the parasite through direct contact with feces, or through contaminated water or food. An important distinction to be made between *Cryptosporidium* spp. and bacterial pathogens is that the former does not grow outside the host, so no multiplication will take place, for example, in water or on contaminated fruits regardless of the environmental conditions. Mature oocysts of *C. parvum* are round, thick-walled structures approximately 4–5 μm in diameter and contain four sporozoites. They are environmentally resistant and can survive for many weeks under cool and moist conditions. The oocysts of most other species are morphologically indistinguishable from *C. parvum*, with some exceptions such as *Cryptosporidium muris* and *Cryptosporidium andersoni* which are somewhat larger.

Transmission of Cryptosporidiosis

The transmission of cryptosporidiosis is facilitated by the ability of oocysts to survive for weeks to months in the environment. Routes of transmission include waterborne, person-to-person (i.e., the fecal–oral route), zoonotic, and foodborne. Although there is considerable overlap amongst these routes of transmission, water is numerically the most important mode of transmission. Numerous waterborne outbreaks of cryptosporidiosis have occurred worldwide as a result of oocyst contamination of drinking water sources. For example, the largest waterborne outbreak of any kind in the US occurred in the spring of 1993 when an estimated 403 000 people became ill with cryptosporidiosis in Milwaukee, Wisconsin. Recent surveys worldwide have indicated that low levels of *Cryptosporidium* oocysts are relatively common in raw and treated water. Fecal material from domestic animals has the potential to contaminate surface water through run-off, and may lead to infections in other animals and in humans. This source of oocysts is, in fact, generally thought to be responsible for the majority of waterborne outbreaks. The mishandling of sewage may, however, represent another important source. In addition to drinking water, numerous outbreaks worldwide have been associated with recreational water, including swimming pools, splash pads, and aquatic parks.

Direct person-to-person transmission may occur following the ingestion of oocysts in fecal matter, and is associated with poor hygiene (e.g., children in daycare, institutionalized patients), sexual practices, and caring for an infected person. Autoinfection may also occur when the so-called thin-walled oocysts are released into the gut lumen. These oocysts are responsible for chronic and life-threatening disease in immunocompromised individuals.

In the case of zoonotic species of *Cryptosporidium*, such as *C. parvum*, calves, rodents, puppies, kittens, and many other animals serve as important reservoir hosts in zoonotic transmission. Although many such infected animals are asymptomatic, *Cryptosporidium* can cause clinical disease and death in young animals. Young farm animals are very commonly infected with *C. parvum*. For example, a number of studies have reported a 100% cumulative prevalence in herds of young cattle. Given the extremely large number of oocysts excreted by an animal in a single day, veterinary personnel, cattle farmers, and other animal handlers, including petting zoo visitors, are at an increased risk of infection. There are also serious implications with respect to contamination of surface water through agricultural runoff.

Foodborne transmission of cryptosporidiosis is thought to be much less common than waterborne or person-to-person transmission. For example, approximately 8% of domestically acquired cases of cryptosporidiosis in the US are foodborne. Nevertheless, a number of foodborne outbreaks have also been reported worldwide. Contamination of food or equipment during harvest, packaging, transport, or food preparation may occur directly from the hands of food handlers who are infected, or have family members that are infected, and is associated with poor personal hygiene, namely insufficient hand washing. The irrigation of crops with contaminated water or the use of contaminated water to mix pesticides or wash produce are other possible sources. Contamination of produce by livestock, either through direct access or through the application of manure to crop lands, has also been proposed.

Symptoms, Diagnosis, and Treatment

Fewer than 10 *Cryptosporidium* oocysts may cause infection in healthy adults, although infectivity and virulence may be dependent on the species and genotype. The incubation time has been estimated to be between 2 and 10 days, with 7 days being the most frequently reported period. Cryptosporidiosis is an enteric disease which is self-limiting in immunocompetent individuals. The disease is characterized by watery diarrhea and a variety of other symptoms including cramping, abdominal pain, weight loss, nausea, vomiting, fever, and headache. More than 90% of acute infections present with watery diarrhea, 50% present with nausea, vomiting, and abdominal pain, and 36% present with fever. Symptoms generally last 1–2 weeks in immunocompetent patients; however, oocyst excretion persists for 1–4 weeks after symptoms are resolved. Asymptomatic infections were originally thought to be rare but more recent evidence suggests that they are not uncommon. Cryptosporidiosis is an AIDS-defining illness, and symptoms in some immunocompromised patients become chronic, debilitating, and potentially life threatening.

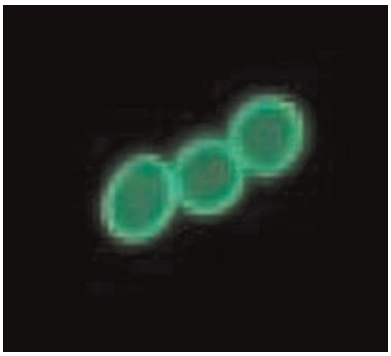

Figure 1 Oocysts of *Cryptosporidium parvum* stained with fluorescein isothiocyanate (FITC)-labeled monoclonal antibodies.

Specifically, patients may experience profuse diarrhea and considerable weight loss.

Detection of *Cryptosporidium* oocysts in stools by microscopy is the principal method of diagnosing cryptosporidiosis. Oocyst shedding may be intermittent, requiring that multiple stools be examined by microscopy. Oocyst concentration methods such as sucrose flotation, or sedimentation in a solution of formalin-ethyl acetate or formalin-ether, can be used when there is low oocyst shedding. Though wet-mounts are often used in clinical laboratories, permanent stains such as acid-fast generally reveal the parasite. Fluorescent stains such as auramine–rhodamine are also commonly used. Fluorescence-labeled monoclonal antibodies specific to epitopes on the oocyst wall are commercially available and, when used with an epifluorescence microscope, generally provide higher sensitivity and specificity than conventional staining methods (Figure 1). Various enzyme immunoassays, including the enzyme-linked immunosorbent assay, are also available commercially but are not commonly used in diagnoses. A number of different polymerase chain reaction (PCR) assays to detect *Cryptosporidium* deoxyribonucleic acid (DNA) in fecal samples are currently available, and offer a very high level of sensitivity and specificity. PCR in conjunction with DNA sequencing and/or restriction fragment length polymorphism can also be used to identify *Cryptosporidium* species, genotypes, and subtypes. PCR is generally used in research settings, however, and is not widely used in diagnoses.

As infections are generally self-limiting in immunocompetent individuals, specific therapy is not always necessary in these patients. However, due to the severity of symptoms in immunocompromised patients, effective treatment is extremely desirable. Unfortunately, drug treatment has been largely unsuccessful against cryptosporidiosis. Therapy development has been hampered by the lack of good culturing systems and small animal models that mimic human disease. Although many drugs have been evaluated, none have been completely effective. Paromomycin is used in treating amoebiasis and has some activity against *Cryptosporidium*. Spiramycin and azithromycin have both produced favorable results in children on chemotherapy and in AIDS patients. Nitazoxanide is approved in the US for treating diarrhea caused by *Cryptosporidium* in immunocompetent patients. Short of drug therapy, however, fluid balance and nutritional status should be monitored, and treatment with antidiarrheal agents is often attempted. The advent of highly active antiretroviral therapy in human immunodeficiency virus (HIV)/AIDS has decreased the occurrence of life-threatening diarrhea in these patients.

Prevention of infection is very important, particularly for immunocompromised individuals. Probably the most important measure in preventing infection and transmission is frequent and effective hand washing, especially after using the toilet or changing diapers, before eating, when caring for an ill individual, or following contact with young animals. Food handlers should also take special precautions, including frequent hand washing, thorough washing of fresh produce, avoiding cross-contamination, and avoiding any handling of foods during, and immediately following, diarrheal episodes. Other important preventative measures include drinking only properly treated water, avoiding public swimming during, and for two weeks after, experiencing diarrhea, and heeding all public health recommendations regarding travel in developing countries.

Surveillance in Foods

Although foods are not as important in the transmission of cryptosporidiosis as water or person-to-person contact in terms of the numbers of cases or outbreaks reported, numerous surveys performed worldwide have reported the presence of *Cryptosporidium* on fresh produce. One study in Costa Rica reported the presence of *Cryptosporidium* oocysts on cilantro leaves and roots, and on lettuce obtained from open markets, with lower contamination rates found on radishes, tomatoes, cucumbers, and carrots. A second study in Costa Rica reported oocysts on lettuce, parsley, cilantro, and blackberries. A study on a variety of vegetables obtained from markets in Peru reported the presence of *C. parvum* oocysts on a variety of leafy greens and herbs. In Norway, oocyst contamination was found on imported lettuce and mung bean sprouts. In Poland, leeks, celery, and a variety of cabbages were found to be contaminated. Oocysts have also been detected in water spinach in Cambodia, and on lettuce and cabbage in Spain. Studies in Canada reported the presence of *C. parvum* on spinach, as well as on washed apples and in unpasteurized apple cider. A recent Canadian study found a relatively high prevalence of *C. parvum* on a variety of packaged leafy greens, both domestic and imported, purchased at retail.

A number of studies worldwide have reported on the presence and survival of *Cryptosporidium* oocysts in the gills and tissues of oysters and other molluscan shellfish, including clams, cockles, and mussels, and the potential for transmission to humans through consumption. The presence of oocysts in marine environments is thought to result from the routine dumping of raw sewage and/or agricultural run-off, and filter-feeding shellfish have been shown to readily take them up. Although there have been no reports of human cryptosporidiosis associated with the consumption of shellfish, this is a concern given that shellfish are often consumed raw.

There are numerous hurdles faced in making an association between the consumption of a suspected food and human illness due to a parasitic infection. These include the

relatively long incubation period of the parasite, the difficulty in diagnosing and reporting human cases, and the short shelf-life of some foods. Even when foods are available for testing, there are no standard methods available, and published methods often have low and variable recovery efficiencies. Furthermore, the concentration of oocysts on foods is generally low and, due to the porous and irregular surface of some fruits and vegetables, they are often difficult to remove from foods. As enrichment steps are not possible for protozoan parasites, the success of the recovery is largely dependent on optimization of elution and concentration procedures.

The elution and concentration of protozoan parasites from foods generally involves agitation of a food sample in a buffer with detergent, followed by centrifugation. Other methods for eluting and concentrating oocysts from foods include sieving, sedimentation, flocculation, formal ethyl acetate, filtration, and immunomagnetic separation. Once oocysts are eluted, a variety of microscopical methods (e.g., bright-field, permanent stains, phase-contrast, differential interference contrast, and fluorescence) can be used for their detection on foods. Molecular methods developed for clinical diagnoses have been useful in detecting the presence of DNA from *Cryptosporidium* on foods, as well as in genotyping and subtyping for the purpose of source-tracking.

Foodborne Outbreaks

A number of foodborne outbreaks of cryptosporidiosis associated with the consumption of fresh produce have been reported in the US. One such outbreak occurred in Washington state in 1997 following a catered dinner, and some epidemiological association was made with the consumption of foods containing uncooked green onions. In another outbreak in 1998, a large number of cases were associated with eating at a university cafeteria in Washington, DC. Although no specific food item was implicated in this outbreak, an ill food handler with laboratory-confirmed cryptosporidiosis prepared the raw produce used in meals served during the expected exposure period. This outbreak illustrates the need for good hygienic practices by food handlers, and a restriction from working during periods of diarrheal illness. More recently, an outbreak at a summer camp in North Carolina, USA in 2009 was associated with sandwich-bar ingredients, including ham and lettuce, and possibly tomatoes and onions.

Fresh produce has also been implicated in a number of recent cryptosporidiosis outbreaks reported in Northern Europe. An outbreak in Sweden following a wedding reception resulted in gastroenteritis in both guests and restaurant employees. Fresh parsley was determined to be the most likely source of these illnesses. Another outbreak was associated with the consumption of peeled whole carrots, grated carrots, or red peppers at a company cafeteria in Denmark. Again, the vegetables in this case were thought to have been contaminated by an infected food handler. A large outbreak in Finland was thought to have been associated with the consumption of contaminated lettuce mixture.

There have also been at least four cryptosporidiosis outbreaks associated with drinking unpasteurized apple cider, all in the US. The first such outbreak occurred in 1993 in Maine and involved students and staff attending a school agricultural fair at which fresh-pressed apple cider was consumed. *Cryptosporidium* oocysts were detected in leftover cider and on swabs from the cider press. Apples used in the cider were likely contaminated after falling to the ground near the edge of a pasture on a farm on which an infected calf was identified. In 1996, an outbreak in New York state was associated with drinking commercially produced, unpasteurized apple cider. The apples used in the cider may have been contaminated following washing with fecally contaminated well water. A third outbreak associated with apple cider in 2003 was associated with the consumption of ozonated apple cider in Ohio. In 2004, a fourth outbreak of cryptosporidiosis associated with unpasteurized apple cider was reported in New York. It was not clear, however, how many of the illnesses in this outbreak could be attributed to *Cryptosporidium* and how many to the bacterium, *Escherichia coli* O111, both of which were detected in the cider and in clinical and environmental samples. It is important to note that *Cryptosporidium* oocysts are acid tolerant and are able to survive in apple cider for up to 4 weeks.

Unpasteurized milk has also been associated with outbreaks of cryptosporidiosis in Australia and the UK, as well as in a group of Canadians traveling in Mexico. In the outbreak in the UK in 1995, cases were linked to drinking school milk which was thought to have been inadequately pasteurized. An outbreak associated with a processed food occurred following a social event in Minnesota, US in 1995. This outbreak was associated with the consumption of chicken salad that may have been contaminated by a food worker, who also operated a daycare facility.

Control Measures

Cryptosporidium oocysts are relatively temperature resistant and, as a result, oocysts on fresh produce or in water may remain infectious for considerable periods of time even under extreme environmental temperatures. For example, oocysts can survive for 2 weeks at temperatures as high as 30 °C, and for short periods of time in water which has been frozen at temperatures down to −20 °C. *Cryptosporidium* oocysts will only be rapidly inactivated following exposure to temperatures above approximately 50–60 °C or below −20 °C.

Dessication is another important factor limiting the survival time of protozoan parasites in the environment. Studies have reported very low viability rates of *C. parvum* oocysts after only 2 h of air drying on glass slides at room temperature, or after 4 h of air drying at room temperature on stainless steel surfaces. Although there is little supporting data, dessication may be responsible for significant inactivation of oocysts on fresh produce in the field or during storage, and on surfaces and equipment. However, some fruits and vegetables, such as berries, have moist, irregular surfaces and will likely protect any contaminating oocysts from drying out.

Control measures to reduce the likelihood of contamination of produce at the preharvest stage with *Cryptosporidium* include the use of good quality water for irrigation, mixing of pesticides, or washing and processing, restricting access of livestock and other animals to crop lands and surface waters, monitoring the health of farm workers and encouraging good hygiene, and

using only composted manure as fertilizer. Postharvest control measures include the use of good quality water for washing and processing produce, monitoring and enforcing good personal hygiene in food handlers, prevention of cross-contamination, and the incorporation of Hazard Analysis Critical Control Point plans. *Cryptosporidium* is generally very resistant to most chemical disinfectants. For example, oocysts are much more resistant than bacteria to chlorine, which largely accounts for the importance of the waterborne route of transmission of this pathogen. However, a variety of physical disinfection procedures may be used postharvest. These include high hydrostatic pressure, which has been found to be effective in inactivating *Cryptosporidium* oocysts in fruit juices, and irradiation, which is effective in killing *Cryptosporidium* oocysts on fresh produce. *Cryptosporidium* oocysts in milk, juice, and water are also readily destroyed through pasteurization treatment. At the consumer level, thorough washing of fresh produce is recommended but will not likely be fully effective in removing all contaminating oocysts. Although oocysts are somewhat resistant to freezing, they can be inactivated at −20 °C for more than 24 h or at −15 °C for approximately a week. Alternatively, oocysts will be readily destroyed in foods that are subsequently cooked or baked.

Cyclospora cayetanensis

VA Cama, Centers for Disease Control and Prevention, Atlanta, GA, USA
YR Ortega, University of Georgia, Griffin, GA, USA

Glossary

Anthroponotic A disease that has humans as its source of transmission, and human to human transmission is typical (related to anthroponoses).
Oocyst Cyst that contains zygotes or other immature stages of protozoan parasites.
Sporocyst Cyst that contains reproductive or infectious stages of a protozoan parasite. In the case of *Cyclospora*, two of these structures are observed after the parasite has matured to become infectious; each sporozoite contains two infectious stages called sporozoites.
Sporulation Process by which the immature (freshly excreted *Cyclospora*) further develops into an infectious parasite. A sporulated cyst of *Cyclospora* is characterized by the presence of two sporocysts, each containing two sporozoites.
Unsporulated or nonsporulated cysts Cysts of *Cyclospora* that have not differentiated into the infectious stage. The oocysts of *Cyclospora* are excreted unsporulated by humans.

Background

Historical Information

Cyclospora cayetanensis is an important foodborne gastrointestinal pathogen. It is endemic in several regions of the world, primarily in the developing countries. *Cyclospora* is not endemic in the developed world but has been associated with significant foodborne outbreaks, and in travelers returning from *C. cayetanensis* endemic areas.

Date of Discovery

Cyclospora cayetanensis was fully recognized as a parasite in 1993. It gained significant recognition because of its association with several foodborne outbreaks in the US and other developed countries. The name *C. cayetanensis* dates back to 1992; however, a few other studies previously described organisms that were similar to *Cyclospora*. Perhaps the first report was the 1979 description of a parasite with morphometric and microscopic characteristics of immature (nonsporulated) oocysts. Although the authors considered the observed organism as a possible coccidian, the presence of two sporocysts per sporulated oocysts led them to conclude that it was probably a new species of *Isospora*.

In the following years, other investigators reported similar organisms that autofluoresced when observed under ultraviolet (UV) light. These observations opened the hypothesis that these organisms could be blue-green algae or cyanobacteria, and the term cyanobacterium-like body (CLB) was proposed. The acronym CLB, however, was also used to describe the same organism as a coccidian-like body. Another name also used before *C. cayetanensis* was 'big *Cryptosporidium*.'

Person and Specific Context

Studies from Ortega *et al.* demonstrated that organisms matching the description of CLBs were also found in the fecal specimens from Peruvian patients. In those studies, Ortega demonstrated the coccidian nature of the parasite through sporulation of immature organisms (previously described as CLBs) into a mature oocysts that had two defined sporocysts, and then by excystation showing the presence of two sporozoites per sporocyst. These characteristics allowed the proper identification of this pathogen as a coccidian parasite from the genus *Cyclospora.* Ortega later proposed the species name *C. cayetanensis*. These findings were first presented at the Annual Meeting of the American Society of Tropical Medicine and Hygiene in November 1992 and later published.

Characteristics

Nomenclature

The sporulation of oocysts, followed by excystation led to the classification of the new parasite as *C. cayetanensis.* The genus name corresponds to sporulated coccidian oocysts, having two sporocysts, each with two sporozoites. The species name '*cayetanensis*' was in honor of Universidad Peruana Cayetano Heredia, the Peruvian University where the preliminary studies were conducted.

Taxonomy and Classification

Domain	Eukaryota
Superphylum	Alveolata
Phylum	Apicomplexa
Class	Coccidia
Order	Eucoccidiorida
Suborder	Eimeriorina
Family	Eimeriidae
Genus	*Cyclospora*
Species	*cayetanensis*

Description of the Organisms

Morphology

The oocysts of *C. cayetanensis* are spherical, 8.6 μm in diameter (range 7.7–9.9 μm) and are not sporulated upon excretion. After sporulation, each oocyst contains two ovoid dizoic (containing two sporozoites) sporocysts that measure 4.0 by 6.3 μm (range 3.3–4.4 by 5.5–7.1 μm).

Hosts

Evidence so far indicates that *C. cayetanensis* only infects humans, and no animal model exists. Unsuccessful attempts to infect multiple animal species included nine strains of mice (adult and neonatal immunocompetent and immune-deficient inbred and outbred strains), rats, sand-rats, chickens, ducks, rabbits, jirds, hamsters, ferrets, pigs, dogs, owl monkeys, and rhesus and cynomolgus monkeys.

There are anecdotal reports of the microscopic detection of *C. cayetanensis* in the feces of ducks, chickens, and dogs, and by detection of deoxyribonucleic acid (DNA) in samples from monkeys, however, none of these reports provided evidence of tissue infections.

Nonhuman primates can be naturally infected with other species of *Cyclospora*. Studies in Kenya found *Cyclospora papionis* in baboons, vervet monkeys were infected with *Cyclospora cercopitheci*, and colobus monkeys with *Cyclospora colobi*. This study used sequence analysis of the small subunit ribosomal ribonucleic acid (rRNA), and the findings suggested that those species of *Cyclospora* had marked host specificity.

Survival in Food and/or Environment

Infections with *C. cayetanensis* have been linked to the consumption of some fruits and vegetables eaten raw. Although it is not yet elucidated how the parasite survives in foods or the environment until it becomes infectious, it appears that specific characteristics or topology of the surface of certain fruits and vegetables favor the life cycle of *Cyclospora*. In laboratory experiments, *Cyclospora* oocysts became sporulated after 2 weeks of incubation at room temperature in liquid suspension. However, it is not clear either how soon sporulation occurs, or how long sporulated oocysts do remain infectious in nature.

Laboratory methods are still being generated toward understanding the parasite biology outside the host, mainly in food products. Parasite recovery methodologies are based on elution from the different food matrices. The recovery rates of *Cyclospora* from seeded lettuce were determined at 13–15%. This method was used in a longitudinal survey of produce purchased in a *Cyclospora*-endemic area and collected more than 200 different samples from 15 different markets at three different seasons of the year. Most of the samples were leafy greens, whereas fruits were primarily strawberries. Among all the samples, three vegetables usually eaten raw had *Cyclospora*: huacatay (black mint, *Tagetes minuta*), yerba buena (*Micromeria douglasi*), and lettuce (*Lactuca sativa*). This study highlighted the presence of *Cyclospora* in vegetables likely to be consumed raw, and the challenges associated with persistence of the parasite in produce frequently eaten raw.

Life Cycle

Cyclospora cayetanensis (*Cyclospora*) is considered a monoxenus parasite, infecting only humans, therefore the term anthroponotic. The developmental stages of *Cyclospora* were described from jejunal biopsies of infected humans. Cyclosporiasis starts after a susceptible person ingests sporulated oocysts, i.e., the infectious stage. After ingestion, oocysts are ruptured in the upper gastrointestinal tract and two sporocysts are liberated. Shortly thereafter, two sporozoites are released from each sporocyst, which proceed to infect epithelial cells of the intestine and form type I meronts. In this stage there is asexual reproduction leading to the generation of 8–12 merozoites. The released merozoites invade other enterocytes to form type II meronts, characterized by the presence of 4 merozoites. Merozoites can invade other cells to form additional meronts, or to differentiate into micro- and macrogametocytes, the sexual stages. Oocysts are formed as a result of sexual reproduction when the macrogametocyte is fertilized by the microgametocyte. These oocysts are not sporulated (noninfectious) and are released into the environment, becoming infectious only after sporulation, which is estimated to occur in approximately 2 weeks (**Figure 1**).

Incubation Time

The oocysts of *Cyclospora* are excreted unsporulated and require time outside the host to fully sporulate and become infectious. Laboratory data using oocysts from infected patients has estimated that it will take 1–2 weeks (reported range 1–23 days) for the oocysts to become fully sporulated, thereby infectious. Once a person ingests the infectious oocysts, the infection of epithelial cells will start shortly after excystation. The gastrointestinal manifestations including diarrhea, fatigue, and abdominal cramps are likely to be observed between 1 and 2 weeks postinfection.

Duration of Infection

The length of infection and severity of clinical manifestations will vary between people living in endemic and nonendemic areas. In endemic settings, the infections usually occur in children, mainly those older than 2 years of age, and infrequently in children older than 10. Most infections may resolve spontaneously, and more than 50% may have an asymptomatic course. As children get older, the episodes tend to become shorter, with a decrease in the severity of associated

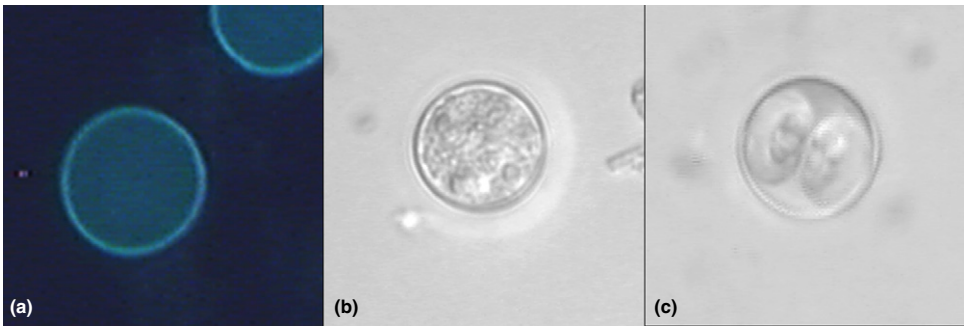

Figure 1 Microscopic observation of oocysts of *Cyclospora cayetanensis*. (a) Autofluorescence under UV light, (b) nonsporulated oocysts observed under differential interference contrast (DIC) microscopy, and (c) sporulated oocysts, containing two defined sporocysts, DIC microscopy.

symptoms. This suggests that immunity may play a role in the clearance of infections. This is not the case in people from nonendemic areas, where confirmed infections usually require antibiotic therapy. Infections usually last 1–2 weeks or longer with intermittent diarrhea if untreated. Longer episodes have anecdotally been reported in immunocompromised patients.

Symptoms

Symptoms vary between unexposed (naïve) and exposed people. Among people not living in the endemic areas, symptoms occur in the vast majority of infected people. The clinical manifestations include: diarrhea, malaise, lack of energy and appetite, mild fever, nausea, flatulence, and abdominal cramps.

Among the residents of endemic areas, clinical infections are primarily detected in children 4–10 years of age. Approximately 40% of infected children may have diarrhea or other gastrointestinal discomforts, including malaise, bloating, and anorexia; however, infections can also be asymptomatic. In these endemic settings, *C. cayetanensis* is infrequently detected in adults.

Jejunal biopsies from infected people have shown altered mucosal architecture with shortening and widening of the intestinal villi due to diffuse edema and infiltration by a mixed inflammatory cell infiltrate. There was reactive hyperemia with vascular dilatation and congestion of villous capillaries. Parasitophorous vacuoles containing sexual and asexual forms, meronts of type I (containing 8–12 merozoites) and II ($n=4$ merozoites) were found at the luminal end of the epithelial cells. These findings demonstrated the complete developmental cycle of the parasite in the jejunum, which may be associated with the host clinical manifestations due to *C. cayetanensis*.

Carrier Duration

It is not known. It is suspected that once the infection has cleared, that person is no longer infectious.

Infectious Dose

It is not known but suspected to be low. *Cryptosporidium*, another coccidia that also causes gastrointestinal illness, requires a minimum of 100–200 oocysts to infect people as demonstrated in human volunteer studies, whereas other investigators propose that only one oocyst is needed to cause illness. The lack of information on *Cyclospora* is in part due to the absence of an animal model to study human cyclosporiasis. Human volunteer studies were unsuccessful in reproducing infections in controlled trials. Laboratory studies have attempted to infect immunocompetent and immunodeficient animals; however, these attempts were unsuccessful and none of the species evaluated developed patent infections or associated clinical symptoms.

Sequelae/Chronic Effects and Complications

Guillain–Barré syndrome and Reiter's syndrome (ocular inflammation, sterile urethritis, and inflammatory oligoarthritis) have been reported in very few cases after infections with *Cyclospora*.

Risks of Misdiagnosis

Cryptosporidium oocysts could be misdiagnosed as *Cyclospora* when stained using the modified gram stain. When using this technique oocysts must be measured as *Cyclospora* oocysts, which measure 10 μm, twice the size of *Cryptosporidium*. Misidentification of *Cryptosporidium* as *Cyclospora* may result in the unnecessary administration of trimethoprim/sulfamethoxazole (TMP/SMX) or ciprofloxacin. Conversely, if *Cyclospora* would be misdiagnosed as *Cryptosporidium*, the error will lead to different therapeutic approaches and patients not receiving TMP/SMX as they should be.

Epidemiology

Statistical Data on Prevalence and/or Incidence of the Disease

Foodborne outbreaks in the US have increased in absolute numbers over the past 30 years. Data analysis from the Foodborne Outbreak Surveillance System revealed 190 outbreaks between 1973 and 1997. During this period, *Cyclospora* and *E. coli* O157:H7 were newly recognized as causes of foodborne illness. In a recent study, it is estimated that more than 11 000 *Cyclospora* illnesses occur in the US.

The transmission of *Cyclospora* through the waterborne route has also been reported. The first report came from

Nepal, where contaminated chlorinated water was identified as the source of *Cyclospora* infections between expatriates in Nepal. A retrospective epidemiological investigation of an outbreak within a hospital in Illinois identified drinking water as the source of infection. A prospective epidemiological study in Haiti identified an artesian well with *Cyclospora* oocysts before the study; however, none of the wells was positive thereafter. Despite reporting important temporal variations in the frequency of *Cyclospora* infections, from 12% in February to 1.1% in April 2001, no epidemiological associations could be established between sources of drinking water and cyclosporiasis. Molecular investigations have reported the detection of parasite DNA in surface waters from California. Overall, these findings indicate that *Cyclospora* may be present in water and that the potential waterborne transmission needs to be further studied.

Currently, *Cyclospora* is primarily considered a foodborne parasite, although before 1996, cyclosporiasis was originally considered to be a diarrheal disease primarily affecting returning travelers. This concept changed in the spring of 1996, when a large foodborne outbreak of cyclosporiasis occurred in North America, affecting 1465 people from 20 states, the District of Columbia, and two provinces. Epidemiological investigations confirmed the vast majority of cases were associated with 55 events that served raspberries. The investigations later demonstrated a significant association between cyclosporiasis and consumption of raspberries imported from Guatemala. Cluster investigations in Florida confirmed that the only food common to this outbreak was raspberries from Guatemala.

Detailed epidemiological descriptions of additional specific events included a wedding reception in Massachusetts and a luncheon in Charleston, SC, USA, where 38 of the 64 attendees met the case definition of cyclosporiasis.

In the spring of 1997, another large outbreak of cyclosporiasis affected the US and Canada. Epidemiological and trace-back investigations identified 41 infection clusters that comprised 762 cases and 250 sporadic cases of cyclosporiasis. Similar to the 1996 outbreak, there were significant associations between *Cyclospora* infections and the consumption of Guatemalan raspberries. As a consequence of this second outbreak, exportation of Guatemalan raspberries was voluntarily suspended in May 1997.

Other fresh produce have also been implicated in the transmission of *Cyclospora*. Basil was directly implicated in a 1999 outbreak in Missouri, where 62 cases were identified. All of these people had previously eaten either pasta chicken salad at one event or tomato basil salad at another event. European countries also have documented cases of foodborne cyclosporiasis. An outbreak in Germany identified that infections were associated with the consumption of fresh salad spiced with fresh herbs, whereas the lettuce was from southern Europe. Snow peas were implicated in an outbreak where 50 potential cases were linked to the consumption of snow peas from Guatemala.

Cyclospora infections had been previously reported in travelers returning from developing countries. Although infections have been reported from multiple countries around the world, the true prevalence of this parasite in any population is frequently unknown. In 1997, *Cyclospora* was reported in 5 of 795 travelers returning from nonindustrialized nations. A study in Nepal reported, that among expatriates living in endemic areas, the annual attack rate for *Cyclospora* was 32% during their first 2 years of residence.

Geographic Distribution

Endemic cyclosporiasis has been reported in several areas of the world, mainly in the developing countries. Although there are socioeconomical and geographical similarities with other related pathogens including *Cryptosporidium*, *Giardia*, and bacterial and viral diseases, there are also marked differences. In general, *Cyclospora* has been reported as affecting children in areas where access to clean water or sanitation is marginal or suboptimal.

Cyclospora infections have been reported in pediatric and adult patients with diarrhea in Tanzania and the sub-Saharan region. In Lagos, Nigeria, the overall prevalence among inpatients with gastrointestinal disease was 0.9%. In Yunnan, China, 4% of preschool children with diarrhea had *Cyclospora*. A prospective study in Peru found that children between the ages of 3–6 years of age were more frequently affected, and infections were rare after 10 years of age. However, cyclosporiasis in upper middle class Peruvians closely resembled the epidemiological and clinical features observed in the industrialized countries. The two study sites in Peru were only a few miles apart; however, the sanitary and socioeconomic infrastructure was markedly different, suggestive of the role of sanitation in the epidemiology of *Cyclospora*.

Age and Locations

Endemic cyclosporiasis has been spottily reported around the world, and more frequently in young people. The first reports suggested that *Cyclospora* infections were more commonly found in children especially those under 5 years of age. In a 2-year study of 5836 Peruvian children 2–4 years of age living in endemic settings, infections were detected in 63 (1.1%) participants. *Cyclospora* infections were reported in children with diarrhea (2/315) in Brazil and 6.1% of people living in impoverished areas in Venezuela. An epidemiological study among Guatemalan children reported significant differences in age susceptibility and gastrointestinal symptomatology. *Cyclospora* was detected in 117 (2.1%) of 5520 specimens, mainly in children 5 years of age. When compared to cryptosporidiosis, *Cyclospora* infections were more strongly associated with diarrhea than *Cryptosporidium* infections. Seven of 132 otherwise normal Venezuelan children ages 1–12 had *Cyclospora* infections, and the highest frequency was observed in children 2–5 years of age. The presence of *Cyclospora* and its association with diarrheal disease was studied in Nepal (Oct 1999–Aug 2002) and Lao PDR (Feb 2002–Jun 2003). Infections were detected in 128/1397 Nepalese participants, with higher rates among children younger than 10 years. Interestingly, only 1/686 specimens collected from Lao PDR was positive for *Cyclospora*. A survey conducted in 285 adolescents from a middle school in West Java, Indonesia found only one case of *Cyclospora*. These reports show that in nonindustrialized nations young children are more frequently

infected, and that the prevalence of cyclosporiasis is not homogenous between different sites or countries.

Nourishment and HIV Status

A study in Egypt found that 5.6% of malnourished children had cyclosporiasis, versus 2.8% of controls. A survey among malnourished children, people infected with the human immunodeficiency virus (HIV), and farm workers from Guatemala identified *Cyclospora* in 1.5% of participants; however, none was identified in raspberry farm workers.

Cyclospora is not considered as HIV opportunistic agent, with similar incidence rates among immunocompromised and immunocompetent people. Nonetheless, a study from Egypt reported 6% *Cyclospora* infections among patients receiving chemotherapy. Additionally, *Cyclospora* infections were reported in 7 of 71 Venezuelan HIV-infected patients.

Seasonality

Findings from a 3-year longitudinal study (1995–98) in children living in an impoverished area of Peru, showed an incidence rate of 0.20 cases per child year, which was constant among children 1–9 years of age. Infections were more frequent during the warmer months, December to May, showing a defined seasonal pattern. Data from a large three-tier survey in Nepal detected *Cyclospora* oocysts in 632/2123 fecal specimens from three health care facilities. Samples from water and leafy greens were also examined, and oocysts of *Cyclospora* were detected in four occasions. A longitudinal study in several areas of Nepal from April 1995 to November 2000 also identified marked seasonality, with higher infection rates occurring during the summer and rainy seasons of the year.

Reservoir of Pathogen

No reservoirs are known. There are anecdotic reports of *Cyclospora* oocysts in the feces of ducks, dogs, chickens, and monkeys. Two dogs from Sao Paulo, Brazil were reported positive for *Cyclospora*, although a follow-up study of 140 dogs from the same city did not find any infected dogs. These findings, in addition to the unsuccessful attempts to establish experimental infections in multiple laboratory animal models, suggest that only humans are susceptible to infections.

Causes of the Outbreaks/Incidences

The factors more frequently associated with the outbreaks of *Cyclospora* are the consumption of raw vegetables or fruits, primarily raspberries and basil. These were either whole or prepared, such as raspberry filling in desserts, and pesto. Other potential sources of infection are herbs consumed raw, for example, black mint, yerba buena, lettuce, and cilantro. Environmentally associated risks have not been reported.

Analytical Methods

Isolation or Recovery from Fresh Produce Matrices

The protocols for the recovery of oocysts of *Cyclospora* are based on the elution of the parasites by physical removal, and there are protocols for water, and fruits and vegetables. From water, the recovery of parasites is achieved through filtration and concentration as described in the United States Environmental Protection Agency (EPA) Method 1623. After the sample is fully processed, the oocysts of *Cyclospora* will be found in the eluate, where they can be observed either by epifluorescence microscopy or detected by the polymerase chain reaction (PCR)-based molecular assays.

The recovery of oocysts from food matrices presents more challenges due to the apparent adhesion of *Cyclospora* to certain vegetables and the inability to culture this parasite The oocysts can be recovered from vegetables through washes using either water, phosphate buffered saline, and elution buffer (laureth-12, Tris, ethylenediaminetetraacetic acid (EDTA), sodium phosphate, and antifoam A) as described in Method 1623 from the EPA, however, no final standard protocol has been agreed upon. The efficiencies of the recovery of *Cyclospora* will vary not only by the method used but also by the vegetable matrix tested. Shields reported that the use of 0.1% Alconox, a common laboratory soap (33–43% sodium carbonate, 10–20% sodium alkylbenzene sulfonate, 5–15% sodium tripolyphosphate, 5–15% tetrasodium pyrophosphate, 1–10% sodium carbonate, and 1–5% sodium alcohol sulfate) yielded higher recovery rates (70–80%) when compared to washes and elution with deionized water. The Bacteriological Analytical Manual from the Food Drug Administration (FDA) also has a method to isolate *Cyclospora* from fresh produce. Briefly, samples of 10–25 g are placed in filter bags with 100 ml of distilled water, and are mixed by rocking for 30 min at room temperature. The washed material is transferred to conical tubes and centrifuged at 2000*g* for 20 min. After the supernantant is discarded, the remaining pellet is resuspended in 2.5 ml of 20% celite in sodium chloride EDTA tris–bovine serum albumin (NET–BSA) buffer (0.1 M Tris, pH 8.0, 0.15 M NaCl, 0.001 M EDTA, 1% weight/volume bovine serum albumin), followed by mixing for 15 min. Then, 1 ml of 10% polyvinyl polypyrrolidone is added to the resuspended pellet, mixed again, and then filtered through a 0.45–0.2 μm membrane. The resulting sample can be split for microscopic examination (approximately 10%) and the remainder can be used for filtration on Flint Technology Associates (FTA) membranes for PCR detection. Among vegetables and fruits, special consideration needs to be placed on berry preparations, as they need to be processed as soon as possible. Other leafy vegetables such as lettuce can be stored and examined after overnight storage. Regardless of the elution method used, the concentrated washes are examined either by microscopy, or DNA extraction followed by PCR amplification.

Identification

The identification of *Cyclospora* can be done by microscopic observation of oocysts in fecal samples of infected people, water samples, or from the eluates from contaminated produce. The oocysts can be observed using phase contrast, bright field, or differential interference contrast (DIC) microscopy. Autofluorescence, a diagnostic feature of *Cyclospora*, can be observed using epifluorescent microscopy, using excitation

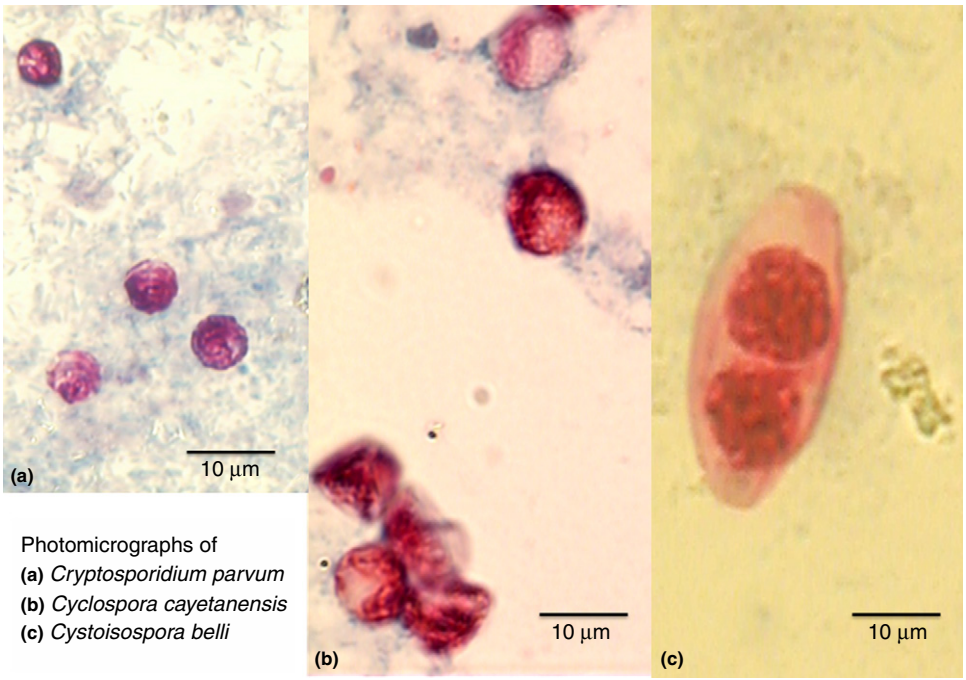

Figure 2 Acid fast staining of coccidian parasites with foodborne potential. (a) *Cryptosporidium parvum*, (b) *Cyclospora cayetanensis* – note the characteristic uneven staining, and (c) *Cystoisospora belli.*

filters of 360/40 nm, long pass dichroic mirrors of 400 nm, and emission filters of 420 nm (Figure 1a). Kinyoun, Ziehl Nielsen, or carbolfucsin-modified acid fast stains can be used to visualize the oocysts; keeping in mind the characteristic uneven staining of *Cyclospora* oocysts (Figure 2b). Safranin stains are also available and it was previously reported that most oocysts will uptake this stain showing a bright pink color.

Microscopic methods are not always the best for examining the environmental or produce samples. Oocysts could either be in small numbers, their morphology might have been affected during the handling and processing of the samples, or many other food or environmental structures may look alike and even autofluoresce. In these cases, PCR-based methods can be very useful for the identification of *Cyclospora*.

A PCR assay amplifying the 18S rRNA gene was developed for the detection of *Cyclospora* in clinical specimens. This PCR method is very sensitive, however not specific when used to test environmental or food samples. The digestion of the amplified products with the restriction enzyme *Mnl* I allowed the discrimination between *Cyclospora* and *Eimeria* from animal species. Other molecular PCR-based assays include oligonucleotide-ligation assays as well a real-time PCR amplification of the ITS1 locus. The detection limits of the PCR-based assays could be optimized by improvements in the yields of DNA extraction as well as the avoidance of PCR inhibitors. An alternative for sample collection and PCR amplification was the use of FTA filter membranes, where the eluates or test solutions are filtered through the FTA, which is then used directly for PCR amplification.

Control and Preventive Measures

Primary Sources (Prevention of Contamination in Food), or Underlying Factors (i.e., Prevention of Contamination in Environment, Water Treatment)

The transmission of *Cyclospora* is associated with the consumption of contaminated foods. In areas of known endemnicity, infections can be reduced by avoiding the consumption of raw fresh produce and drinking purified or boiled water, as *Cyclospora* is highly resistant to chlorination. Thus, chlorination alone should not be considered as a safe water treatment. Preventative measures at the farm level, should be based on the establishment of good agricultural practices, with an emphasis on the use of clean potable water for spraying the crops.

The current methods to evaluate the efficacy of any control and preventative measures against contamination with *Cyclospora* are based either on data from oocyst sporulation/excystation, or results from surrogate coccidian parasites. These limitations are the result of the lack of infectivity assays, either animal or culture models.

Any disinfection or sanitation method has to also be compatible with the organoleptic characteristics of the food products. Thus far chemical methods have not proven very effective. Short-time exposure to commercial bleach (5% sodium hypochlorite) has been used to purify and clean viable *Cyclospora* oocyts for laboratory experiments, therefore, commercial bleach does not appear to inactivate the parasite. Exposure to chlorine dioxide, at a concentration of 4.1 mgl^{-1} for 20 min was not effective in reducing the sporulation of *Cyclospora*, although it was highly effective at inactivating

Cryptosporidium parvum, another important coccidian parasite of humans and mammals.

Physical methods rely on timed temperature exposures. Freezing at −15 °C for 24 h or −20 °C for 48 h did not interfere with the sporulation of *Cyclospora*. Exposure to temperatures close to refrigeration or ambient temperature such as 4 and 23 °C for periods of at least 7 days had no effect on sporulation. Exposure to warmer temperatures of 37 °C for up to 4 days, or 50 °C for 1 h resulted in the reduction of the sporulation rates, however, minimal parasite sporulation was still detected.

Extreme temperatures were more effective against the viability of *Cyclospora*. Exposures to temperatures of −70 °C for at least 60 min, 70 °C for at least 15 min, or parasite exposure to 100 °C were effective in preventing sporulation. Microwave-induced heating also can inactivate *Cyclospora* oocysts, occurring when the internal temperature of the product reaches ≥80 °C.

The lack of an animal model or *in vitro* system to determine the viability of the parasites has also led to the use of other coccidians like *Eimeria* and *Toxoplasma* as surrogate parasites. The evaluation of γ-ray irradiation showed that exposures of 0.5 kGy were effective against *Toxoplasma* oocysts, whereas 1 kGy was needed to inactivate the oocysts of *Eimeria acervulina*. High hydrostatic pressure and exposure to UV light have also been tested. The rationale for the hydrostatic pressure was that it would release the labile sporozoites from the environmentally resistant oocyst and sporocyst walls, whereas the exposure to UV light intended to interfere with biological processes within the parasites. Pressures of 550 MPa, applied at 40 °C for 2 min, or UV exposure at 261 mW cm^{-2}, led to an effective reduction of the infectious potential of both *Toxoplasma* and *Eimeria*. However, data from *in vivo* assays using animal infectivity studies demonstrated that these methods did not completely inactivate *Eimeria*, and only reduced its infectious potential. The use of a lower pressure of 340 MPa, applied for only 60 s was shown to be equally effective.

Measures at Different Levels of the Food Chain

At the farm level, water quality is of extreme importance. Although ozone and UV radiation have proven effective to kill *Cryptosporidium* oocysts, it is suspected that *Cyclospora* is resistant to these inactivation strategies. This in part is due to the autofluorescence of *Cyclospora* oocysts, suggesting that the

UV light may be reflected from the oocysts and only lower doses may actually penetrate the oocysts.

The simplest measures are based on the detection of markers of contamination with human fecal material. which should not be present in the agricultural soils or water, and emphasizing that good sanitation practices within the farms are crucial to prevent the contamination of crops. From the farm perspective, the facilities should consider adequate bathrooms, with potable water and soap. Among farming practices, workers should avoid the use of the same tools for soil operations and harvesting, primarily to minimize potential cross-contamination by farm tools.

Regulatory or Education Measures

Farm workers should be aware that good hygiene will prevent fecal contaminants from being introduced into the food products. There are no specific regulations specifically addressing *Cyclospora* in foods. However, in the USA, the Global Food Safety Initiative (GFSI) and the Food Safety Modernization Act (FSMA) are two recent efforts aimed to assure the overall quality and safety of food products. GFSI is a private initiative that is focused on providing technical assistance and support to less developed businesses in the development of food management systems. They use a step-wise approach that begins with a self-assessment of practices by the producer, which leads into passing to a higher level of technical requirements and assessment. The overall goal is that the producers will eventually reach accreditation against recognized international standards.

The FSMA came into law in the USA as a response of the public health burden presented by foodborne diseases. A significant difference is that this law is focused on preventing contamination of the food products. The law provides the USFDA the authority to regulate practices starting at the farm level, all the way to postharvest processing. This law will cover products that could be contaminated with *Cyclospora*.

Additional measures to prevent contamination of food products come from the guide on good agricultural practices and manufacturing practices for fruits and vegetables These documents provide recommendations to growers, packers, transporters, and distributors that are aimed to minimize the risk of foodborne diseases. It includes guidance on the basic principles for the proper use of water and organic fertilizers, employee hygiene, sanitation of the fields and processing facilities, as well as transportation (**Table 1**).

Monitoring

No routine monitoring procedures are in place.

Entamoeba histolytica

GL Nichols, European Centre for Disease Prevention and Control, Stockholm, Sweden; University of East Anglia, Norwich, Norwich UK, and University of Thessaly, Thessaly, Greece

Glossary

Amebiasis An infection with *Entamoeba histolytica* with or without clinical manifestations. Its use is usually restricted to this pathogen although some references to other parasitic amebae have used this term.

Dysentery An inflammatory infection of the intestine, particularly the colon, with severe diarrhea containing mucus and/or blood. *Shigella* dysentery usually has more pus in the feces whereas amebic dysentery contains more blood. Historically, dysentery was called flux or bloody flux.

Historical Evidence

The history of *Entamoeba histolytica* has been reviewed. Feder Losch (1875) found amebae in fecal samples in Saint Petersburg, but it was Fritz Schaudinn (1903) who first established the differentiation between *E. histolytica* and *Escherichia. coli* and decided on the species name *E. histolytica* as the parasite was seen to cause tissue lysis. Emile Brumpt (1925) established that *E. histolytica* contained two morphologically indistinguishable species, *E. dysenteriae* in symptomatic infection, and *Entamoeba dispar* in asymptomatic carriers but description of the former came after the description of *E. histolytica* and was therefore not accepted. During the 1960s, axenic culture medium for *E. histolytica* was developed which allowed *in vivo* and *in vitro* studies and in the 1970s isoenzyme electrophoresis was used to separate *E. histolytica* virulent and avirulent strains. William Petri *et al.* (1987) demonstrated that the 170 kDa protein with greater antigenicity was the Gal/GalNac-specific lectin. Diamond and Clark (1993) described again Brumpt's original 1925 hypothesis, concluding that there was enough evidence to support the existence of two morphologically indistinguishable species, a pathogenic and a nonpathogenic one, corresponding to *E. histolytica* and *E. dispar,* respectively. The World Health Organization (WHO) accepted this hypothesis in 1997. Other nonpathogenic *Entamoeba* species are known to occur in humans, including *Entamoeba hartmanii*, *E. coli*, *Entamoeba gingivalis*, *Entamoeba chattoni*, and *Entamoeba moshkovskii*. *Entamoeba moshkovskii* has been considered a potential pathogen in Australia but the evidence is limited. *Entamoeba histolytica*-like organisms from monkeys are genetically distinct from human strains.

Definitions

Entamoeba histolytica and *E. dispar* are anaerobic parasitic protozoa which have trophozoites with a single nucleus. They form cysts (10–16 μm diameter) with a single nucleus when immature, which differentiate into four nuclei when mature. The cysts contain glycogen in a vacuole and usually have chromatoid bodies. The nucleus is vesicular, spherical, and its membrane is lined with small chromatin granules and a small central spherical karysome. Because *E. histolytica* and *E. dispar* cysts are morphologically indistinguishable using light microscopy they are reported as *E. histolytica/dispar*. Trophozoites with ingested red blood cells in fresh stool or other specimens, and trophozoites in tissue biopsies are both strongly correlated with amebic dysentery caused by *E. histolytica*. *Entamoeba histolytica* and *E. dispar* cysts are differentiated using polymerase chain reaction (PCR) protocols that differentiate them.

Cultural Characteristics

Culture of *E. histolytica* has proved useful in the investigation of virulence factors but is unhelpful as a diagnostic procedure. Media used in maintaining trophozoite viability include Roswell Memorial Park Institute (RPMI-1640), Dulbecco's Modified Eagle Medium, phosphate-buffered saline for ameba, and Hank's balanced salt solution.

Entamoeba dispar can outgrow *E. histolytica* in axenic cultures.

Typing

Typing pathogenic amebae has been useful in establishing the species *E. histolytica* and *E. dispar,* but subtyping has had less utility than, for example, *Cryptosporidium*. The differentiation of pathogenic and nonpathogenic amebae in the 1970s was conducted using isoelectric enzyme focusing of the enzymes glucose phosphate isomerase, phosphoglucomutase, and L-malate: NADP + oxidoreductase (oxalacetate-decarboxylating) (ME) (5;10;11). PCR analysis of the

chitinase genes has been used to examine the differences in the isolates of *E. histolytica*, and a microarray system has potential for typing *E. histolytica*. A tandem repeat PCR method was used to differentiate *E. histolytica* and *E. dispar*.

Virulence Factors

Entamoeba histolytica causes amebic colitis through disruption of the mucus layer, followed by binding to and destruction of the epithelial cells. It is unclear why only some infections with *E. histolytica* result in the disease. A study of human colon invasion found that *E. histolytica* infection removed the protective mucus coat during the first 2 h of incubation, detached the enterocytes, and then penetrated into the lamina propria by following the crypts of Lieberkuhn. Cell lysis and inflammation result in the secretion of proinflammatory molecules such as interleukin 1 beta, interferon gamma, interleukin 6, interleukin 8, and tumor necrosis factor (TNF) within 4 h of incubation. TNF-alpha protein is expressed in people infected with *E. histolytica* infection. The virulence of pathogenic *E. histolytica* has been attributed to the capacity of the parasite to destroy tissues through the expression and/or secretion of various molecules, but animal models of the disease suggest the host's inflammatory response is primarily responsible for tissue damage. Host–parasite interactions mainly involve anchored glycoconjugates localized in the surface of the parasitic cell. The damage observed in invasive amebiasis is thought to be linked to interactions between polymorphonuclear leukocytes (neutrophils and lymphocytes) and *E. histolytica* trophozoites. *Entamoeba histolytica* has an effect on the intestinal epithelial cells, causing DNA degradation, mitochondrial dysfunction, and apoptosis. Several essential biochemical processes are situated in mitochondria and in *E. histolytica*, its anaerobic and parasitic lifestyle has led to the evolution of tiny mitochondria known as mitosomes, which are one of the simplest known mitochondrial compartments of all eukaryotes. In liver abscesses there is destruction of liver cells as a result of a strong inflammatory response. The monocyte locomotion inhibitory factor, a heat stable oligopeptide found in the supernatant fluid of *E. histolytica* axenic cultures, may contribute to the delayed inflammation observed in amebic hepatic abscess. Three virulence factors (Gal-lectin, cysteine proteinases, and amebapores) were thought to be the main proteins involved in pathogenesis, but other molecules such as lipophosphopeptidoglycan, peroxiredoxins, arginase, and lysine and glutamic acid-rich proteins are also implicated. *Entamoeba histolytica* possesses an array of protein kinases.

Virulent and avirulent strains from the same culture collection have been examined to investigate the determinants of virulence and differential gene expression has been examined using outputs from the *E. histolytica* genome. In chronic amebiasis, the host immune response is not able to eliminate the parasites. The parasite stimulates active immunosuppression of the host.

Entamoeba histolytica exhibits an abundant population of small RNAs with an unusual 5-polyphosphate structure that may play a role in gene silencing. *Entamoeba histolytica* possesses a higher level of NADP-dependent alcohol dehydrogenase activity than *E. dispar*, but it is difficult to directly link these raised levels to virulence. Iron chelation interrupts the completion of the fermentative pathway of *E. histolytica* by removing the metal cofactor indispensable for the structural and functional stability of alcohol dehydrogenase 2, thus affecting trophozoite survival. Virulent *E. histolytica* has a greater ability to reduce O_2 and H_2O_2 than avirulent isolates. Hydrogen peroxide induces an apoptosis-like programed cell death. The susceptibility of people to *E. histolytica* seems to be linked to leptin (an adipocytokine) signaling in enterocytes.

Gal/GalNAc Lectin

URE3-BP is important in the regulation of two amebic virulence genes, the Gal/GalNAc lectin and ferredoxin. N-glycoconjugates with terminal alpha (1–3) linked mannose residues participate in the adhesion and subsequent cytotoxicity of *E. histolytica* to cultured hamster hepatocytes. These include the Gal/GalNAc lectin.

Cysteine Proteinases

Entamoeba histolytica contains at least 50 cysteine proteases; however, only three *Entamoeba histolytica* cysteine proteinases (EhCPs) (EhCP1, EhCP2, and EhCP5) are responsible for approximately 90% of the cysteine protease activity in this parasite. EhCPs contribute to the disruption of the epithelial cell during invasion of the colon. The degree of virulence of *E. histolytica* isolates, as determined in hamster liver, has been linked to different levels of CP5 mRNA in trophozoites freshly isolated from hepatic amebic lesions and suggest cysteine protease activity is involved in pathogenesis and the digestion of erythrocytes. *Entamoeba histolytica* infection and protease activity can cause selective damage to enteric neurons.

Amebapores

Amebapores are proteins that form oligomeric pores in target cell membranes that are present in the cytosol of the parasite within cytoplasmic granules. When released they can rapidly puncture the host cells. The expression of amebapores is more important in liver disease than colonic infection.

Iron and Infection

Entamoeba histolytica can grow using free iron, lactoferrin, transferrin, ferritin, hemoglobin, or hem as the sole iron supply and the ferritin is internalized through clathrin vesicles. It has been found that the amebae internalized holotransferrin (holoTf), which transports iron into all cells, through clathrin-coated pits, suggest that holoTf endocytosis could be important for the parasite during colonization and invasion of the intestinal mucosa and liver.

Genetics and Evolution

Some eukaryotic parasites have evidence that horizontal gene transfer (HGT) has played a role in their evolution. A study screening the completed genomes of *E. histolytica* and *Trichomonas vaginalis* found 68 and 153 recent cases of HGT respectively, with the gene enzymes involved in metabolism. These genes were from prokaryotic donors that share similar environmental niches (e.g., gut and vagina). *Entamoeba histolytica* isolates from across Africa are genetically heterogeneous.

Animal Models

Hamsters are a model for the development of amebic liver abscesses. Experimental infection of rhesus monkey's (*Macaca mulatta*) results is a disease that is similar to that seen in humans. Amebiasis in the murine model can be prevented by vaccination with the Gal/GalNAc lectin through a T cell-dependent mechanism. Trophozoites of *E. histolytica* HM-1:IMSS can become less virulent with long-term maintenance in axenic cultures, but cholesterol appears to prevent this.

Detection Methods

Diagnosis has traditionally required observation of trophozoites of *E. histolytica* containing erythrocytes in stool samples, aspirates from intestinal and other organs, biopsy material, or in mucus from rectal ulcers. Enzyme-linked immunosorbent assay tests are available for the detection of *Entamoeba* antigen and specific *E. histolytica* lectin antigen in fecal samples. Although the demonstration of active amebae or cysts is the best way to make definitive diagnosis, serology is the method of choice for the diagnosis of amebic liver disease. For microscopic examination, the Eosin-Y staining technique was found to be the easiest to perform, and was as accurate as the commonly used Wheatley trichrome technique for the detection of trophozoites in feces. Samples need to be examined within 6 h of stool collection to obtain good microscopic results.

PCR has been used in the developing countries for parasite detection. Primer pairs have been designed to amplify species-specific products for the differentiation of the species *E. histolytica* and *E. dispar* by PCR, and real-time PCR can be useful in the diagnosis of amebic abscesses. Preparation methods can improve PCR sensitivity.

A commercially available fecal antigen detection test specifically identifies *E. histolytica*. A novel one-step, closed tube, loop-mediated isothermal amplification assay for detecting *E. histolytica* has been reported. A multiplex tandem PCR assay for the detection and identification of four common pathogenic protozoan parasites, *Cryptosporidium* spp., *Dientamoeba fragilis*, *E. histolytica*, and *Giardia intestinalis*, from human clinical samples has been established. Freezing the fecal samples has been shown to give better PCR detection.

Health Effects

Entamoeba histolytica invades the colonic mucosa producing ulcerative lesions and profuse bloody diarrhea (amebic dysentery). Acute amebic colitis has a gradual onset, with a 1–2 week history of mild-to-moderate abdominal pain and tenderness, tenesmus (feeling the need to defecate). There are frequent watery diarrheic stools (e.g., five or more episodes per day) usually with abundant mucus and blood, and contain motile amebic trophozoites. During the chronic stages of the infection these symptoms disappear, and only cysts are found in the feces. Most patients experience abdominal pain, whereas some have intermittent diarrhea alternating with constipation. Fever is less unusual, whereas other associated symptoms include weight loss and anorexia.

Feces are almost always positive for occult blood if frank blood is not present. The dysenteric symptoms usually resolve within a few days following appropriate treatment. Severe cases of amebic colitis are characterized by bloody dysenteric stools, diffuse abdominal pain, high fever, and severe dehydration, and patients usually appear quite ill. Other presentations of acute intestinal amebiasis include extensive fulminant necrotizing colitis, toxic megacolon, and perianal ulceration.

Systemic infection can lead to abscess formation, particularly in the liver and lungs. Clinical complications, such as fulminating necrotic colitis and intestinal perforations, are the main cause of death in cases of invasive intestinal amebiasis.

Epidemiology

Entamoeba histolytica occurs worldwide, with natural infections in humans and other primates. Infection is most common in developing countries, where sanitation, water supply, and hygiene are rudimentary. Infection due to *E. histolytica* in endemic areas has been difficult to estimate and dysentery or bloody diarrhea can be misdiagnosed as amebiasis where laboratory diagnosis is unavailable. Human susceptibility to *E. histolytica* appears to be the norm. Although asymptomatic carriage of *E. dispar* can be common, carriage of *E. histolytica* is not uncommon. As a result the mortality rate of infected people is difficult to estimate. However, the WHO suggest that there are over 100 000 amebiasis-related deaths worldwide every year and mortality is probably linked to nutritional status.

In developing countries mixed parasitic infections can be common and can influence postinfection chemokine and cytokine responses. The frequency of invasive intestinal amebiasis is thought to range from 2.2% to 16% of patients with acute amebic dysentery and case fatality from 0.5% in uncomplicated cases to 40% in patients with amebic dysentery complicated by peritonitis (**Figure 1**).

Outbreaks

In the early twentieth century, outbreaks were commonly attributed to food handlers, but an outbreak in three hotels in Chicago in 1933, and a stockyard fire outbreak in 1934 emphasized the importance of waterborne transmission, particularly where there is direct contamination of drinking water with wastewater. A waterborne outbreak on a Royal Air Force base in 1950 was also linked to gross fecal contamination of a drinking water borehole source. Outbreaks of *E. histolytica* can

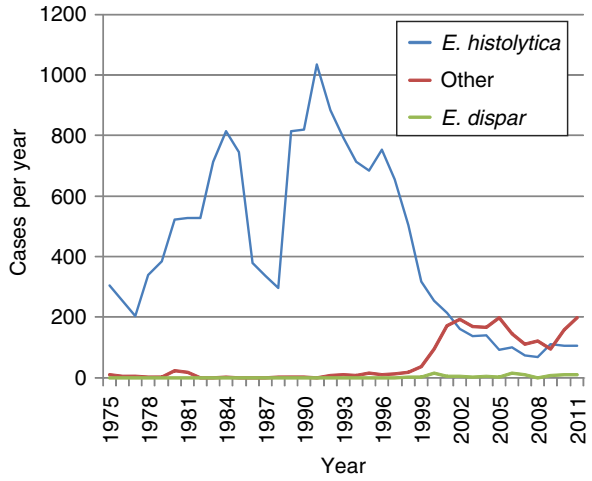

Figure 1 Reported cases of *E. histolytica* and *E. dispar* in England and Wales.

occur in institutions with poor hygiene such as mental homes. A community outbreak in Hecun Town, Jiangshan City, China was thought to be linked to poor personal hygiene. Outbreaks linked to sexual transmission have been reported. Outbreaks of gastroenteritis can involve *E. histolytica*. A review identified nine waterborne outbreaks involving *E. histolytica* and inadequate treatment or breaks in distribution can be important as can the contamination of groundwater with sewage. A waterborne outbreak of gastroenteritis in Taiwan affecting 730 students was due to the contamination of underground well water by sewage. Both *Shigella sonnei* and *E. histolytica* were isolated from the patients. As with other enteric pathogens, family outbreaks can occur. In developing countries outbreaks may be linked to particular farms, even where an obvious transmission route may not be identifiable. Poor hygiene or contaminated water supply were the likely reasons for the outbreaks. Travel is a significant risk factor for sporadic amebiasis, and outbreaks linked to travel have been reported. An outbreak in people returning from Thailand identified consuming ice to be a risk factor. An unusual outbreak of amebiasis associated with a chiropractic clinic and the source of infection was contaminated equipment used for colonic irrigation. The direct contamination of the colon, where the amebae invade, was thought to be important in this outbreak. A review of waterborne outbreaks of protozoan parasites undertaken by Karianis *et al*. in 2007 found nine outbreaks associated with water.

Entamoeba histolytica can contaminate fresh produce, and in developing countries, the unsanitary conditions in markets make transmission likely, with no hand washing facilities and contaminated water sources. Indeed, there is thought to be a close relationship between personal hygiene, sanitary food conditions, and amebic infection. In developed countries, outbreaks are very unlikely unless a water supply becomes grossly contaminated, although infection in travelers returning from the Indian subcontinent is not uncommon. Asymptomatic carriage of the organism appears to be relatively common in certain populations and this has implications for foodborne transmission from food handlers.

An epizootic outbreak of amebiasis affected two mantled guerezas (*Colobus guereza*) and one Hanuman langur (*Semnopithecus entellus*) in an open range recreation park. An outbreak in a colony of spider monkeys has also been reported.

Case–Control Studies

Sexually active men who have sex with men (MSM) were more likely to be seropositive for antibodies to *E. histolytica* than either low-risk MSM or a control group. This is true for developing as well as developed countries.

A case–control study conducted between 2006 and 2009 examined factors associated with the presence of anti*E. histolytica* antibody titers of ≥ 128 by indirect hemagglutination assay, among people seeking voluntary counseling and testing (VCT) for human immunodeficiency virus (HIV) infection. It was shown that 57 out of 4802 persons (1.2%) were seropositive for *E. histolytica* infection compared to 228 seronegative controls. The MSM, fecal–oral contamination, lower educational achievement, and older age were associated with increased risk for amebiasis among persons seeking VCT for HIV infection.

Routes of Transmission

Transmission of *E. histolytica* generally occurs by fecal excretion of cysts followed by oral ingestion of contaminated food or water. However, fecal–oral transmission may occur within households and long-term care institutions, and sexual transmission can occur heterosexually through oral–anal sex and among MSM. Cysts of *Entamoeba* survive well in moist conditions and may be transmitted via contaminated food or water, or direct contact. Waterborne spread appears to occur where there is gross contamination of drinking water with sewage.

Reservoirs and Environmental Occurrence

Amebic trophozoites are only present in the human body and do not play a role in transmission, except for the occasional case associated with organ transplant. As *E. histolytica* is not found in agricultural animals and people do not usually come into close contact with monkeys and apes, the source of infection is exclusively other infected humans. The cysts can survive outside the body for only a few days in feces but can be present in night soil, sewage, and water, and for short periods on foods, on the hands of infected food handlers, or through flies contaminating food. The cysts remain alive outside the body at temperatures just above freezing for periods of up to 3 months. At moderate temperatures they will survive between 9 and 30 days in water. They cannot withstand desiccation or high temperatures. Cysts are killed within 10 min by desiccation on the surface of hands, but survive for longer (45 min) if trapped in fecal material under fingernails.

Infections in Animals

Entamoeba histolytica can be detected in both old world and new world monkeys, including rhesus monkey, silver leafed

monkey, baboon, spider monkey, cynomolgus monkey (*Macaca fascicularis*), macaque, mantled guereza (*C. guereza*), Hanuman langur (*S. entellus*), colobus monkey, Abyssinian colobus monkey, De Brazza's guenon, white-faced saki, and Geoffroy's spider monkey. Some simian isolates can be differentiated from human strains but are still regarded as *E. histolytica*, and others better fit into *Entamoeba nuttalli* or the nonpathogenic *E. chattoni*. The *E. histolytica* like strains are able to cause liver abscesses in monkeys. *Entamoeba histolytica* has also been isolated from gorilla and chimpanzee. Dogs, cats, rodents, and other mammals can be infected but are not thought to contribute to transmission.

Water Treatment

Entamoeba histolytica cysts are larger than *Cryptosporidium* oocysts and are removed from water by slow sand filtration and conventional flocculation, sedimentation, and rapid sand filtration. *Entamoeba histolytica* cysts are relatively resistant to chlorine ($>3\ \mathrm{mg\,l^{-1}}$ for 30 min needed for killing). They are readily removed from water by conventional water treatment process of coagulation, sedimentation, and filtration. Brief boiling or pasteurization is sufficient to eliminate/kill *E. histolytica* cysts, which are sensitive to 60 °C for 1 min. Solar disinfection has been used to kill *E. histolytica*, with temperatures above 56 °C being effective. Cysts of *E. histolytica* can survive for 9 and 30 days in water, but cannot withstand desiccation or high temperatures. Cysts die within 10 min by desiccation on the surface of hands. Although *E. histolytica* is distributed worldwide, infection is not endemic in Europe or generally in the industrialized world and most reported cases are in people returning from abroad or regions of the world with poor sanitary infrastructure. The risk of infection from drinking water is low as *E. histolytica* cysts are unlikely to be present in large numbers in source waters of these regions and multiple barrier treatment including disinfection will provide effective control.

Foodborne Transmission

Although the evidence for foodborne transmission of *E. histolytica* is slim, there is circumstantial evidence that sporadic transmission occurs. Food handlers probably play an important role in sporadic food-related disease in developing countries where carriage is common. The detection of parasite ova and cysts on raw vegetable is much reduced by washing. Hand washing is thought to be protective for people catching *E. histolytica* and other parasites. Disinfectants are more effective at decontaminating foods contaminated with *E. histolytica* compared to *Cryptosporidium parvum*.

Preventive and Control Measures

Entamoeba histolytica can be transmitted by the poor personal hygiene of food handlers, contamination of ready-to-eat foods such as fruits or vegetables, from drinking water, and by insect vectors such as flies.

As with other protozoa, cooking food is an effective control, although contamination from the hands of infected food handlers can still be important. Because restaurants in developed countries commonly employ recent immigrants from developed countries, reducing transmission should focus on pathogen screening of new employees and good kitchen hygiene training. In the developing countries *E. histolytica* cysts can be transmitted through foods such as salads, fruits, or vegetables that have been contaminated from irrigation or wash water, or through handling at market (where toilets and hand washing may not be available), or in food preparation. Water contaminated by human waste is the primary vehicle for infection and treatment should include filtration as well as chlorination. In developing countries, improvements to reduce amebiasis and other fecal–oral pathogens need to focus on waste disposal, improvements in water infrastructure, treatment and household storage, and hygiene education and support in order to reduce the exposure of people to human feces.

Entamoeba

Entamoeba histolytica is an anaerobic parasitic protozoan that affects primates. *Entamoeba histolytica* is estimated to infect approximately 50 million people worldwide although there can be many asymptomatic cases. Symptoms can include fulminating dysentery, bloody diarrhea, weight loss, fatigue, and abdominal pain. The ameba can penetrate the intestinal wall and reach the blood stream and internal body organs, such as the liver, spleen, lungs, and even the heart and brain. There is an approximately 1–3% mortality rate in those with overt symptoms. A closely related species, *E. dispar*, is considered to be nonpathogenic but this species are hard to distinguish morphologically. The cysts are transmitted through consumption of contaminated water or food, such as salads, fruits, or vegetables that have been washed in water containing the cysts; handling objects that have been in contact with contaminated soil or animal feces, and by anal sex. More cases occur in the rainy season than in the dry season. One cyst may be enough to initiate an infection with an incubation period of 2–4 weeks. Although water is the primary vehicle for infection, raw fruits and vegetables may also be contaminated, and normal chlorination treatment for potable water is not effective in destroying the cyst. The most dramatic incident in the USA was the Chicago World's Fair outbreak in 1933 caused by contaminated drinking water. There were 1000 cases and 58 deaths; defective plumbing allowed sewage to contaminate the drinking water. More recently, food workers are suspected of causing a few sporadic infections, but there has been no single large outbreak in industrialized countries

PROTOZOA

Giardia lamblia

RD Adam, University of Arizona College of Medicine, Tucson, AZ, USA

Glossary

Cyst The environmentally stable form of the life cycle for protists with complex life cycles. This form has reduced metabolic activity and does not replicate.

Diplomonad (Literally two bodies) a phylogenetic class of organisms that includes the *Giardia* species as well as other genera of free-living and parasitic species. They are characterized by a body with dyad symmetry and two symmetrically placed nuclei.

Encystation This is a developmental process in which the trophozoite stage is transformed into the cyst stage.

Excystation This is a developmental process in which the cyst stage is transformed into the trophozoite stage.

Ova and parasite A microscopic examination of feces for the detection of eggs and parasites; it is used in the diagnosis of multiple helminthic and protozoan intestinal infections.

String test A diagnostic test for giardiasis (or for several other infections) in which a capsule at the end of a string is swallowed, followed by removal after 4 h to overnight and microscopic examination of the end of the string.

Trophozoite The vegetative form of the life cycle for protists with complex life cycles. This form replicates within the host and causes the disease symptoms.

Ventral disk The ventral surface of the trophozoite which attaches by mechanical means to the intestinal wall of the host, or to other surfaces.

Background

The first description of *Giardia lamblia* (synonym *Giardia duodenalis*, *Giardia intestinalis*) was reported by Leeuwenhoek who gave a classic description in 1681 of what is probably *Giardia*, as he observed his own diarrheal stool under the microscope. His description was translated by Dobell and reads as follows:

> "I have ordinarily of a morning a well-formed stool; but now and then hitherto I have had a looseness…when I went to stool some 2, 3, or 4 times a day…My excrement being so thin, I was at divers times persuaded to examine it…All the particles aforesaid lay in a clear transparent medium, wherein I have sometimes also seen animalcules a-moving very prettily; some of 'em a big bigger, others a bit less, than a blood-globule, but all of one and the same make. Their bodies were somewhat longer than broad, and their belly which was flatlike, furnisht with sundry little paws, wherewith they made such a stir in the clear medium and among the globules, that you might e'en fancy you saw a pissabed (woodlouse) running up against a wall; and albeit they made a quick motion with their paws, yet for all that they made but slow progress."

Later, Lambl independently discovered *Giardia* in 1859 and described it in greater detail, and the organism was subsequently named after him.

Characteristics

Giardia species are flagellated protists that are classified within the diplomonads (which literally means two bodies) (Figure 1). Most of the diplomonads have two nuclei, each forming one of the two bodies. The other diplomonads include *Spironucleus* spp. and *Hexamita* spp. These other diplomonads are not pathogenic for humans, but include fish pathogens and free-living organisms. *Giardia* and other diplomonads were proposed as early diverging eukaryotic organisms on the basis of rudimentary metabolism and cell biology that was lacking some of the canonical eukaryotic features. These observations suggested that these 'archaea' had emerged from the eukaryotic lineage before the acquisition of mitochondria and other organelles. This hypothesis was supported by small subunit rRNA sequences that suggested an ancient divergence from the eukaryotic line. However, subsequent data have suggested that most or all of the absent eukaryotic features have been lost secondarily. *Giardia* may still be a relatively early diverging organism, but probably not more than some of the other protists (protozoans).

Giardia trophozoites lack several of the organelles that are found in most eukaryotes. Mitochondria appear to have been replaced by a remnant called a mitosome. Standard Golgi have not been identified, although Golgi can be identified in encysting organisms. Peroxisomes have not been identified. Nucleoli were thought to be absent, but recent reports have described nucleoli. Trophozoites have minimalist metabolisms that match their minimalist genomes. As predicted by the lack of mitochondria, the metabolism of the trophozoites is strictly anaerobic, utilizing anaerobic glycolysis when using sugar for energy production. Both purines and pyrimidines are obtained from the host by the use of salvage pathways. Similarly,

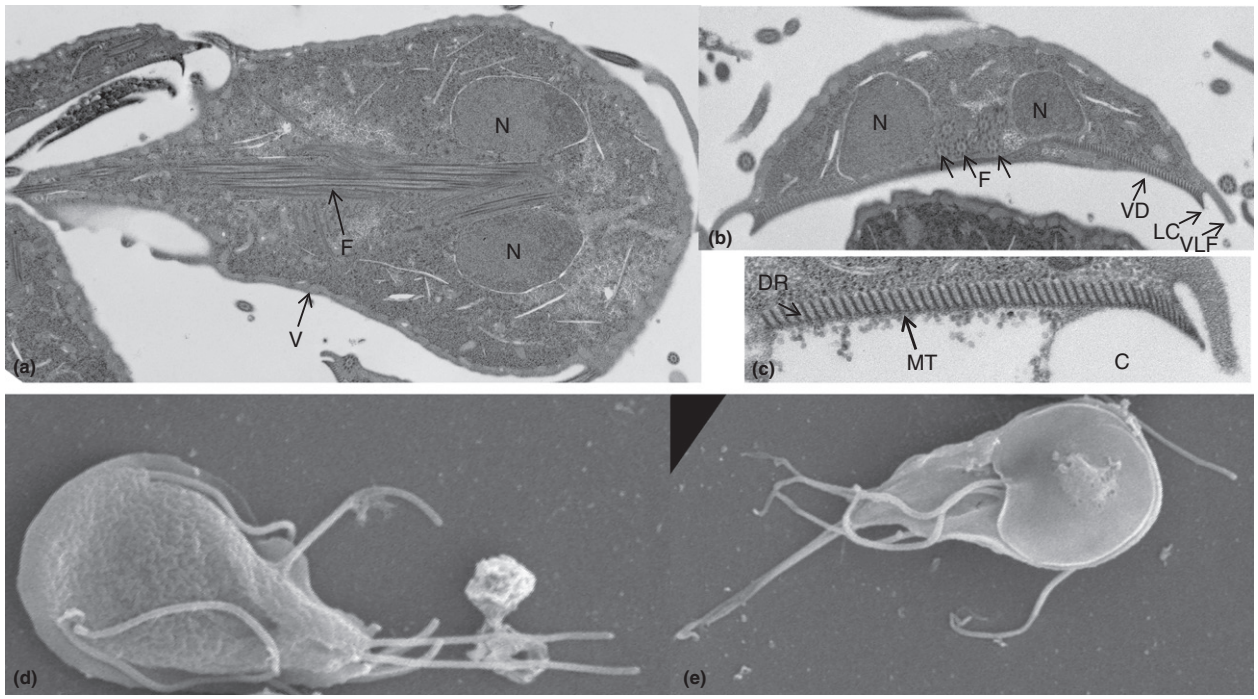

Figure 1 Electron micrographs of *Giardia trophozoites*.

there is no endogenous fatty acid synthesis, so lipids are obtained from the host, as are most amino acids.

Giardia lamblia was not generally accepted as a human pathogen until the 1960s when it was clearly associated with a number of outbreaks of diarrheal disease, and subsequently became recognized as the most common cause of waterborne outbreaks of diarrhea. In addition, a number of epidemiologic studies have shown a link between diarrhea and the presence of *Giardia* trophozoites or cysts in fecal specimens. These epidemiologic observations have also been supported by descriptions of trophozoites in the small intestinal mucosa accompanied by abnormalities of the small intestinal mucosa in patients with diarrhea.

Giardia species were initially named according to the host species from which they were obtained, leading to a large number of *Giardia* species names. Subsequently, a detailed microscopic description of *Giardia* by Filice in 1952 described only three morphologic types that were distinguishable by light microscopy, *Giardia agilis* from amphibians, *Giardia muris* from rodents, and *Giardia duodenalis* from a variety of mammals and birds. However, with the advent of electron microscopy, several species within the *G. lamblia* (*G. duodenalis*) morphologic type were distinguished by ultrastructural differences, including *Giardia microti* (voles and muskrats), *Giardia ardeae* (herons), and *Giardia psittaci* (psittacine birds). Because of these changes in species designation, all the organisms remaining within *G. lamblia* are mammalian parasites (Table 1).

Even within this narrower species definition of *G. lamblia*, there are seven distinct genotypes or assemblages with different levels of host specificity (see Table 1). None of these genotypes can be distinguished morphologically, but all can be easily distinguished by molecular sequencing. Genotypes A (Nash Groups 1 and 2) and B (Nash Group 3) are the only types known to infect humans. Genotypes A and B have also been identified in a variety of wild animals, so there are probably occasions when zoonotic transmission occurs. One of the biggest controversies revolves around whether transmission between dogs and humans occurs, and if so, whether it occurs commonly. Some studies, including our own recent results from a shantytown near Lima Peru, have found that dogs rarely carry Genotypes A or B. However, other studies

Table 1 *Giardia* species and genotypes

Species	*Genotype (of* G. lamblia*)*	*Host*
Giardia lamblia (*G. duodenalis*, *G. intestinalis*)		
	A	Humans and other mammals
	B	Humans and other mammals
	C	Dogs
	D	Dogs
	E	Livestock
	F	Cats
	G	Rats
Giardia agilis		Amphibians
Giardia muris		Rodents
Giardia microti		Rodents
Giardia psittaci		Psittacine birds
Giardia ardeae		Herons

have found the opposite. In addition to Genotypes A and B, five *G. lamblia* genotypes have subsequently been described from dogs (C and D), livestock (E), cats (F), and rats (G), and have never been identified in humans. Genotypes A through G differ substantially when compared by molecular sequencing. So far, the sequences of Genotypes A (WB isolate) and B (GS isolate) have been reported. The sequences of these two organisms differ by nearly 20%, so it is likely that they will be designated as separate species in the future. Ironically, we have nearly returned to the pre-1952 convention of naming *Giardia* species after the host of origin, although with substantially greater understanding of the molecular basis for the distinction.

Life Cycle

The *Giardia* species have a two-stage life cycle which includes the environmentally resistant cyst that initially establishes infection and the vegetative trophozoite which replicates in the small intestine and causes the disease manifestations. The cyst wall has an outer filamentous layer composed of *N*-acetylgalactosamine and three cyst wall proteins (CWPs 1–3). Inside the outer layer are two cell membranes. The cyst has a markedly decreased metabolic activity, which along with its protective outer layer allows it to survive for more than a month in the environment, especially at cooler temperatures. Infection is initiated by the ingestion of as few as 10–100 cysts and is followed by excystation when the cyst passes through the acidic environment of the stomach followed by entry into the duodenum, resulting in the production of two trophozoites from each cyst. However, despite the role of a low pH in inducing excystation, it should be noted that excystation has also been induced by bicarbonate at a neutral pH, and that achlorhydria does not prevent human infections. Therefore, it is clear that the acidic pH is not required for excystation. Pancreatic and endogenous proteases probably play an important role in excystation.

The trophozoite colonizes the proximal small intestine where it obtains its nutrients from the host and causes the disease manifestations. The trophozoites are pear shaped and are approximately 12–15 μm in length and 5–9 μm in width (**Figure 1**). The dorsal surface is convex, whereas the ventral surface attaches to the intestinal epithelium by means of its concave ventral (sucking) disk. The attachment appears to be purely mechanical in nature, and trophozoites adhere just as vigorously to a glass surface while being cultivated *in vitro*. The four pairs of flagella play roles in attachment and motility. A median body is also part of the cytoskeleton, and its morphology can be used to distinguish some of the *Giardia* species, but its function remains unknown.

Trophozoites replicate by binary fission and *Giardia* has always been assumed to be asexual. However, recent population genetic data in addition to the presence of meiosis-specific genes in the sequenced genome, have raised the possibility that there may be a cryptic sexual cycle as well. *Giardia* species are the only human pathogens that have two nuclei. The nuclei are symmetrically placed anteriorly in the trophozoite and are similar in appearance. They replicate at nearly the same time (in contrast to ciliates such as *Paramecium* that have a micronucleus and macronucleus). The nuclei are both transcriptionally active and each has a complete copy of the genome. In fact, trophozoites are tetraploid or approximately tetraploid, so that each nucleus is diploid.

Encystation occurs in the small intestine as a result of exposure to bile salts and cholesterol starvation. Trophozoites complete nuclear replication and karyokinesis, so a single cyst has four nuclei and is poised to divide into two trophozoites when it excysts after infecting the next host.

Pathogenesis

The mechanism by which *Giardia* causes intestinal disease is not well understood. Invasion of the intestinal epithelium has never been convincingly demonstrated, and extra-intestinal infection does not occur. It has been suggested that the malabsorption occurs as a result of trophozoite adherence followed by mechanical blockage of absorption. However, contradicting this hypothesis is the observation that the intestinal wall is highly efficient for absorption of nutrients, so it is unlikely enough that the small intestinal surface is covered by trophozoites to cause malabsorption. Therefore, most of the recent studies have focused on a potential immunopathologic etiology of malabsorption. The intestinal epithelial microvilli are diffusely shortened by activated T lymphocytes which are activated as part of the response to the trophozoites. Lymphocyte activation and subsequent apoptosis of the epithelial cells results in disruption of the epithelial tight junctions, increasing permeability and causing the diarrhea.

However, there is also evidence that the host benefits from an effective immune response. There is evidence for acquired resistance to disease from epidemiologic studies. For example, a large waterborne outbreak of giardiasis at a Colorado ski resort resulted in a much higher frequency of symptoms in visiting skiers than in local residents despite having the same water source. This suggested that the local residents had developed partial protection from symptomatic disease as a result of prior exposure. In addition, there is evidence supporting a beneficial role for the humoral immune response from multiple studies in which the severity and duration of giardiasis were increased greater in patients with common variable immunodeficiency. Despite the evidence in animals for a potentially beneficial role of the cell-mediated immune response, there is little evidence in humans that giardiasis is increased in frequency or severity in patients with HIV infection or other illnesses characterized by deficiency of cell-mediated immunity. It may well be noted that the immune response is a double-edged sword in which there may be situations where the immune response decreases symptoms and others where it contributes to the symptoms of infection.

The organism itself does not have any known toxins or virulence factors. The genome does encode a family of approximately 300 cysteine-rich proteins, called variant-specific proteins (VSPs). One of the 300 VSPs coats the trophozoite surface at a time. The organism is then able to switch expression from one VSP to another during the course of an intestinal infection so that one coat is replaced by another VSP that is resistant to antibodies stimulated by the original VSP. It is likely that antigenic variation of the VSPs contributes to the prolonged

nature of the infection, but whether the VSPs contribute to the symptoms of infection is not known. In addition to their potential role in evading the immune response of the host, there is also circumstantial evidence that they may allow the trophozoite to adapt to different intestinal environments. Different hosts have different intestinal proteases and different VSPs can have different protease susceptibilities. This observation has led to the interesting hypothesis that the role of antigenic variation is to allow the organism to adapt to different intestinal environments.

Clinical Manifestations

The hallmark presentation of giardiasis is chronic diarrhea with malabsorption and weight loss. However, that presentation occurs only for a minority of infected persons. Overall, the majority of infections are asymptomatic, but there are reports of outbreaks of giardiasis with symptomatic attack rates of 100% or near 100%. The most likely explanations for the differences in the rate of symptomatic disease are differences in virulence of organisms, or the presence or absence of prior exposure and partial immunity. The role of partial immunity is noted above and the evidence for differences in pathogenicity for different organisms comes from human volunteer studies in which no recipients of a Genotype A1 organism developed infection, whereas all five recipients of a Genotype B isolate developed infection and three were symptomatic. It is also possible that other differences such as inoculum size or differences in intestinal bacterial flora could affect the degree of symptoms, but these latter possibilities have not been studied.

Infection is initiated by the ingestion of as few as 10–100 cysts and when symptoms develop, they typically occur in approximately 1 week after exposure, but the incubation period can range from 1 or 2 days to 2 weeks. Symptomatic patients nearly always have diarrhea, consisting of loose stools that are greasy in consistency and described as malodorous (Figure 2). Other gastrointestinal symptoms include nausea and vomiting, abdominal bloating, and flatulence. Because *Giardia* infects only the small intestine and is a noninvasive pathogen, blood and white cells are not seen in stools. Fever is unusual but a low-grade fever is sometimes present at the beginning of illness. Systemic symptoms are unusual with the exception of fatigue or malaise, which are found in approximately two-thirds of symptomatic patients.

The duration of symptoms is nearly always greater than 1 week, which distinguishes giardiasis from most forms of viral or bacterial gastroenteritis. The average duration ranges from 2 to several weeks in different series and is sometimes measured in months in the absence of treatment. Malabsorption with weight loss is a key component of the presentation for these patients with prolonged illness. The history of weight loss is helpful in distinguishing giardiasis from irritable bowel syndrome, which is not associated with weight loss. Diarrhea with weight loss can be seen with celiac disease or tropical sprue as well as less common illness such as Whipple's disease, so these illnesses should be considered in patients with a compatible history. It is also noteworthy that approximately one quarter of patients with symptomatic will have symptoms of irritable bowel syndrome after recovery from the acute episode. These patients should be worked up for persistence of giardiasis, but in the absence of documented infection, they do not benefit from anti-Giardia therapy.

When giardiasis is suspected, the diagnosis can usually be established by microscopic examination of fecal material for the presence of cysts or trophozoites (stool for ova and parasite). The cyst is detected much more commonly than the trophozoite, but identification of the trophozoite correlates more closely with symptomatic infection. The yield from a single ova and parasite examination is inadequate, so three successive stool samples are examined when suspicion is high. Alternatively, there are enzyme immunoassays (EIAs) or fluorescent antibody-mediated tests that have about the same sensitivity when used with a single specimen as ova and parasite examination done with three stool specimens. The

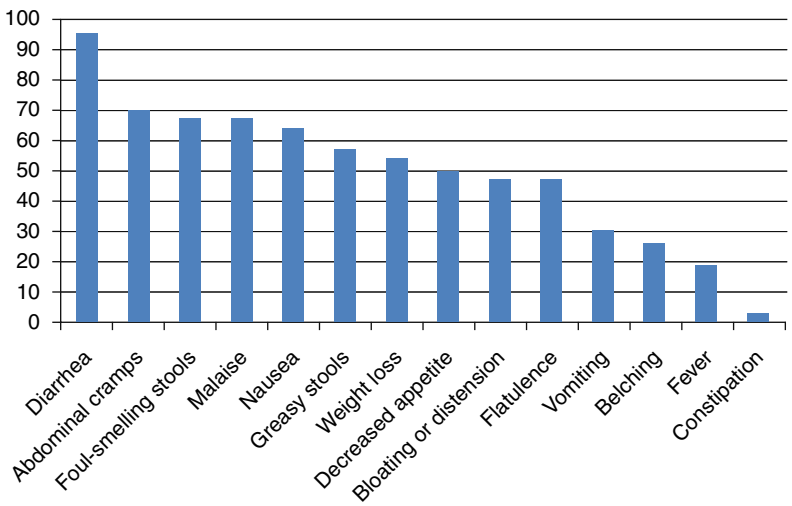

Figure 2 The frequency of symptoms found in patients with symptomatic giardiasis. The numbers on the left indicate the percentage of patients with the designated sign or symptom; the numbers represent a weighted average from a series of clinical studies of symptomatic patients. Signs and symptoms of giardiasis are along the x-axis.

fluorescent antibody-mediated test, which detects Giardia cysts, may have slightly higher sensitivity and specificity than the EIA (and also detects *Cryptosporidium* oocysts at the same time), but the EIA is more commonly used because it is less labor-intensive. Obviously, if detection of other intestinal parasites is desired, then the ova and parasite examination is preferable. Polymerase chain reaction (PCR) tests have been described in the literature, but are not yet clinically available. There are no serologic tests that are useful for the diagnosis of giardiasis.

There are occasional patients with malabsorption and weight loss due to *Giardia* who have consistently negative diagnostic studies. In these patients, *Giardia* trophozoites can be detected in small intestinal contents by endoscopy or by using the string test. The string test is performed by having the patient swallow a capsule at the end of a string. The capsule advances to the small intestine where it stays 4 h to overnight. The string is removed followed by microscopic examination of the end of the string for trophozoites. The advantage of the string test over endoscopy is that it is simpler, but the disadvantage is its inability to identify other illnesses such as celiac disease, which can be in the differential diagnosis.

Epidemiology

Giardia is the most commonly identified intestinal protozoan throughout the world, in both developed and developing areas. However, the epidemiology differs markedly between developed areas which generally have good water supplies and developing areas with inadequately purified water. The typical pattern in developing regions is a high rate of endemic transmission, which may include surprisingly low levels of symptomatic disease. For example, 95% of children living in a shantytown near Lima, Peru, were infected by the age of 2 years and after treatment 98% were reinfected within 6 months. Other studies of children in highly endemic areas have also demonstrated nearly universal infection in early childhood and reinfection shortly after treatment. These children are rarely symptomatic, although growth stunting may be associated with these apparently asymptomatic infections.

In contrast, giardiasis in developed regions is less common and frequently occurs in outbreaks of symptomatic disease. *Giardia lamblia* is one of the most commonly documented causes of waterborne outbreaks of illness in the US and in other developed regions. The most recently reported large outbreak was from Bergen, Norway, where more than 3000 residents of this small city developed symptomatic infection. Although drinking water was incriminated as the source of infection, the source of the original contamination was never determined. Waterborne outbreaks are facilitated by the fact that infected individuals may excrete up to 10^9 cysts per day in the feces in comparison with an infective dose of 10–100 cysts. The cysts can survive for more than a month in temperatures that are near 4 °C. At higher temperatures, the duration of cyst viability decreases substantially, which may explain that within the US, the incidence of giardiasis is higher in the northern states. The annual frequency of reported cases in the US varies from approximately 4 to 20 cases per 100 000 population among the various states with an average of 7 cases per 100 000 for the entire country. However, it is likely that these numbers obtained by a passive case reporting system greatly underestimate the case rate. A report taking this likelihood into account estimated the rate in the US to be between 50 and 1000 cases per 100 000 population annually. In that report, the annual rate of hospitalization for severe giardiasis was estimated at 2 per 100 000, a rate that is similar to that for shigellosis.

Municipal water supplies in developed regions have very low rates of contamination with *Giardia*, although occasional studies have raised the possibility that ingestion of tap water is a risk for acquisition of giardiasis. The risk is increased when drinking water is obtained from shallow wells and from surface water that is not adequately purified (such as chlorination without filtration). The source of contamination of the shallow well and surface water remains highly controversial in that zoonotic sources are frequently blamed but seldom documented. The controversy centers on how often genotypes of *Giardia* that infect humans (A and B) are found in animals. Genotypes A and B have been found in beavers, and beavers have occasionally been incriminated as sources of contamination that led to human infections. However, data incriminating other animals as sources of contamination are lacking. As noted above, some studies have found Genotypes A and B in dogs, whereas others have not, so it is unclear if dogs are a potential source. Genotypes A and B have not been identified in livestock animals, so they cannot be considered as a source of contamination leading to human infection.

Water used for recreational purposes is probably more common than drinking water as a source of human infection in the US. The implicated sources range from swimming pools to wilderness water supplies. Mountain backpacking is a well-recognized risk factor for acquisition of giardiasis. Beavers are commonly blamed as the source of contamination of the wilderness water, but this remains controversial. Within the US, the incidence of giardiasis peaks in the late summer, which probably reflects the high use of recreational water facilities in the summer. The frequency of giardiasis is also substantially higher in children less than 10 years of age than for adults, which may reflect greater use of recreational water facilities. Alternatively, the higher incidence in children could be the result of a lack of preexisting immunity, or alternative sources of infection, such as day care centers.

Although less frequent than waterborne outbreaks, a number of foodborne outbreaks of giardiasis have been reported in the literature (**Table 2**). When considering the potential risk of foodborne giardiasis, the key question is how and when the contamination occurs. Theoretically, the contamination can occur at any time before harvest until after preparation of the food. Cysts passed by the mammalian host are fully infectious as during the time of passage in the feces, so unlike some other parasitic infection, there is not a delay between the time of contamination and the beginning of the risk to those ingesting the food. It is also important to note that because the cyst is not a replicative form, they will not replicate in food items. Cysts are also not heat stable, so cooking will inactivate the cysts. When outbreaks occur, they are typically associated with food handlers who are themselves infected and contaminate the food during the preparation

Table 2 Foodborne outbreaks of giardiasis

Year of report	*Foods implicated*	*Source of food contamination*	*Number of people ill*	*Attack rate (%)*
1993	Raw sliced vegetables	Asymptomatic food handler	27	14% of those who ate the raw vegetables
1992	Ice	Asymptomatic carrier in household of food handler	27	75
1990	Fruit salad	Food handler who had a 2-year-old child with asymptomatic giardiasis	10	40 (82 for those who ate the fruit salad)
1989	Sandwiches	Food handler with an asymptomatic child	88	35% of nursing home residents
1989	Taco ingredients	Unknown	22	19
1988	Noodle salad	Symptomatic food handler with two asymptomatic *Giardia*-infected children	13	81
1981	Home-canned salmon	Asymptomatic carrier in household of food handler	29	48

process. For example, an outbreak of giardiasis in Minnesota resulted in infection of half of 60 employees at a school, but none of the students had documented giardiasis. The source of the outbreak was traced to home-canned salmon opened by a woman caring for her grandson who was subsequently found to have asymptomatic giardiasis. This outbreak points out the potential risk of transmission from asymptomatic carriers of *Giardia*. Other foodborne outbreaks have also been associated with asymptomatic food handlers who had significant contact with infected children (Table 2).

Sexual transmission has been reported on several occasions in men who have sex with other men. It is also worth noting that transmission of *Entamoeba histolytica* has been identified in women having sex with other women, and because the transmission patterns of *Giardia* and *E. histolytica* are similar, it is likely that sexual transmission in these settings results from ororectal or orogenital contact.

Children in day care centers are at an increased risk for acquisition of giardiasis. These infected children may be symptomatic or asymptomatic, and sometimes symptomatic infection results in family members of children who became infected in day care centers.

There are several factors that make the detection of environmental contamination with *Giardia* challenging. The cyst is the environmentally stable form of the life cycle, and as so, it is the transmissible stage. However, the cyst does not replicate in the environment, so culturing them is not an option. Attempts to identify *Giardia* cysts in the environment generally focus on detection in water. Methods that are currently used by the US Environmental Protection Agency (EPA) to detect *Giardia* cysts include filtration followed by cyst concentration. The cysts are then separated by an immunomagnetic method, which allows the examination of large volumes of water and separates the cysts from other artifacts that might be confused with *Giardia* cysts. The cysts are then evaluated microscopically using fluorescent staining and differential interference contrast (DIC). However, because cysts can remain morphologically normal even after they are no longer viable, additional testing is required to determine whether the cysts are viable. Viability is ultimately defined as the ability to establish infection in a host after ingestion. The best surrogate test is to place the cyst under conditions that promote excystation and determine their ability to develop into trophozoites. However, this approach is laborious and not widely applicable, so the usual determination of cyst viability is by the exclusion of vital dyes, such as fluorescein diacetate or propidium iodide. To further complicate the analysis, the cysts from multiple *Giardia* species all appear morphologically identical, but only Genotypes A and B of *G. lamblia* have the potential to cause human disease. Thus, it is difficult to know whether the identified cysts pose a risk of human infection or not. In addition, PCR-mediated approaches to identifying the cysts after immunomagnetic separation are coming into use. PCR-based methods have the potential of identifying cysts at the species and genotype level, which will be useful in determining whether the cysts pose a risk to humans.

Control and Prevention Measures

Symptomatic giardiasis should be treated. Asymptomatic giardiasis should generally be treated in areas with low prevalence or where there is significant hazard to others from the infected person (e.g., food handling). A number of effective agents are available for treatment (Table 3). The agent of first choice in most cases is metronidazole or one of the other nitroimidazoles, especially tinidazole. The key advantage of tinidazole is the high degree of efficacy of single dose treatment, whereas metronidazole must be given for 5–10 days to allow a similar degree of efficacy. Severe toxicity is rare with the nitroimidazoles, but nausea and vomiting occur frequently, as does a metallic taste. These drugs have a disulfiram-like effect, so the concurrent use of alcohol is contradicted. These drugs are mutagenic for bacteria, but are now very widely used with no evidence for carcinogenesis in humans, so the concern of cancer causation has generally been laid to rest. Likewise, early concerns about use in pregnancy have been ameliorated by the lack of demonstrated teratogenesis despite extensive use during the second and third trimesters for other purposes. However, there are inadequate data to allow the same level of comfort in using the nitroimidazoles during the first trimester. In fact, the only agent commonly

Table 3 Treatment of giardiasis

Drug	*Full dose (adults or children weighing more than 40 kg)*	*Pediatric dose (or adults weighing less than 40 kg)*	*Duration (days)*	*Comments*
Metronidazole	250 mg tid	5 mg kg^{-1} tid	5–7	Most commonly used treatment in the US
Tinidazole	2 g	50 mg kg^{-1}	Single dose	The only available single dose treatment
Albendazole	400 mg qd	Same as adult	5	Better tolerated than metronidazole, but may be less effective Contraindicated in pregnancy
Nitazoxanide	500 mg bid	100 mg bid (ages 1–3 years), 200 mg bid (ages 4–11 years)	3	
Quinacrine	100 mg tid	2 mg kg^{-1} tid	5	Not commercially available in the US, but can be obtained from a compounding pharmacy
Furazolidone	100 mg qid	2 mg kg^{-1} qi	7–10	Somewhat less effective than other agents, but commonly used in children because of the available liquid form
Paromomycin	8–10 mg kg^{-1} tid	8–10 mg kg^{-1} tid	5–10	Less effective, but commonly used in pregnancy because it is not absorbed

recommended during early pregnancy is the nonabsorbed aminoglycoside, paromomycin. However, paromomycin is less effective than nitroimidazoles, so the choice of treatment during early pregnancy should take these factors into consideration.

Albendazole is a tubulin inhibitor with broad spectrum antihelminthic activity and has been shown to be highly effective for treating giardiasis, although perhaps slightly less effective than the nitroimidazoles. The related drug, mebendazole, has also been studied, but is much less effective. Nitazoxanide has been developed more recently and is reasonably effective for giardiasis as well as other protozoan and bacterial pathogens, but is less effective than the nitroimidazoles. For many years, quinacrine was the treatment of choice, but in the years since metronidazole effectively replaced its use in the US, it is no longer generally available. It is still useful in combination with metronidazole for treatment of refractory giardiasis, and if necessary can be obtained from a compounding pharmacy. Furazolidone has commonly been recommended for children in the past because it is better tolerated than quinacrine, but is seldom used today.

Human giardiasis can be prevented to the extent that ingestion of cysts can be prevented. There are no available vaccines for preventing human infection and, although there is a vaccine used in animals, its efficacy is not well documented. Therefore, successful prevention results from interrupting the cycle of transmission from human (or perhaps infected animal) to the environment and back to another human. For these reasons, the single most important factor in effective control of giardiasis is the availability of pure water. Giardiasis became a nationally reportable infection in 2002 and is reported by state health departments to the CDC through the National Electronic Disease Surveillance System. This approach should facilitate efforts to maintain water purity by earlier and more comprehensive detection of outbreaks when they occur.

Municipal water supplies typically utilize a process that includes coagulation/flocculation, clarification, and filtration through sand or diatomaceous earth. These steps are highly effective at removing *Giardia* cysts. The final step of the purification process uses chlorination, which plays an important role in inactivation of bacterial and viral pathogens. However, *Giardia* cysts are relatively resistant to chlorination, so this step is less important for *Giardia*.

When people travel to developing areas or backpack within the US, additional water purification steps are necessary. Portable or household filters are available with pore sizes of less than 1 μm; these filters are highly effective in removing *Giardia* cysts. Because *Giardia* cysts are rapidly inactivated by heat, adequate purification can be provided boiling for 1 min or by treatment at 55 °C for 5 min. Halogenation with iodine or chlorine is also effective for inactivating cysts, but requires a longer duration of exposure than for bacterial pathogens.

Foodborne transmission occurs most frequently as a result of handling food by infected preparers. These food preparers may be symptomatic or asymptomatic, so exclusion of people with diarrhea from handling food can be helpful in preventing giardiasis and other foodborne illnesses, but certainly will not prevent all risks of contamination. Therefore, consistent attention to hand washing and the use of gloves or other mechanical barriers to direct hand to food contact are important. It is also possible for fresh produce to be directly contaminated by cysts, so washing these items in purified water may reduce the risk by washing away some of the cysts, but will not eliminate the cysts. It is important to note that washing with inadequately purified water can actually introduce contamination where none existed before.

Research Priorities

There are at least two major research questions that would inform attempts to prevent human giardiasis. The first is a better understanding of the sources of environmental contamination. If zoonotic transmission occurs frequently, then significant effort should be given to preventing water or direct human exposure to fecal material of these infected animals. However, if most human cases result from other infected humans, then the major effort should go into interrupting transmission that might occur from human contamination of water or food, or human infections that result from day care contact or sexual transmission. Another major priority is the development of improved methods of detecting significant environmental contamination. It is a challenge to identify small numbers of cysts, especially in nonaqueous sources, and if cysts are found, to determine whether they pose a risk of human infection.

Cystoisospora belli (Syn. *Isospora belli*)

AJ Rodriguez-Morales, Universidad Tecnológica de Pereira and Office of Scientific Research, Pereira, Risaralda, Colombia
DM Castañeda-Hernández, Fundación Universitaria del Área Andina, Pereira, Colombia

Glossary

Anthroponosis An infectious disease in which its etiological agent is carried by humans and is transferred to other humans and animals.
Foodborne disease Any disease resulting from the consumption of contaminated food, pathogenic bacteria, fungus, viruses, or parasites that contaminate food, as well as chemical or natural toxins such as poisonous mushrooms.
Organism life cycle A period involving all different generations of a species succeeding each other through means of reproduction, whether through asexual reproduction or sexual reproduction; a period from one generation of organisms to the same identical point in the next.
Surveillance In public health and epidemiology, the discipline of continuously gathering, analyzing, and interpreting data about diseases, and disseminating conclusions of the analyses to relevant organizations, to intervene in their patterns in order to control and prevent them.
Taxonomy The science of classification, in microbiology the arrangement of microorganisms into a classification.

Introduction

Cystoisosporiasis (formerly isosporiasis) is a human intestinal disease caused by the parasite *Cystoisospora belli* (syn. *Isospora belli*). The coccidian parasite, *C. belli*, infects the epithelial cells of the small intestine, and is one the least common intestinal coccidia that can infect humans (e.g., *Toxoplasma*, *Cryptosporidium*, *Microsporidium*, and *Cyclospora*).

The Pathogen

Cystoisosporiasis is found worldwide, especially in tropical and subtropical areas. Infection often occurs in immunocompromised individuals, notably in patients with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), and outbreaks have been reported in institutionalized groups in the USA. The first documented case was in 1915. Until 2005 the etiological agent belonged to the genus *Isospora* (Table 2). In 2005 it was included in the genus *Cystoisospora*. In Table 1 other species belonging to this genus are shown. These genuses belong to different families. *Isospora* belongs to family Eimeriidae (Table 2) and *Cystoisospora* to Sarcocystidae. Both families belong to the suborder Eimeriorina (order Eucoccidiorida of the phylum Apicomplexa).

Humans are the only known hosts for *C. belli*, which has no known animal reservoir, however other species are present in animals such as *Cystoisospora suis* (pigs), *Cystoisospora rivolta* and *Cystoisospora felis* (cats), and *Cystoisospora canis* and *Cystoisospora ohioensis* (dogs) (Table 1). Owing to this animal-species specificity it has been suggested this infection cannot be zoonotic.

Cystoisospora belli infection usually causes a mild and protracted illness unless the patient is immunocompromised. Clinical presentation may mimic those of inflammatory bowel disease and irritable bowel syndrome.

Transmission

Exposure to contaminated food or water predisposes to this infection. Because an external stage in the environment is required for the oocysts to mature (Figure 1), direct person-to-person transmission is unlikely. Accordingly, cystoisosporiasis is more common in areas with poor sanitation. The disease is also more common in patients with AIDS.

At time of excretion from an infected patient, the immature oocyst contains usually one sporoblast (rarely two) (Figure 1, step A). In further maturation after excretion, the sporoblast divides in two (the oocyst now contains two sporoblasts); the sporoblasts secrete a cyst wall, thus becoming sporocysts; and the sporocysts divide twice to produce four sporozoites each (Figure 1, step B). Infection occurs by ingestion of sporocysts-containing oocysts: the sporocysts excyst in the small intestine and release their sporozoites, which invade the epithelial cells and initiate schizogony (Figure 1, step C). On rupture of the schizonts, the merozoites are released, invade new epithelial cells, and continue the cycle of asexual multiplication (Figure 1, step D). Trophozoites develop into schizonts which contain multiple merozoites. After a minimum of 1 week, the sexual stage begins with the development of male and female gametocytes (Figure 1, step E). Fertilization results in the development of oocysts that are excreted in the stool (Figure 1, step A).

Foodborne *C. belli* Infection

Cystoisospora belli can be transmitted through food and water. It is an uncommon infectious agent compared to other viruses, bacteria, and protozoa that cause waterborne and foodborne illness. The immature form of the parasite known as oocytes are ingested with water and food and then need to mature in the human gut before it becomes infective. After completing its life cycle in the human body, newly formed oocytes are then eliminated in the stool. Contaminated vegetables and raw food serves as a source for this parasite infection.

The parasite is transmitted via the feco–oral route. Oocytes that are passed out in the stool of infected humans or animals

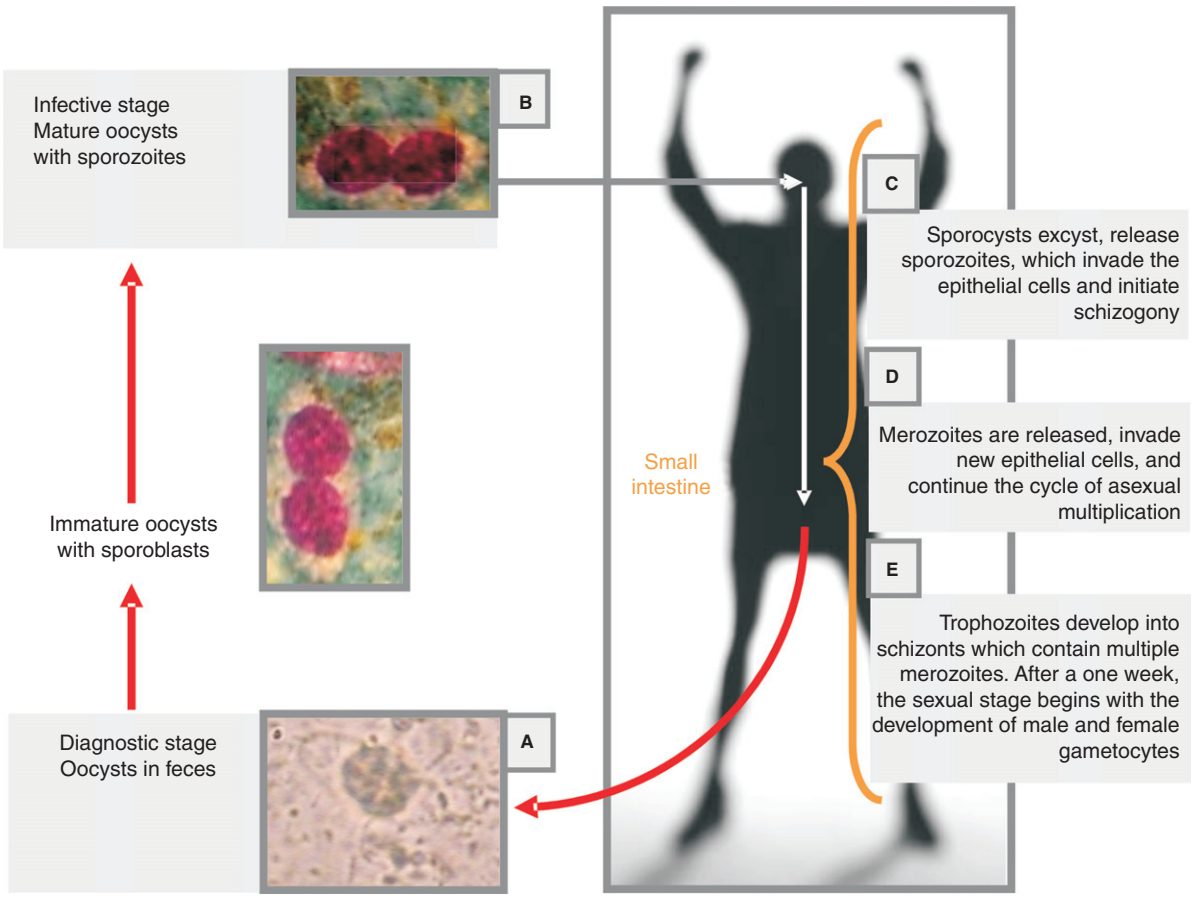

Figure 1 Transmission and life cycle of *Cystoisospora belli* in human beings.

may contaminate water that is then ingested. Outbreaks may occur when a common water supply and food is contaminated. However, these infections are uncommon in most developed nations. People with weakened immune systems, patients who are immunocompromised and those living in areas with poor sanitation are at the greatest risk of infection.

Particularly during past century, sporadic outbreaks were reported in mental institutions and in daycare centers in the US.

Epidemiology

Cystoisosporiasis has a worldwide distribution, although it is more common in tropical and subtropical climates. The exact incidence of cystoisosporiasis in humans is unknown. *Cystoisospora belli* has been reported as the cause of outbreaks of diarrheal illness in daycare centers and mental institutions and has been implicated in traveler's diarrhea in endemic areas, although is not clear how to define an specific endemic area for this parasite. Some data support the endemicity concept. A study of cystoisosporiasis among persons with AIDS in Los Angeles County, California, USA, found that this foodborne parasite was reported in 127 (1.0%) of 16 351 persons with AIDS during the study period. Prevalence of infection was highest among foreign-born patients (3.2%), especially those from El Salvador (7.4%) and Mexico (5.4%), and in all persons of Hispanic ethnicity (2.9%). It has been estimated that among patients with AIDS who are from South America, 10% with chronic diarrhea have cystoisosporiasis. In patients with AIDS who are from Haiti and Africa, 7–20% with chronic diarrhea have cystoisosporiasis.

This parasite has rarely been reported as a cause of travelers' diarrhea in immunocompetent patients. However, in a immunosupressed traveler, particularly with persistent diarrhea, this disease should be considered in the differential diagnosis.

The infection often occurs in immunodepressed individuals although some reports in immunocompetent and asymptomatic individuals have been published. Outbreaks have been reported in institutionalized groups in the USA. In spite of this, there are few studies designed to study the population prevalence of this parasite as well as the burden of this foodborne disease. Even more, this parasite and disease is not usually considered in the record or surveillance in most countries.

Clinical Presentation

The infection causes acute, nonbloody diarrhea with crampy abdominal pain, which can last for weeks and result in malabsorption and weight loss. In immunodepressed patients, and in infants and children, the diarrhea can be severe. Eosinophilia may be present (differently from other protozoan infections). Although not common, extraintestinal disease in HIV/AIDS patients has been described (compromising mediastinal and mesenteric lymph nodes, liver, spleen, and lamina propria of the intestinal mucosa).

Although isosporiasis is generally a self-limited infection, patients who are treated tend to improve in 2–3 days, whereas those who do not remain sick considerably longer. Immunocompetent hosts generally respond very rapidly to antiparasitic therapy. Immunocompromised hosts also respond well, though less rapidly; however, they have a high relapse rate once therapy is stopped and thus typically require indefinite prophylaxis after therapy.

Diagnosis

The diagnosis of cystoisosporiasis is based on a combination of clinical, epidemiological, and diagnostic tests. Cystoisosporiasis is an AIDS-defining illness, so an appropriate workup for HIV infection should be performed, if necessary, particularly CD4 T-cell counts.

Microscopic demonstration of the large, typically shaped oocysts (**Figure 1**), is the basis for diagnosis. Because the oocysts may be passed in small amounts and intermittently, repeated stool examinations and concentration procedures are recommended (three or more).

If stool examinations are negative, examination of duodenal specimens by biopsy or string test (Enterotest®) may be needed.

The oocysts can be visualized on wet mounts by microscopy with bright-field (**Figure 1**), differential interference contrast, and epifluorescence. They can also be stained by modified acid-fast stain (**Figure 1**).

Prevention and Control

Cystoisosporiasis is a foodborne and waterborne illness. Consequently, the practice of hygienic measures may help in preventing transmission. It is important to avoid possible exposure to contaminated food and water as far as possible. Appropriate isolation measures should be used because shedding of oocysts may last for weeks.

Sarcocystis

YR Ortega, University of Georgia, Griffin, GA, USA
IM Sulaiman, Southeast Regional Laboratory, Atlanta, GA, USA

Glossary

Coccidia A subclass of spore forming, single-celled, microscopic, obligate intracellular parasite.
Heteroxenous Requiring more than one host to complete a life cycle.
Oocyst Hardy, thick-walled spore resistant to environmental conditions and able to survive for prolonged periods of time outside the host.
Protozoa A diverse group of unicellular eukaryotic organisms.
Sporocysts Thin-walled cysts containing sporozoites. Two sporocysts are contained within a *Sarcocystis* oocyst.

Background

Miescher, for the first time, in 1843, reported *Sarcocystis* cysts in striated muscle of a house mouse. These cysts had the appearance of white threads and were thereafter referenced as Miescher's tubules. These tubules, when mature, contain a large number of cellular forms known as spores or Rainery's corpuscules. Similar observations were reported in muscle from a pig in 1865, which Kuhn called *Synchytrium miescherianum*. Finally in 1882, Lankester introduced the name *Sarcocystis* and renamed the organism as *Sarcocystis miescheriana*. The taxonomic position of *Sarcocystis* was uncertain, and in 1967 electron microscopy demonstrated that the sarcocysts had organelles similar to those in the Apicomplexa. In 1972, Fayer cultivated the spores in mammalian cells, thereby obtaining the sexual stages. Later, other investigators demonstrated that *Sarcocystis* was a heteroxenous parasite because sexual and asexual stages were produced in two different hosts. In 1976, *Sarcocystis hominis* was described by Dubey and in 1977 Heydorn described *Sarcocystis suishominis*. Future transmission studies using *Sarcocystis fusiformis* to infect various animals (potential definitive hosts) provided more information on the biology, role of intermediate and definitive hosts, and the naming of three new species, *Sarcocystis bovicanis, Sarcocystis bovifelis*, and *Sarcocystis bovihominis*.

In general, a host can be infected with pathogenic and nonpathogenic species of *Sarcocystis*. Among the four species found in cattle (*S. bovifelis, S. bovihominis, Sarcocystis cruzi*, and *Sarcocystis hirsuta*), *S. cruzi* is pathogenic to cattle. Of the *Sarcocystis* in sheep (*Sarcocystis arieticanis, Sarcocystis tenella, Sarcocystis gigantean*, and *Sarcocystis medusiformis*), *S. arieticanis* and *S. tenella* are pathogenic species to sheep, of the four species reported infecting pigs (*S. medusiformis, S. meischeriana, Sarcocystis porcifelis* and *S. suihominis*), only the *S. porcifelis* is confirmed to be pathogenic to pigs. There are five pathogenic species infecting horses, including *Sarcocystis asinus, Sarcocystis bertrami, Sarcocystis equicanis, Sarcocystis fayeri*, and *Sarcocystis neurona*. Condemnation of meats for human consumption occurs if *S. cruzi* is identified in beef meats and *S. hirsuta and S. meischeriana* infections can result in condemnation as it affects the meat quality (visible cysts easily identifiable).

The taxonomy of genus *Sarcocystis* is still not clear and its relationship with other closely related genera including *Besnoitia, Caryospora, Cystoisospora, Frenkelia, Isospora, Hammondia, Hyaloklossia, Lankesterella, Neospora*, and *Toxoplasma* is being examined by experts worldwide. Phylogenetic studies have revealed *Isospora* to be the closest genus to *Sarcocystis*.

Characteristics

Sarcocystis belongs to the phylum Apicomplexa, class Sporozoasida, subclass coccidiasina, order Eucoccidiorida, suborder Eimeriorina, family Sarcocystidae, and subfamily Sarcocystinae. Much confusion over the biology and variability of the tissue stages in the intermediary and definite hosts has made it difficult to describe and validate different *Sarcocystis* species. In 1986, Levine listed all the recognized names of 122 species, of which definitive and intermediary hosts are known to only 56 species. Intestinal sarcocystosis in humans is believed to be caused exclusively by *S. hominis* and *S. suishominis*.

The life cycle of *Sarcocystis* is similar to that of most of the other Apicomplexa. Two hosts are required by *Sarcocystis* to complete its life cycle: an intermediate and a definitive host (Figure 1). Sporulated oocysts (Figure 2(a)) containing two sporocysts each with four sporozoites are excreted in the feces of the definitive host.

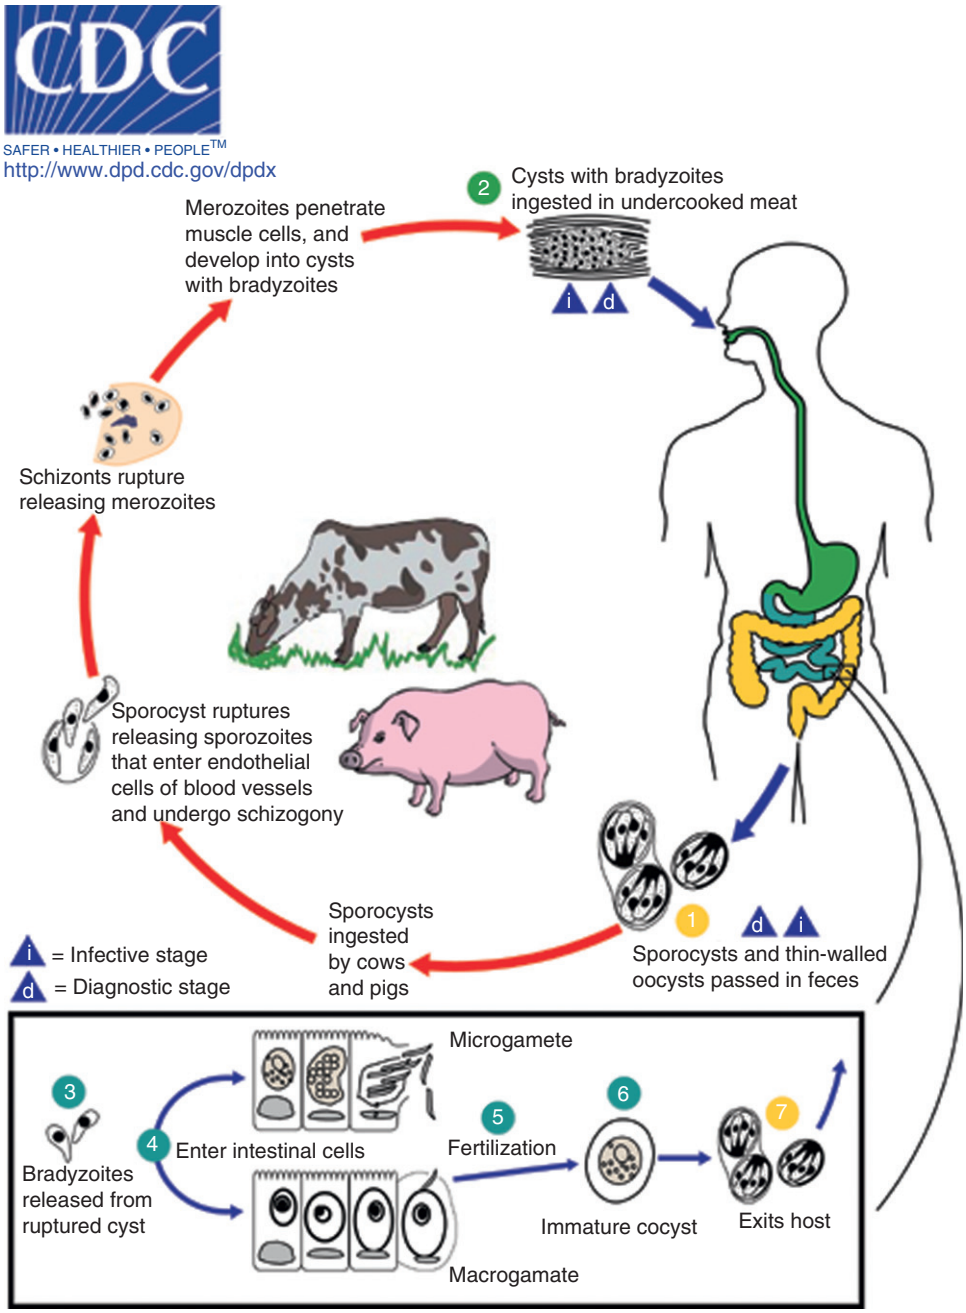

Figure 1 Life cycle of *Sarcocystis* parasite. http://www.dpd.cdc.gov/dpdx.

In the intermediate host (pigs, cattle, sheep, and other animals), the sporozoites are released in the intestinal lumen, migrate through the gut epithelium, and eventually invade small arteries throughout the body where the first generation of asexual stages is produced (merogony). Two subsequent generations of merozoites are reproduced asexually downstream in the direction of the blood flow to arterioles, capillaries, venules, and veins throughout the body. The fourth generation of merozoites (metrocytes) is formed in the muscles and initiate sarcocyst formation. As the sarcocyst matures, the metrocytes (small, rounded, and noninfectious) will begin to form the crescent-shaped bradyzoites. This process can take up to 2 months and the sarcocysts in the muscle can persist for several months. The definitive host acquires infection when the sarcocysts are ingested via contaminated undercooked meat.

The sarcocysts can be found in any striated muscle of the body and to a lesser extent, also in smooth muscle. Sarcocysts have also been reported in neural tissue such as the spinal cord, brain, and Purkinje fibers of the heart.

When the definitive host ingests meat containing mature sarcocysts (full of bradyzoites), the sarcocyst wall is ruptured or digested and the bradyzoites are released, which in turn infect the cells from the intestinal lamina propria. Each bradyzoite will then differentiate to form the macro- and

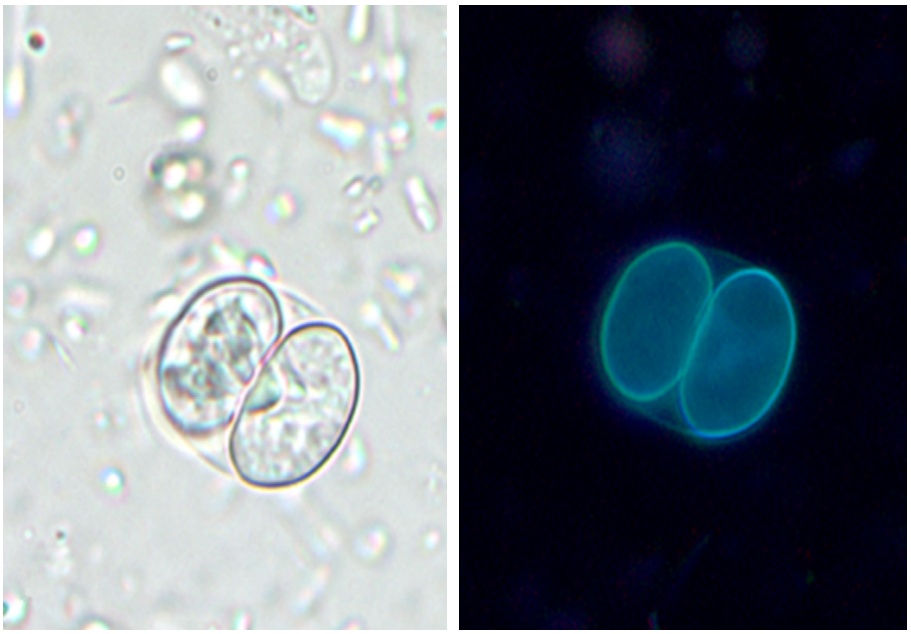

Figure 2 Sporulated *Sarcocystis* sp. oocysts: (a) bright field microscopy, (b) autofluorescence. http://www.dpd.cdc.gov/dpdx/HTML/ImageLibrary/Sarcocystosis_il.htm.

microgametocytes. After fertilization, sporogony occurs, producing a mature oocyst, each containing two sporocysts. The oocyst and sporocysts are then excreted in the feces; however, it is uncommon to find intact oocysts in the feces, but rather individual sporocysts.

Oocysts of *S. suishominis* measure 12.3–14.6 μm × 18.5–20 μm and the sporocysts contain four sporozoites and a residual body. Sporocysts of *S. hominis* and *S. suishominis* measure 9.3 × 14.7 μm and 10.5 × 13.5 μm, respectively.

Intermediate host specificity for *Sarcocystis* spp. is thought to be high in some species but not in others. In the case of *S. hominis*, cattle and water buffalo can acquire the infection, whereas *S. suis* can infect pigs. Humans can serve as intermediate hosts for several *Sarcocystis* spp. Humans and other nonhuman primates can serve as definitive hosts of *S. hominis* and *S. suishominis*. Dogs and coyotes serve as definitive host for *S. cruzi*. The use of molecular methods may help clarify and provide a more accurate speciation of sarcocysts in infected individuals. The presence of virulence factors in *Sarcocystis* has not been described and needs to be studied. This parasite can be found worldwide, particularly where livestock are bred.

Clinical Manifestation

In general, patients with intestinal sarcocystosis (anthroponotic) present with chills, mild fever, diarrhea, vomiting, and respiratory problems, whereas the zoonotic sarcocystosis disease leads to the formation of muscle cysts with symptoms of muscle weakness and transitory edema. In humans, infection with *Sarcocystis* is of short duration and often asymptomatic.

Studies with human volunteers have demonstrated that the first signs of infection are observed 3–6 h after ingestion of contaminated meats. Human volunteers in Germany had nausea, stomach ache, and diarrhea. These symptoms lasted for approximately 36 h. In China, volunteers ingested meats containing a large number of sarcocysts. They developed abdominal pain, distension, watery diarrhea, and eosinophilia between weeks 1–4. When humans act as intermediate hosts, most have no symptoms. Fewer have been diagnosed by the presence of intramuscular cysts. In other cases, patients can present with vasculitis and/or myositis. In China, a man developed these cysts in the chest intermittently for 16 months. Masses appeared with overlaying erythema and then subsided spontaneously after 2 weeks. In another report, an individual from India developed lumps and pain in his limbs.

Diagnosis

Sarcocystis oocysts can be identified in the feces using bright field microscopy, phase contrast microscopy, or differential interference contrast microscopy. The two sporocysts can be observed (Figure 2(a)); however, the oocyst wall is barely visible. Sporocysts can be easily observed using an epifluorescence microscope where sporocysts appear as two bright oval structures (Figure 2(b)). The thin oocyst wall usually breaks, releasing the sporocysts and diagnosis is based on identification of the sporocyst. Diagnosis can be facilitated by flotation methods using cesium chloride, zinc sulfate, or sucrose rather than sedimentation methods such as the formalin-ethyl acetate.

In humans, sarcocysts are usually found in skeletal and cardiac muscle and less frequently in the larynx, pharynx, and upper esophagus. Sarcocysts can be identified in hematoxilin–eosin stained tissue sections. When histological

sections are stained using the periodic acid-Schiff reaction, the cyst wall can be observed; however, it can vary in morphology, overall size, and presence or absence of septa depending on the age of the cyst and type of infected tissue.

In recent years several immunologic and molecular biologic methods have been developed and are used in the detection and differentiation of the pathogenic and nonpathogenic *Sarcocystis* species. Immunologic methods have been found to be highly conserved and cross-reactive throughout the genus; therefore, these methods cannot be used for genetic differentiation at species level. However, nucleic acid-based molecular tools have been found to be more powerful and can differentiate *Sarcocystis* at an interspecies level. For this purpose, the small subunit (SSU) rRNA gene has been most extensively characterized. In general, SSU rRNA-based molecular methods have been effectively employed in species identification in animal hosts (Table 1). Nevertheless, these molecular tools have not been used to detect *Sarcocystis* species in humans.

Treatment

Currently there is no recommended prophylaxis or therapeutic treatment available for treating intestinal or tissue sarcocystosis disease in humans. Because infection is usually asymptomatic,

self-limiting, and of short duration, controlled studies to determine the efficacy of various drugs to control this infection have not been done. Cotrimoxazole or furazolidone are frequently used to treat coccidial infection, but have not been fully evaluated for treatment of human sarcocystosis. Whether immunosuppressive drugs may help control the vasculitis and myositis while at the same time allowing parasite proliferation has not been determined.

Epidemiology

The prevalence and incidence of the sarcocystosis disease caused by pathogenic *Sarcocystis* species are widespread, but vary among various infected hosts. In humans, prevalence of intestinal sarcocystosis disease is low and generally not associated with illness, except in human volunteer studies where large numbers of sarcocysts (>100) were ingested. The number of cases of *Sarcocystis* infection is probably underreported. Most cases have been reported by physicians, public health workers, and research scientists.

In humans, infection has been reported in individuals ranging in age from a 26-day-old infant to a 75-year-old man. Most cases of muscular sarcocystosis infection have been reported in tropical and subtropical regions, particularly Asia and Southeast Asia. Intestinal sarcocystosis in humans has been reported more frequently in humans in Europe. In a study in children from Germany, 10.4% and 7.3% were positive for intestinal sarcocystosis. In another study in Tibet, more than 42% of beef samples collected from a marketplace had sarcocysts and when fecal samples of locals were examined, 21.8% were positive to *S. hominis*.

A very high percentage (80% or more) of *Sarcocystis* infection has been reported in several domestic and companion animals including cattle, sheep, camels, pigs, goats, water buffalo, and yaks. Potential and unknown sources of sarcocystosis include camels, llamas, water buffalo, yaks, and pigs (other than domestic *Sus scrofa*). Meat from reptiles, birds, and wild mammals may also be a source of this infection in humans. Dogs and cats could also excrete sporocysts infectious to humans.

Sarcocystis can be acquired by ingestion of raw or undercooked meats containing sarcocysts. The infectious dose for *Sarcocystis* is unknown; however, in Chinese volunteers fed with less than 2000 sarcocysts developed symptoms within 1 week. In another study in Germany, 11 medical students and seven members of staff ate raw pork meat containing various concentrations of sarcocysts. The symptoms on day 2 were the same for all the participants, but the severity of the illness seemed to be related to the amount of contaminated meat ingested. Those that ingested a low number of sarcocysts were asymptomatic but clinical presentation varied according to the individual.

Prevention and Control

Intestinal sarcocystosis can be prevented by thoroughly cooking or freezing meat. Infected pork and beef products were noninfectious when cooked at high temperature (more than 60 °C for at least 20 min) or frozen for 48 h at -4 °C and 24 h at -20 °C before feeding to dogs. Under controlled experimental conditions, anticoccidial drugs such as amprolium and salinomycin have been effective in precluding acute illness and death in infected calves and lambs. Therefore, in order to prevent *Sarcocystis* infection in humans, animals for human consumption should not be exposed to contaminated water and feed containing *Sarcocystis*. If this is not feasible, meat of these animals should be thoroughly frozen for at least 2 days or fully cooked to kill pathogenic infectious parasites. Municipal water treatment procedures are generally effective at stopping *Sarcocystis* from contaminating tap water. However, if water control measures of municipal and well water are breeched, additional kill steps should be taken to prevent contamination. Boiling water can inactivate the oocysts that may be present in drinking water. These precautionary measures should control and prevent the *Sarcocystis* infection.

PROTOZOA

Toxoplasma gondii

EM Hanafi, National Research Center, Cairo, Egypt
A Taylan Ozkan, Refik Saydam National Public Health Agency, Ankara, Turkey
DD Bowman, Cornell University, Ithaca, NY, USA

Glossary

Bradyzoite The slowly dividing forms of *Toxoplasma gondii* that persist in cells within tissues of the body, including muscle; these forms are enclosed in a cyst wall and are resistant to degradation by digestive enzymes. This is the stage in meat that transmits the infection when meat is eaten undercooked or raw (Greek, *brady* = slow; *zoite* = small life).

Oocyst The stage of *T. gondii* in the feces of cats that is responsible for transmission of the parasite through contaminated soil, water, or food. This is an environmentally resistant stage that is surrounded by a resistant wall (Greek, *oo* = egg, and *cyst* = cyst).

Paratenic host These are hosts that serve to increase the transmission of a parasite to its final host. In the paratenic host, the parasite may undergo multiplication or development, but they are not required for transmission. (The feline final host can be infected either via the ingestion of infective oocysts directly or by the ingestion of hosts containing bradyzoites, i.e., paratenic hosts; the paratenic host is not required for the completion of the life cycle of this species.) Infections in paratenic hosts can be passed from host to host, such as mouse, to rat, to ultimately the final host, the cat.

Sabin-Feldman dye test (SFDT) A test based on the presence of certain antibodies that prevent methylene blue dye from entering the cytoplasm of *Toxoplasma* organisms; it is used for serologic diagnosis of toxoplasmosis.

Tachyzoite The stage of *T. gondii* that divides rapidly in many cell types during acute infections, before rupturing the cells and infecting additional cells (Greek, *tachy* = fast; *zoite* = small life).

General Information

Toxoplasma gondii is an obligate intracellular parasite of virtually any nucleated cell of warm-blooded vertebrates. The definitive host of *T. gondii* is the cat and related wild felids; these are the only hosts that shed stages into the environment to contaminate pastures, food items, and water. People get infected through the ingestion of oocysts. However, because the parasite can be in the tissues of warm-blooded vertebrates, including pigs, sheep, goats, chickens, etc., people can also be infected through the ingestion of undercooked or raw meat. Tragically, whatever the route of infection, the establishment of a primary infection in a pregnant woman can have marked effects on the developing fetus that may become infected *in utero*. Rare forms of transmission to people have also included tissue transplantation and blood transfusions. The ingestion of raw goat milk and human milk has been linked circumstantially to the transmission of infection.

In summary, infections in humans occur primarily in four different ways (Figure 1):

1. Accidental ingestion of the oocysts that have developed to the infective stage a day or so after being passed in the feces of cats (touching hands to mouth after gardening, cleaning a cat's litter box, or ingesting something contaminated with sporulated oocysts).
2. Ingestion of infective stages in animal tissue through the consumption of raw or undercooked meat, or raw milk, from infected animals.
3. Transmission from mother to fetus.
4. Transmission through organ transplants or blood transfusions.

History

In 1908, Nicolle and Manceaux in studies on leishmaniasis at the Pasteur Institute in Tunisia, found an organism in the tissues of a hamster-like rodent, the gundi, *Ctenodactylus gundi*. They named the new organism *Toxoplasma gondii*, based on the morphology (*toxo* = arc or bow, *plasma* = life or form, Greek) and the host in which it was found. At about the same time, Splendore discovered the same parasite in a laboratory rabbit in Brazil, and Darling observed the first human case in Panama. In 1923, the first case of congenital toxoplasmosis was recognized in the retina of a blind, hydrocephalic 3-month-old child in Prague. The role of this parasite as a human pathogen became more widely known in the 1930s and 1940s after it was reported as the cause of encephalitis in a child who died after birth, and descriptions of fatal cases in adults. The 'dye test' developed during this time by Sabin and Feldman for the detection of infection supplied much of our

 doi:10.1016/B978-0-12-378612-8.00138-4

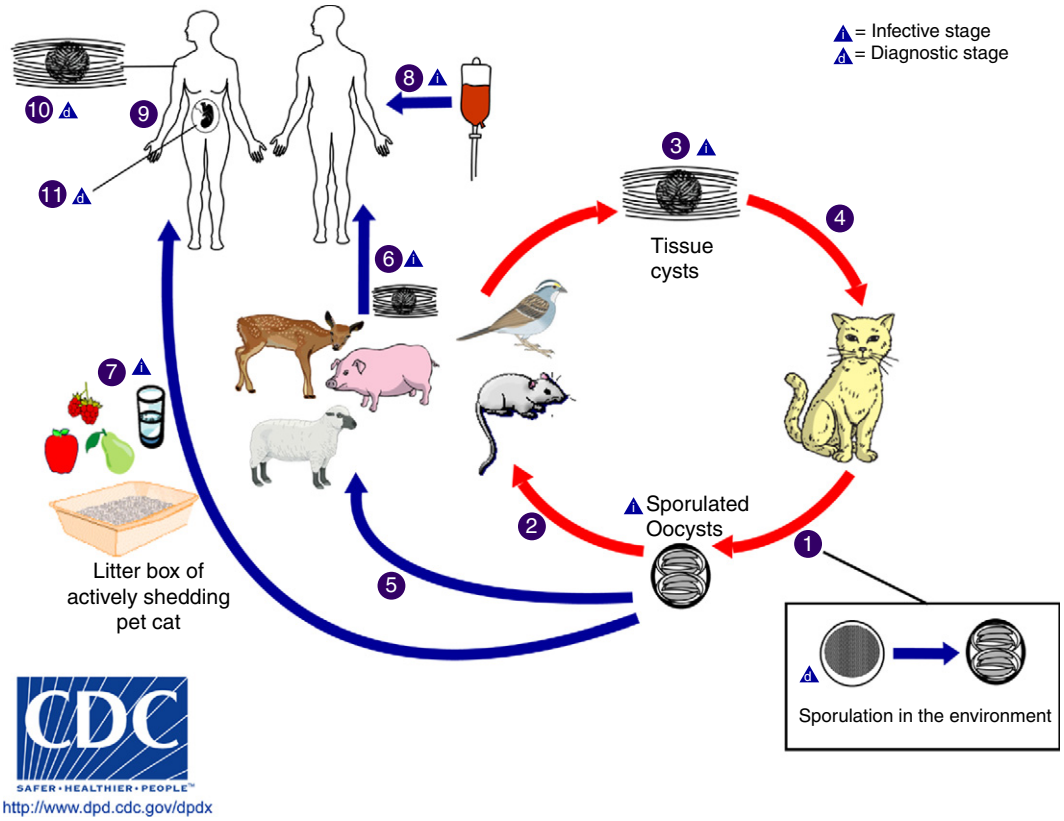

Figure 1 Life cycle and epidemiology of *Toxoplasma gondii*. (1) The only known definitive hosts are members of family Felidae (domestic cats and their relatives). Unsporulated oocysts are shed in the cat's feces. (2) Although oocysts are usually shed only for 1–2 weeks, large numbers may be shed. Oocysts take 1–5 days to sporulate in the environment and become infective. Intermediate hosts in nature (including birds and rodents) become infected after ingesting soil, water or plant material contaminated with oocysts. (3) Oocysts transform into tachyzoites shortly after ingestion. These tachyzoites localize in neural and muscle tissue and develop into tissue cyst bradyzoites. (4) Cats become infected after consuming intermediate hosts harboring tissue cysts. (5) Cats may also become infected directly by ingestion of sporulated oocysts. Animals bred for human consumption and wild game may also become infected with tissue cysts after ingestion of sporulated oocysts in the environment. Humans can become infected by any of several routes: (6) eating undercooked meat of animals harboring tissue cysts; (7) consuming food or water contaminated with cat feces or by contaminated environmental samples (such as fecal-contaminated soil or changing the litter box of a pet cat); (8) blood transfusion or organ transplantation; or (9) transplacentally from mother to fetus. (10) In the human host, the parasites form tissue cysts, most commonly in skeletal muscle, myocardium, brain, and eyes; these cysts may remain throughout the life of the host. Diagnosis is usually achieved by serology, although tissue cysts may be observed in stained biopsy specimens. (11) Diagnosis of congenital infections can be achieved by detecting *T. gondii* DNA in amniotic fluid using molecular methods such as PCR.

knowledge on the prevalence of *T. gondii* in people through the monitoring of serum for antibodies to *T. gondii*.

It was in 1960 that Leon Jacobs and others suggested that transmission of infection might occur through the ingestion of undercooked meat, and supported this idea by demonstrating the resistance of *T. gondii* from tissue cysts to proteolytic enzymes. Studies then identified various food-animals as being infected with this parasite. Then, a small outbreak of disease was described in a group of medical students at Cornell University in New York, NY, USA, who had eaten undercooked hamburger. The ingestion of meat and vertical transmission during pregnancy were the only means of transmission that were known for the next 10 years.

In 1969–1970, it was shown that a stage passed in the feces of cats was capable of transmitting infection with this agent. Dr JP Dubey who was involved with this work published a recent review of the history of these events. The cat was first implicated as a potential source of infection when it was shown that transmission involved the shedding of a stage called 'oocysts' in the feces of cats. Later work revealed that cats excrete oocysts into the environment following either the ingestion of oocysts or by the ingestion of bradyzoites in the tissues of prey animals such as mice and birds.

Life Cycle

Relative to food safety, three stages in the life cycle of *T. gondii* are of most importance: the oocyst, the bradyzoite, and the tachyzoite. The oocyst is the environmentally resistant stage shed in the feces of cats. The oocyst is not infectious when passed, but requires a day or longer in a soil or water environment where with warmth, moisture, and sufficient aeration, the contents of the oocyst sporulate to produce the

infectious sporulated oocyst. The sporulated oocysts contain sporozoites that will infect a host on the ingestion of an oocyst. The bradyzoite is the 'dormant' stage that is found in the tissues of warm-blooded vertebrates, and is the stage obtained by the consumption of contaminated meat. Ingestion of either sporulated oocysts or bradyzoites by a human, results in an in infection with the rapidly dividing tachyzoite stage. After a series of multiplications as tachyzoites in various tissues, the organisms will undergo a change to the bradyzoite form that will slowly divide within cells and form the cysts that can contain thousands of bradyzoites. It is the tachyzoite form that causes acute disease in people. This is the stage that rapidly multiplies in many cells of the host, crosses the placenta to infect prenatally, and is responsible for disease in acute infections, including people who are infected via transplantation and blood transfusion, and in cases of new infections and recrudescences in the immunocompromised.

These three stages vary in their resistance to environmental extremes. The oocysts in the environment are quite resistant to environmental and chemical destruction. Oocysts will survive dilute bleach or chlorine, but are readily destroyed by desiccation or high temperatures. The oocysts can persist in moist environments for months to years. The bradyzoites are resistant to pepsin digestion (compared with tachyzoites), which provides their ability to infect a host following ingestion and passage through the stomach. The tachyzoites have the function of undergoing rapid multiplication within cells for the purpose of increasing numbers and infecting more cells before being controlled by the host's immune system, thus they are the stage that is most sensitive to environmental conditions outside the body of a warm-blooded vertebrate.

Prevalence in People

A recent review of infections in people shows that, internationally, various countries have prevalence rates that can vary anywhere from less than 10% to more that 60% of the population (Figure 2). It can be assumed that the majority of asymptomatic infections are acquired from the ingestion of oocysts in water, food or soil, or tissue cysts in meat, because prenatal infections are often associated with sequelae that manifest as disease. In Turkey, seropositivity by the Sabin-Feldman dye test (SFDT) to toxoplasmosis was 42.5% in healthy blood donors.

Risk of congenital toxoplasmosis varies greatly with the area where the studies have been performed. In Brazil, some 9 (95% confidence interval 6–13) of 10 000 newborn infants were infected congenitally with *T. gondii*, and among 200 newborns who had been exposed to *T. gondii in utero*, the maternal to fetus transmission rate was found to be 18.5%. In the Netherlands, the rate of congenital infection was found to be approximately 20 newborns per 10 000 births. Other incidence studies have shown rates of congenital toxoplasmosis of 0.7/10 000 in Sweden, 0.8/10 000 in Massachusetts, USA,

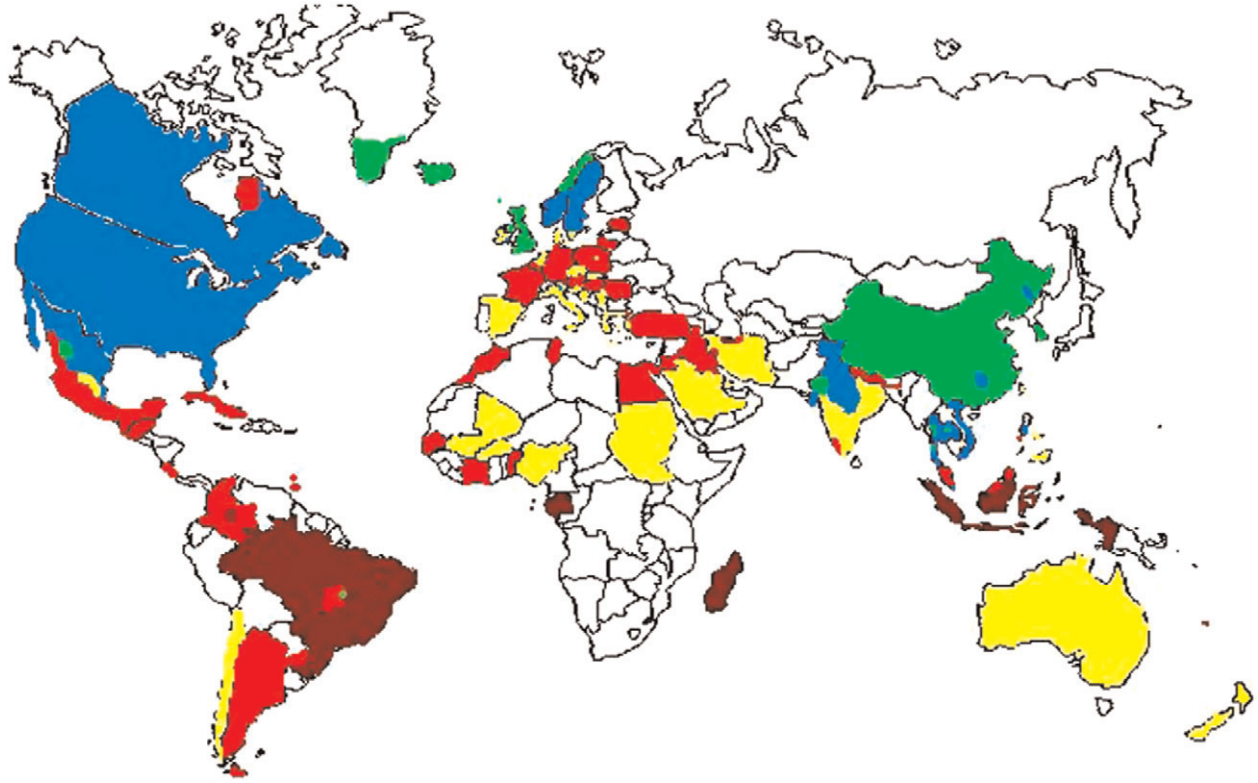

Figure 2 Global status of *Toxoplasma gondii* seroprevalence. Dark red equals prevalence above 60%, light red equals 40–60%, yellow 20–40%, blue 10–20%, and green equals prevalence <10%. White equals absence of data.

0.8/10 000 in London, England, 1.2/10 000 in Switzerland, 3/10 000 in Spain, 4/10 000 in Denmark, 11/10 000 in Poland, and 19 to 32/10 000 in Paris, France.

Foodborne Transmission

Dr Dubey (2010) recently published the second edition of his book *Toxoplasmosis of Animals and Humans* where he summarizes the literature and presents in-depth tables on the serology of food animals for the prevalence of infections from around the world. He has articles on sheep, goats, pigs, cattle, water buffalo, horses, camels, chickens, Australian marsupials, marine mammals, deer, and bears; other chapters cover humans, cats, dogs, wild canids, rodents, and various wild animals, including antelope and bats. For the sections that follow, this information is a targeted summary of Dr Dubey's in-depth articles that are fully referenced.

As described below, the animals that are important potential sources of infection through meat are sheep and lambs, goats, and camels. Pigs and chickens raised in commercial large-scale facilities are virtually *T. gondii*-free, but these animals are likely sources of oocysts if the animals are raised outdoors. Work in Europe has shown that the management of commercial hogs under organic conditions can produce *T. gondii*-free meat if careful attention is paid to rodent control and preventing the access of cats. Cattle and horses do not appear to be significant as food-animal sources of toxoplasmosis. People are also likely to be infected directly from soil or from the ingestion of unwashed fruits and vegetables contaminated with soil. Recently, it has also been shown that waterborne transmission may be more common than once believed.

Transmission via Meat

The prevalence of *T. gondii* in different hosts will vary depending on how they are raised; animals on pastures have easy access to oocysts as opposed to animals in confinement facilities with adequate biosecurity in place. Thus, sheep, goats, horses, and camels that tend to be pastured for the most part wherever they live in the world are likely to have infections from oocysts. Although, however, in much of the developed world, pigs and chickens are often raised indoors on large farms where they have only a slight chance of getting toxoplasmosis. However, if these same hosts are raised outside, as they are by smallholders in the developed world and throughout much of the developing world, they are very likely to acquire infections with *T. gondii*. It appears that cattle are not important in the epidemiology of toxoplasmosis even though they are raised on pasture.

1. Cattle: Although cattle have been diagnosed as serologically positive for *T. gondii*, there have been very few successful isolations of the organism from beef. Dr Dubey reports that although he isolated *T. gondii* from one seropositive cow, the muscle tissue was not infectious to cats (12 cats fed 6 kg of beef) nor to 150 infected mice. A homogenate of the intestinal mucosa was found to contain *T. gondii* that produced an infection in mice. In a survey of beef in the US, 2094 meat samples from commercial grocery stores were fed in pools (100 g from each of six beef samples) to 350 cats. None of the cats shed oocysts. Attempts to isolate *T. gondii* in Uruguay by feeding 20 g beef samples to cats failed to isolate any organisms. Polymerase chain reaction (PCR) performed on meat in Switzerland did detect *T. gondii* DNA in meat of 3% of adult cows, 6% of 50 heifers, 2% of 100 bulls, and 1% of 100 calves.
   Dr Dubey states in his text that beef does not appear to be important in the epidemiology of foodborne toxoplasmosis, but it cannot be ruled out. There are two reports from more than 30 years ago that link infection to the consumption of raw beef, in one case in five medical students mentioned above who bought meat from a butcher who claimed that pork contamination was highly unlikely, and three people who developed toxoplasmosis after eating raw beef in a Syrian restaurant in Pennsylvania.
2. Sheep: Sheep are known to be infected with *T. gondii* because it induces abortions in pregnant ewes, and organisms can be found in the placenta and fetuses. Sheep have high serologic titers to *T. gondii* throughout the world. *T. gondii* has been isolated from the tissues of sheep in Brazil, the US, France, England, Denmark, Egypt, and Iran. In Switzerland, *T. gondii* DNA was detected by PCR from 6% of 150 sheep.
3. Goats: Goats appear similar to sheep in having persistent infections with *T. gondii* and in having abortions associated with infections obtained during pregnancy. As with sheep, *T. gondii* has been isolated from tissues of goats. In Italy, attempts to isolate *T. gondii* from 10 seropositive goats failed. However, overall it is believed that goats harbor the organisms in a fashion similar to sheep.
4. Camels: Camels have been examined serologically in Egypt (two studies, 25.3 and 17.4%), Iran (4.2%), Saudi Arabia (two studies, 16 and 0%), and Sudan (67%). *Toxoplasma gondii* infections have been identified in camels in Egypt by feeding meat from the tissues of 38 asymptomatic camels to 4 cats. The oocysts recovered were verified to be *T. gondii* by bioassay in mice. The only report of disease in a camel is from Iowa, USA, where the animal became ill approximately a month after becoming anorectic and aborting a near-term fetus. This camel developed fluid in the thoracic cavity that contained numerous tachyzoites of *T. gondii*. The camel was treated with trimethoprim sulfadiazine but still succumbed. A necropsy was not performed.
5. Horses: Horses have been shown to be serologically positive for *T. gondii* around the world. A low seroprevalence (less or equal to 1%) of anti-*Toxoplasma* antibodies has been observed in horses in some European countries. Higher antibody prevalences have been observed in Turkey, and it has been suggested that the major risk for horses becoming infected is farming as opposed to animals held for racing.
   There have been no isolates of organisms made from horses. Two horses inoculated intravenously with tachyzoites of the RH strain of *T. gondii* in Brazil developed transient fever 4–8 days postinoculation, but had no

organisms detectable in the tissues at 3 months post-inoculation. There is a report of transplacental transmission of *T. gondii* in a pregnant horse fed oocysts. Thus, overall, it would appear that horses pose little threat of transmission of *T. gondii* through the consumption of their meat.

6. Pigs: Serologically, the prevalence in pigs around the world is quite high. This is due to pigs coming into contact with oocysts from cats as they root in soil, and probably through the ingestion of rodents. In pigs in poorly managed farms, the prevalence of infection will be higher than in well-managed farms. The recent trend to move pigs back outdoors will likely increase the rate of infection in pigs. In a study in the Netherlands, 0 of 621 conventionally raised indoor pigs, 8 of 660 organic pigs, and 30 of 635 free-range pigs were found to be serologically positive for *T. gondii*. Seventy-two percent of the organic farms did raise *T. gondii*-free pigs. However, a number of the organic farms, and the farms that had free-range pigs, kept cats for rodent control, and this probably provided a source of oocysts for the pigs.
   It has been possible to recover *T. gondii* from pigs on numerous occasions. Organisms have been recovered from pigs in Argentina, Brazil, Uruguay, Austria, Portugal, the Czech Republic, Yugoslavia, and the US. In a sampling of 2094 commercial meat samples from grocery stores in 28 metropolitan areas in the US that was fed in pools to cats as a bioassay, *T. gondii* was isolated from seven of the samples, i.e., from 0.3%. In a sampling of 2800 pig hearts in Canada, there were no *T. gondii* isolated, although 8.6% of these pigs were serologically positive for *T. gondii*.
7. Chickens: Chickens that are raised in backyard flocks have an excellent chance of being serologically positive for *T. gondii* and having organisms in their tissues. In samplings of a number of free-range chickens from around the world, *T. gondii* was isolated from up to 16% of the birds. When chickens were kept indoors, the numbers were markedly less, and a number of samplings had no organisms being isolated. There was no positive breast meat in the 2094 meat samples from grocery stores in the US where the samples were pooled and fed to cats as part of the bioassay. Overall, commercial chicken meat in the US and elsewhere where the chickens are raised in confinement appears basically free of *T. gondii*, whereas outdoor chickens have a very high chance of containing organisms in their tissues. The prevalence of *T. gondii* in chicken eggs is extremely low, and the consumption of raw eggs is not considered an important risk for toxoplasmosis.
8. Wild animals: *Toxoplasma gondii* organisms have been found in muscles of naturally infected deer, bear, moose, and pronghorn antelope, and can encyst in elk. Thus, wild animal meat can serve as a source of infection for hunters and their families, especially when care is not taken while eviscerating and handling, or when their meat is served undercooked. More importantly, viscera and meat scraps left at the site of the kill could serve to infect cats and further spread *T. gondii* in the environment.
9. Marine mammals: The finding of *T. gondii* in marine mammals deserves mention. The marine environment is contaminated with *T. gondii* oocysts, and fish-eating marine mammals are found infected with *T. gondii*. The prevalence of *T. gondii* infection in susceptible marine mammals can be quite high, with prevalences of 36% in sea otters, 42% in sea lions, 16% in ringed seals, 50% in bearded seals, 11.1% in spotted seals, 98% in Atlantic bottlenose dolphins, and 6% of 53 walruses using an IFAT.
10. Australian marsupials: Australian marsupials are highly susceptible to infection with *T. gondii* and many have died in zoos around the world from acute disease due to oocyst ingestion. Kangaroos have died following attempted vaccination with the attenuated vaccine that is used to prevent the disease in sheep in Europe. Organisms have been isolated from harvested kangaroos in Tasmania. Also, kangaroos, wallabies, bandicoots, and wombats have been found to be serologically positive for the infection, suggesting chronic infections with bradyzoites.

Transmission via Milk

Milk was implicated as a source of infection of *T. gondii* in several reports. *Toxoplasma gondii* was detected in the milk of goats that were experimentally inoculated during lactation. *Toxoplasma gondii* tachyzoites were found in the milk of ewes and cows, and an infection has been described in a breast-fed child whose mother had recently acquired the infection. Also, camels experimentally infected with *T. gondii* oocysts can excrete the tachyzoites in their milk, and *T. gondii* cysts were also detected in the brains of milk inoculated mice and suckling camel calves. The presence in milk, and the ability of some tachyzoites to survive for up to 2 hours in pepsin digest solutions may be of public health significance for nomads and others who choose to consume raw milk. However, other agents in raw milk can also be harmful, so there are many good reasons for pasteurizing or boiling milk before it is consumed.

Transmission via Fruits and Vegetables

Cats, both domestic and wild, are the sole source of environmental contamination. Many farms own cats for rodent control and many people have cats as pets. From six pig farms in the USA, cat feces, feed, and water samples have been found to contain the oocysts of *T. gondii*. Calculations made for the state of California, USA, has suggested that the annual burden of oocysts produce by cats in that state is 94 to 4671 oocysts per square meter.

The high prevalence of infection, based on serology, in groups of vegetarians, reaching almost 50%, provides evidence that oocysts represent an important source of infection in humans. Infection may occur by working in soil containing oocysts, as when gardening, or eating unwashed fruits or vegetables (shown to be a risk factor in a study with pregnant women). Also, in the US, a large serological survey of people by the Centers for Disease Control and Prevention in Atlanta, GA, for *T. gondii* and the soil transmitted nematode *Toxocara canis*, found the odds ratio equal to approximately 2.0 (meaning that one was twice as likely to be infected with the

second agent if they already had the other), which is an indication that *Toxoplasma* may be acquired in the same manner as *T. canis* which is considered unlikely to be transmitted in meat.

Waterborne Transmission

The first verified waterborne outbreak occurred in 1979 amongst US Army soldiers during training exercises in Panama, who drank unfiltered water from streams contaminated with oocysts, which were likely from jungle cats. In 1995, a large outbreak occurred associated with a single water reservoir in Victoria, British Columbia, Canada. There were some 100 people known to be affected, of which 19 had retinitis and 51 had lymphadenopathy. Based on routine serological screening done on pregnant women in the area served by the reservoir, and controls from other regions, it was estimated that some 2900 to 7700 people had been infected during the outbreak. In another large outbreak in Brazil, 155 people are believed to have been infected drinking unfiltered water from an underground storage tank. The water was contaminated by oocysts washing into the tank, and the water was shown to contain oocysts by both PCR and bioassay. Other places where waterborne toxoplasmosis has been suggested or implicated include Columbia, India, Poland, Turkey, Cuba, Granada, Taiwan, and China. There is some indication that endemic toxoplasmosis, as opposed to outbreaks, may be due to the drinking of unfiltered municipal water or well water. There is also some suggestion that recreational waters may also be a source as they are for *Giardia* and *Cryptosporidium*. It may be that the large number of cases of toxoplasmosis in developed countries that cannot be explained by foodborne or soil transmitted infections may be due to waterborne oocysts.

Food-Associated Risks for People

There have been reports from around the world of people being infected by many different foods of animal origin, including: dried seal meat, seal liver, raw caribou meat, rare kangaroo meat, undercooked lamb satay, raw mutton, raw spleen and liver of domestic pigs and wild boars, and others. These studies indicate that transmission of the parasite to humans is influenced not only by the potential contamination of various food sources, but also by the individual behavior of consumers in different ethnic groups and geographical regions. General eating habits have a significant impact because, among the major food animals, viable *T. gondii* has been found in pork, mutton, chicken, and horse meat and the proportion of human beings with *T. gondii* infection from these meats is higher in populations that eat undercooked meat (European and Asian) than in populations that thoroughly cook meat before consumption (Oriental and African). Of course, the background prevalence in the animals being eaten will also play a role; if people eat rare pork in an area with a high prevalence of *T. gondii* in the pigs, then the chance of acquiring an infection will be greater than in another country where commercial pork is virtually *Toxoplasma* free. Also, it is possible for animals to be seropositive and not have cysts in their tissues. Thus, beef and buffalo meat rarely contains viable organisms, although these animals may have a very high level of seroprevalence in some areas. However, if animals such as pigs, sheep, and goats are seropositive, they are very likely to contain infectious tissue cysts. Of course, people who are strict vegans and infected with *T. gondii* have acquired their infections from oocysts, whether in soil due to poor hand hygiene, ingesting oocyst contaminated fruits and vegetables, or drinking contaminated water. Overall, gustatory habits and hygiene are more important than other socio-cultural factors for preventing foodborne toxoplasmosis.

Travelling from an area of low risk to a region of high risk is another factor that can increase one's chances of acquiring a primary infection with *T. gondii*. Usually people tend to change their habits when entering different environments, and thus, they may become temporarily at risk from sources of infection that are not important epidemiologically in their home situation. Likewise, changing eating habits and developing preferences for new food types may impact the potential sources of foodborne infections with *T. gondii*, for example, meat from camels and kangaroos, which are often served undercooked in restaurants in areas where they are found, is a potential new source of infection for non-indigenous visitors.

Detection in Animals, Meat and Environmental Samples, and Determination of Clonal Types

The *T. gondii* infective stages are present in low numbers in contaminated water and foods, so rapid and sensitive methods are necessary for their detection. Tissue culture and animal models available for *Toxoplasma* are time-consuming, expensive, and labor-intensive. Therefore, PCR amplification has become the preferred method. Most PCR assays used for *T. gondii* identification use primers targeting the *B1* gene. It is a 35-fold-repetitive gene that is highly specific and conserved among strains of *T. gondii*. Ultimately, it is hoped that the determination of clonal types may elucidate the ability to assess the potential virulence of a specific isolate and will lead to means of tracing infections back to the specific source.

Detection in Meat and Determination of Viability

There are several means by which *Toxoplasma* can be detected in meat. Some of these assays monitor the presence of antibodies in sera, body fluids, or tissue juices, some examine tissue for the presence of organismal DNA, and some assess the presence of infection by inoculation of tissue into other hosts. Some of these assays identify animals as having an infection (serology and PCR), whereas other assays assess the presence of viable organisms in the tissue (mouse inoculation and the feeding of tissue to cats); often detection by PCR is considered as indicative of an infection with viable organisms.

The most commonly used methods to assess prevalence have utilized the sera of animals to determine the presence of antibodies. In animals, the detection of chronic infections often relies on serological testing with the fairly species-independent modified agglutination test (MAT). The other assay

that is commonly used to determine the serologic status of infection has been the enzyme-linked immunosorbent assay (ELISA), where the typical antigen that is used is the crude soluble extract of tachyzoites. This assay has also been adapted to work with meat juice. The ELISA-type tests, as opposed to the MAT, require the availability of secondary antibodies that recognize individual species such as cow, sheep, pig, etc.

The development of the PCR has made it possible to detect DNA in the tissues of animals. This can be done before or after pepsin digestion of the meat. The material is then subjected to PCR with different primers. Unlike the MAT or ELISA, this methodology detects the presence of DNA from actual organisms. The typical primers that are used are the B1 primer, for which there are 35 copies in the genome, and a 529 base-pair fragment, for which there are 300 copies in the genome, the latter being 10 to 100 times more sensitive than the B1 primer. Although it is likely that the recovered DNA is from living organisms, it is possible that they are nonviable and that simply the DNA remains.

Viability is typically detected through the inoculation of mice with ground tissues or material concentrated by pepsin digestion of tissue, or feeding the suspect tissues to cats that are never known to have been exposed to *T. gondii*. Mice are inoculated either intraperitoneally or subcutaneously. After the mice are infected, they need to be monitored closely. If the mice die during the first 2 weeks of infection, tachyzoites can be found in peritoneal washes and in stained tissue press preparations. After 2 weeks, the organisms become scarcer, and over several weeks it may be somewhat difficult to tell if the mice are infected. If the mice live, organisms can be found in brain tissue following grinding and dispersion in saline or presses of small amounts of tissue between microscope slides. In some cases, the infection of mice can also be monitored using serology using either the MAT or an ELISA for mouse IgG. Cats can be used for bioassays by feeding them tissue from animals; cats can be fed up to 500 g of flesh, whereas a mouse inoculum is usually restricted to approximately 0.25 g. After infection, the feces of cats are monitored for the presence of oocysts by daily fecal examination for several weeks beginning several days after the cat is fed the meat.

Detection in Water or Food

The detection of *T. gondii* oocysts in water is difficult. The problem is that the numbers are small and, unlike the case for *Cryptosporidium* oocysts and *Giardia* cysts, there are no immunomagnetic beads to aid in the diagnosis. *T. gondii* was successfully isolated from a waterborne outbreak in Brazil from small reservoirs held on roofs. This was done by filtering the water through membrane filters and then feeding the filters to *T. gondii*-free pigs and chickens. The chickens and the pigs fed with the filters developed *T. gondii* infections. Chickens have been utilized to sample soil for the presence of oocysts by allowing them to feed from the ground in areas where the oocysts might be present; this has also allowed the sampling of different areas for the presence of different genotypes of the organism using oocyst-derived infections.

Molecular Characterization of Different *Toxoplasma gondii* Genotypes

In North America and Europe, the majority of the isolates of *T. gondii* obtained from humans and livestock appear to fall into three clonal lineages. The three *T. gondii* lineages or genetic types are called I, II, and III. In North America and Europe, type II is most commonly associated with human toxoplasmosis, both in congenital infections and in patients with AIDS. Several studies have indicated that the majority of isolates from agricultural animals are also type II, including pigs in the USA and sheep from Britain and France. Chickens in North America show a higher prevalence of type III strains than type II, consistent with an early survey that indicated both type II and type III strains being common in animals. The reasons for the apparent differences between animal (types II and III) and human (largely type II) infections are unclear. More recent surveys, using an expanded set of restriction fragment length polymorphism (RFLP) markers, have indicated that although the majority of isolates from sheep in North America are type II, a number of other distinct genotypes are also present. Also, i South America, there appears to be a greater diversity of genotypes than elsewhere. It has not yet been possible to directly identify specific types with specific signs or disease outcomes in humans or animals. Also, at this time, the molecular methods used in toxoplasmosis do not seem to generate the same type of molecular fingerprinting that allows trace-backs to occur when associated with discovering the source of outbreaks. However, it is likely that methods will soon become available for *T. gondii* that may help indicate from what specific source an individual has acquired his or her infection.

Risks from Food Animals

Foodborne toxoplasmosis in humans may result from exposure to different stages of *T. gondii*. Thus, besides infections obtained from oocysts, infection can also occur from the ingestion of tissue cysts or tachyzoites contained in the meat of food animals. It is likely that transmission of the parasite to humans is influenced not only by the potential contamination of various food sources, but also by the individual behavior of consumers in different ethnic groups and geographical regions.

Pigs

Infected pork is an important source of *T. gondii* infection for people in many countries. This parasite also causes mortality in pigs, especially neonatal pigs. Most pigs acquire *T. gondii* infection postnatally by ingestion of oocysts from a contaminated environment or ingestion of infected tissues of animals. Pigs infected experimentally by inoculation of tachyzoites or by the ingestion of oocysts or tissue cysts, undergo weight loss, anorexia, and fever, but generally recover after three weeks. *T. gondii* organisms can survive in living pigs for more than 1 year after experimental infection.

Sheep

Among livestock, toxoplasmosis causes its greatest losses in sheep. *Toxoplasma gondii* may cause embryonic death and

resorption, fetal death and mummification, abortion, stillbirth, and neonatal death in these animals. Antibodies to *T. gondii* have been found in sheep with high prevalence rates worldwide. The prevalence of antibodies in ewes was more than twice that in lambs, and seroprevalence was shown to increase with age, reaching 95% in 6-year-old ewes in some flocks. A few studies analyzed risk factors associated with *T. gondii* seropositivity in sheep, and found the important factors to be the presence of cats on a farm, the use of surface water for drinking. Farm size and altitude were also factors associated with infection rates, with prevalences being higher at lower altitudes and on larger farms.

Goats

Infection with *T. gondii* in goats not only results in significant reproductive disorders, such as abortion or neonatal mortalities, but also has implications for public health because consumption of infected goat meat can facilitate zoonotic transmission. *Toxoplasma gondii* is pathogenic for goats, and the parasite has been detected from soft tissues such as brain, cardiac muscle, liver, lungs, lymph nodes, and diaphragm. The microscopical lesions consist of multifocal necrotic areas in most tissues. Symptoms in goats include acute enteritis, necrosis of mesenteric lymph nodes, encephalomyelitis, interstitial pneumonia, and necrotic placental lesions with groups of numerous *T. gondii* tachyzoites and sometimes tissue cysts.

Poultry

Although *T. gondii* cysts may be found in edible tissues of poultry products, they are probably not important in the transmission of toxoplasmosis to human beings because these products are usually frozen for storage and are thoroughly cooked to avoid diseases that could be caused by contamination with other organisms. A recent paper reviewed worldwide reports of clinical toxoplasmosis in experimentally and naturally infected chickens and concluded that clinical toxoplasmosis is rare in chickens. However, free-range chickens are considered important indicators of soil contamination with the environmentally-resistant oocysts, and so may serve as a source of *T. gondii* infection in cats, and possibly in humans.

Beef (Cattle and Buffaloes)

Currently, it is believed that beef (and probably buffalo meat) play a very small role in the epidemiology of toxoplasmosis. It appears that this niche in cattle is filled by *Neospora caninum* with its dog–bovine cycle. *Neospora caninum* is not zoonotic.

Horses Used for Food

Currently, horses, like cattle, are considered of little or no importance in the epidemiology of toxoplasmosis, even in countries where horse meat is eaten.

Prevention and Control

Animal Production Practices

Keeping cats out of the animal barns, and housing animals indoors, can reduce *T. gondii* infection. It is also important to keep rodents out of barns as they are likely a source of infection in pigs (via tissue cysts). Producers should also avoid garbage feeding. As a result of changes in animal husbandry, the prevalence of viable *T. gondii* in animals is reduced, and hopefully, this will also reduce the prevalence of *T. gondii* in humans.

Food Processing and Preparation Practices

Vegetables should be washed thoroughly before eating because of possible contamination with soil, and people should wash their hands thoroughly with soap and water after handling potentially contaminated soils or meat. Before consumption, meat should be cooked until a temperature of 66 °C (151°F) has been reached. Heating at 60 °C or 100 °C for 10 min, freezing at either − 10 °C for 3 days or − 20 °C for 2 days, or irradiation at doses of 75 or 100 krad kills tissue cysts. The cysts of bradyzoites can be killed by freezing at − 12 °C, but at 4 °C to 6 °C, the cysts can survive for up to 2 months.

Cats

Cats should be fed only dry, canned, or cooked food, and never be fed uncooked meat, viscera, or bones. Efforts should be made to keep pet cats indoors to prevent hunting. Also, spaying and neutering is important to try and reduce as much as possible the burgeoning feral cat populations around the world. Seronegative pregnant or immunocompromised individuals should avoid cleaning the cat's litter box, especially before the consumption or preparation of food. Also, because younger animals are more likely to be seronegative and shed oocysts if infected, these households should not consider the adoption of a kitten, whereas an older cat in the household has probably already been infected with *T. gondii* and is unlikely to shed oocysts.

Vaccination

The only vaccines available for *T. gondii* are to prevent abortion in sheep and neonatal mortality in lambs. This vaccine, Toxovax® (MSD Animal Health), is available in Europe and New Zealand. The vaccine contains attenuated tachyzoites that does not persist in tissues of sheep. Ewes vaccinated with the S48-strain vaccine can retain immunity for at least 18 months. Attempts to date to produce a commercial vaccine to stop oocyst shedding by cats have not been successful. At this time, it is unlikely that a vaccine will be developed to prevent infections in humans, but the development of recombinant vaccines that would prevent fetal damage during pregnancy are being considered. Other objectives of vaccination would be to prevent the development of bradyzoites in pigs or other animals. These vaccines remain fairly theoretical at this point in time, but they would be embraced by the industry if developed.

Serologic Screening During Pregnancy

Serologic screening in women during pregnancy is an important way to reduce the transmission of *T. gondii* to the fetus. This tends to be cost effective in countries with a fairly high prevalence, but becomes cost ineffective in areas where there are low prevalence rates. When women are found to seroconvert during pregnancy, they can be treated to protect the developing infant.

Consumer Education

Of major importance to the consumer is that the meat of some animals represents a potential source of infection if their meat is consumed raw or poorly cooked. In many parts of the world, people prefer raw or undercooked pork and mutton, and these are important sources of infection if the meat comes from producers that have not been carefully controlled for the presence of cats within the area where the animals are reared. Unfortunately, there is not yet a means of certifying the meat *Toxoplasma*-free, but there is a chance that in certain parts of the world this could become a reality using proper production methods coupled with diagnostics that could identify infected pigs at slaughter. It should also be remembered that when pregnant women travel from a country of low prevalence to a country of high prevalence, they may be increasing their risk of infection at this critical time.

Conclusion

Toxoplasma gondii remains a common infection in humans that can be acquired from undercooked meat containing bradyzoites, or oocyst-contaminated foods and water. Commercially grown chickens and pigs can be reared virtually *T. gondii* free, and with care, hogs defined as organic can also be reared virtually *T. gondii* free. Mutton and goat meat remains a major potential source of infection if eaten raw or undercooked. Backyard chicken flocks and small holder farms with sheep, goats, pigs, and cats on the premises are very likely to produce meat containing viable *T. gondii*. Beef is no longer considered important in the epidemiology of this disease. An increased risk of becoming infected with *T. gondii* is associated with ingestion of raw uncooked vegetables, uncooked lamb, goat, or pork, and various other meats such as camel, deer, rabbit, etc. Recently, it has also been found that contaminated water may be a more common source than considered previously. The diagnostic tests to detect infections in humans and animals continue to improve, and it is expected that at some point it might be possible to determine a specific source for an individual infection. Women who are pregnant and seronegative for antibodies to *T. gondii* should be cautioned by medical practitioners to remain cautious about participating in behaviors that could jeopardize the developing fetus through the acquisition of and the infection with this agent.

HELMINTH-CESTODE

Contents

Echinococcus granulosus and *Echinococcus mutilocularis*

PR Torgerson, University of Zurich, Zurich, Switzerland

Glossary

Human alveolar echinococcosis An infiltrative lesion of the liver with metastasizes to other organs in the late stage caused by the larval (metacestode) stage of *Echinococcus multilocularis*. It is often fatal if not treated.

Human cystic echinococcosis A disease resulting in a space occupying lesion in any organ, but most commonly in the liver or lungs. The lesion is cystic in nature and caused by the larval (metacestode) stage of *Echinococcus granulosus*.

Hydatid disease An alternative name given to cystic echinococcosis. Occasionally it is also used for alveolar echinococcosis.

Metacestode The larval form of a tapeworm or cestode found in an intermediate host. The metacestode causes disease as a space-occupying lesion resulting from the growth of the metacestode. In humans the metacestode of Echinococcus spp. cause echinococcosis.

Characteristics of *Echinococcus* and Life Cycle

Echinococcus spp. are cestode parasites belonging to the family Taeniidae. All taeniid parasites have complex life cycles that include a carnivorous definitive host and a mammalian intermediate host in which the larval or metacestode develops. It is the larval stage that is pathogenic to humans and other mammals. The adult stage is a small tapeworm 2–7 mm in length that inhabits the small intestine of carnivores such as dogs or foxes. *Echinococcus granulosus* generally infects dogs (Figure 1) whereas for *Echinococcus multilocularis* the usual definitive host are foxes, but the parasite will also infect dogs (Figure 2). Molecular evidence suggests that *E. granulosus* is really a complex of several species with different intermediate host preferences and variable pathogenicity to man (Table 1, Figure 1). *Echinococcus granulosus* sheep strain (*E. granulosus* sensu stricto) is the most important human pathogen. *Echinococcus* adults characteristically produce taeniid eggs, approximately 40 μm in diameter. These eggs are morphological indistinguishable from eggs produced by tapeworms of the genus *Taenia*. The eggs are passed in the feces of the definitive host and are infective to the intermediate host. The larval stage in intermediate hosts develops as metacestode usually in the visceral organs (see Figure 1). Humans are aberrant intermediate hosts and become infected by ingestion of *Echinococcus* spp. eggs. When humans are infected with the *E. granulosus* complex, cystic echinococcosis (CE) develops, which is a space occupying fluid filled cyst. Alveolar echinococcosis (AE) develops when humans are infected with *E. multilocularis* larvae. This results in a more infiltrative lesion, initially in the liver, which can metastasize in the late stage and is usually fatal if untreated. Echinococcosis can be directly transmitted through contact with infected dogs or foxes or indirectly through a variety of ways including contaminated food or water.

Human Echinococcosis

Human echinococcosis occurs following ingestion of eggs and the development of the metacestode in one or more organs. The liver is the most common site for CE followed by the lungs. Other organs are occasionally affected (Figures 3 and 4). The disease has been recorded in all age groups with the peak age at the time of diagnosis is 30–50 years. Symptomatology depends on: (1) the organ involved, (2) the size and location of the cyst within the invaded organ(s), (3) pressure induced within organ(s), and (4) complications such as rupture and spread of larval tissue with formation of secondary cysts and possible sepsis. Cyst rupture may also lead to anaphylaxis.

The primary lesion for AE is the liver. The slowly growing infiltrative lesion may be present for several years before clinical signs become apparent. These include abdominal pain, jaundice, sometimes fever, and anaemia. This advances

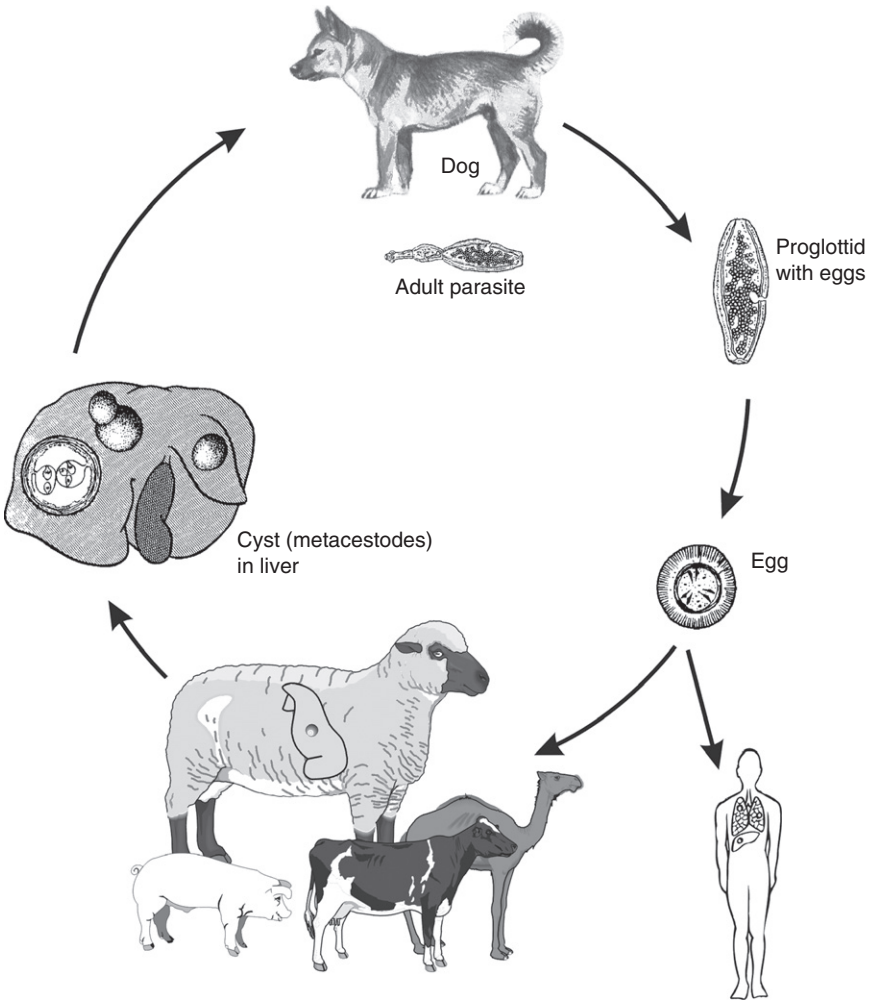

Figure 1 Life cycle of *E. granulosus* complex of genotypes frequently encountered in man. *E. granulosus* sensu stricto commonly utilizes sheep as the intermediate host. *E. ortleppi*, *E. intermedius*, and *E. canadensis* are often associated with cattle, pigs or camels, or wild ungulates respectively. © Institute of Parasitology, University of ZurichDogProglottidwith

to severe hepatic dysfunction, and is often associated with portal hypertension. The lesion will continue to grow and eventually metastasize to other organs and usually has a fatal outcome in the absence of treatment. In Europe, the peak age of diagnosis is approximately 50–55 years. In other endemic areas such as China this may be lower. However, the disease has been recorded in all age groups.

Diagnosis

Ultrasound examination (US), a widely used technique, can confirm the diagnosis of abdominal echinococcosis and indicate if lesions are active. Pulmonary echinococcosis cannot normally be detected by US. Classification systems based on the US appearance of the cyst have been developed for CE and AE, which may provide important information to the physician managing the case.

Nuclear magnetic resonance (Figure 3) or computer aided tomography (CAT-scan) (Figure 4) can be used to confirm the diagnosis, especially for lung and brain cysts, and to perform a pretherapeutic assessment of the lesions, for all locations. Unfortunately, in many remote endemic areas, such facilities are not available. In this case, serological back-up tests may be required to give additional information regarding the nature of the lesion detected by US.

A large number of serological assays have been developed for the diagnosis of human echinococcosis. These are generally more reliable for AE than for CE. Such tests can be used to give the clinician additional information when imaging techniques are inconclusive.

Treatment

There are numerous important reviews on the therapeutic management of CE. However, it still is a controversial subject. Consensus opinion was reached within the World Health Organization-Informal Working Group on Echinococcosis (WHO-IWGE) and the main conclusions published in 1996

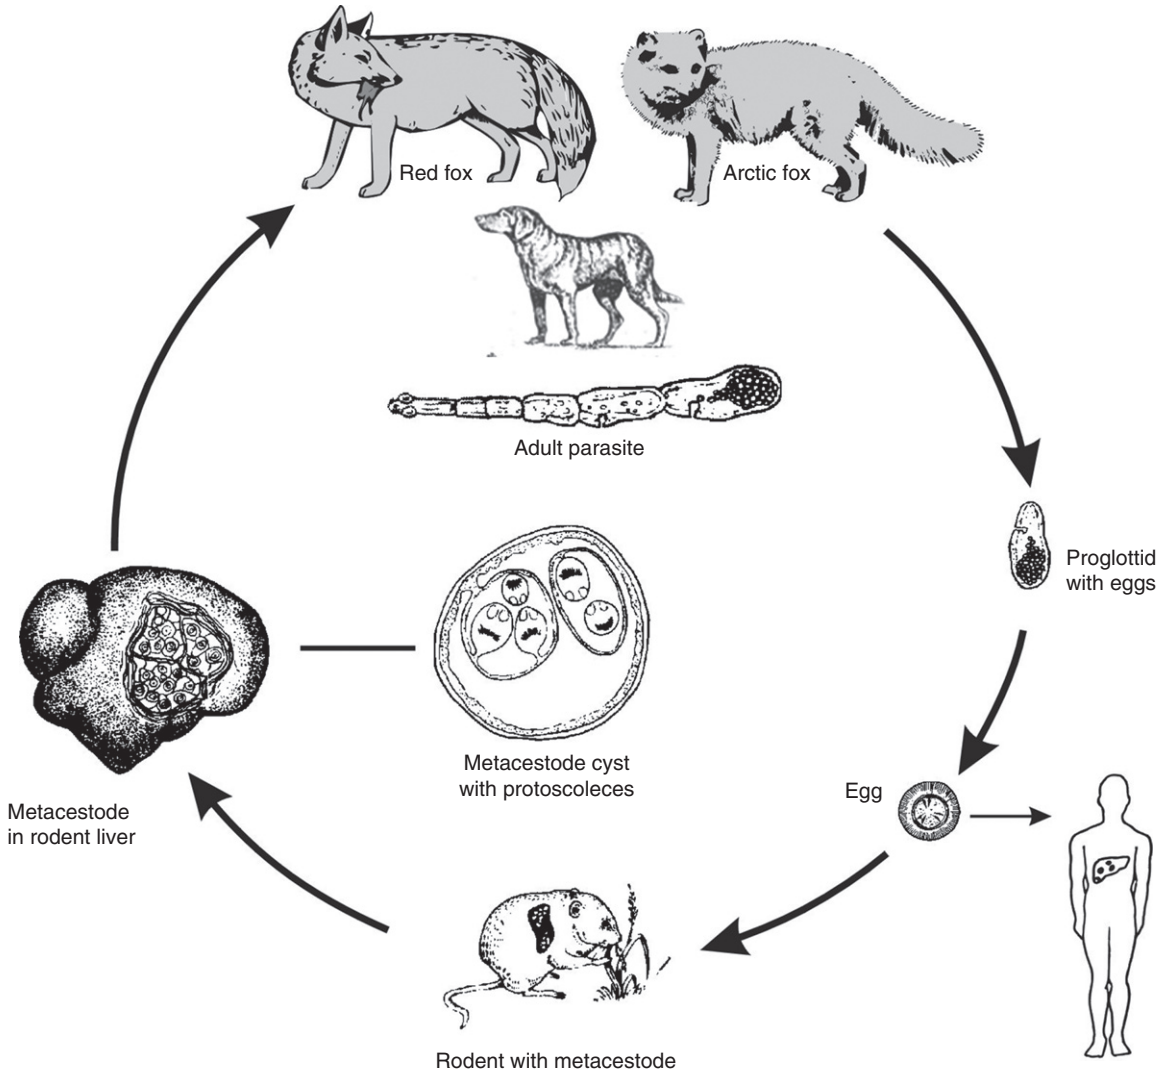

Figure 2 Life cycle of *E. multilocularis*. Man is an aberrant intermediate host and is infected directly or indirectly (for example via contaminated food) from fox or dog feces. © Institute für Parasitologie, Universität Zürich.

Table 1 Aetiology of cystic and alveolar echinococcosis in humans

Echinococcus *species*	*Name (abbreviation) and synonym of disease*	*Common intermediate hosts*	*Geographical distribution*
E. granulosus (sensu stricto)	Cystic echinococcosis (CE)	Sheep	Global
E. ortleppi[a]	Cystic echinococcosis	Cattle	Europe, South Africa, India, Russia, possibly South America
E. intermedius[a]	Cystic echinococcosis	Pigs, camels, possibly goats	Middle East, central Asia, China, India, Africa, eastern Europe, Argentina
E. canadensis[a]	Cystic echinococcosis	Wild ungulates such as deer	Northern Eurasia and North America
E. multilocularis (Eurasia, North America)	Alveolar echinococcosis (AE)	Small mammals	Northern Hemisphere

[a]Previously classified as *E. granulosus*. Further possible species exists – *E. equinus* and *E. felidis*. The former is not thought to be infectious to man whilst the latter's infectivity to man is unknown.

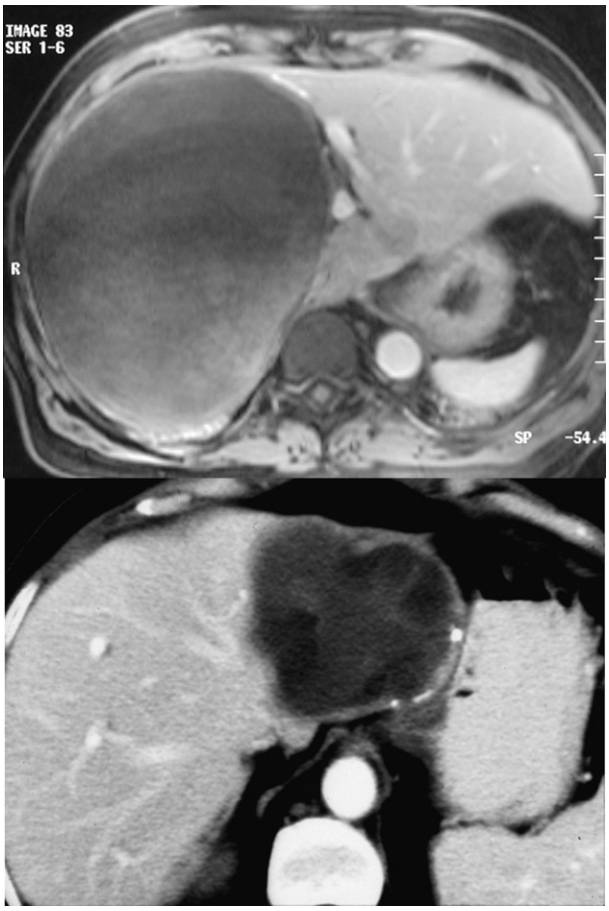

Figure 3 NMR images of cystic echinococcosis. Hydatid cysts can be clearly seen as space occupying lesions in the liver. Images with permission from Aliev MA, Baimakhanov BB, Samratov TU, and Toksanbaev DS (2004) Surgical treatment of cystic and alveolar echinococcosis of the liver. with updated recommendations published in 2010. Surgery was the only option until the late 1970s. Complementary or alternative options are now available, which include nonsurgical interventional and chemotherapy with antiparasitic drugs. Treatment indication should be based on a multidisciplinary discussion and depends on cyst type, number and location, and presence or absence of cyst complication. A proper and long-term follow-up of the patients should assess the efficacy of the treatment, detect treatment complications, and timely disclose recurrences. Percutaneous puncture (PAIR) for inoperable cases is currently accepted as an alternative to surgery in selected cases. This includes puncture of the cyst, aspiration of the fluid content of the cyst, introduction of a protoscolicide, such as hypertonic saline or, preferably, alcohol, and reaspiration. It is carried out under ultrasonic guidance. Detailed practical guidelines have been published by the IWHO-IWGE.

With AE, patients should always be treated with benzimadazoles combined with surgical resection of the parasitic lesion. Based on the WHOPNM (P, parasitic mass in the liver; N, involvement of neighboring organs; M, metastasis)

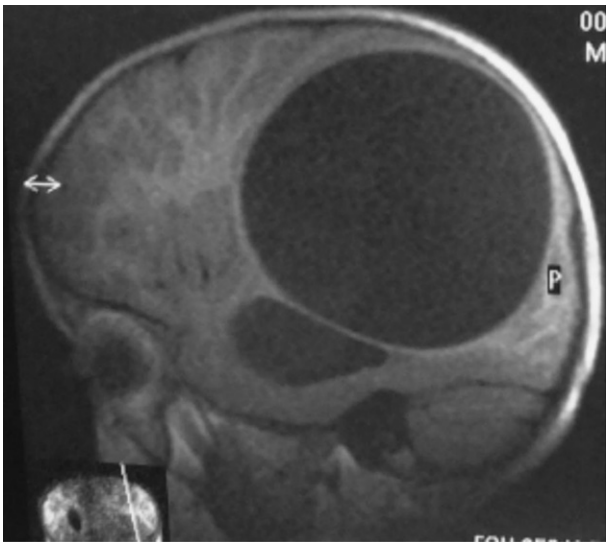

Figure 4 CAT scan of cerebral echinococcosis. Although CNS involvement of echinococcosis is rare, when it does occur it can be a devastating condition. Image supplied by the Government Pediatric Hospital, Bishkek, Kyrgyzstan.

classification of AE cases, an international group of experts has recently suggested various approaches of therapeutic procedures depending on the stage of the disease and on the available resources.

Epidemiology and Transmission to Man

The highest incidences of CE are seen where there is a close association with man and domestic livestock, often using working dogs. A common source of infection for dogs is offal from infected sheep. The resultant high infection levels in these dogs then pose a risk to humans. The cohabitation with dogs and feeding of uncooked viscera is a known risk factor for human CE.

The potential for domestic transmission of *E. granulosus* is highest in countries where the level of education may be poor, veterinary, and medical services are inadequate, and where home slaughter is commonly practiced. In such circumstances, prevalences in dogs can reach between 20% and 50% with perhaps an excess of 50% of the sheep population being infected. Occasionally other species, such as camels and pigs, may also be important intermediate hosts. Dogs themselves are more likely to become infected if they are young, allowed to roam, and fed on raw offal, offal in the community is not disposed of properly, the dogs do not receive anthelmintic treatment, or the dogs' owners are ignorant of the disease.

The distribution of CE is global (Figure 5), but different parts of the world have markedly different human incidences. In Europe, autothochonous CE is generally rare in central and northern Europe, although there are some foci in Eastern Europe, which are believed to be mainly through transmission of the pig strain. The most intensely endemic areas are Spain; where in some districts human incidence rates are 1.1–3.4 per 100 000 per year and Italy, particularly Sardinia where annual human incidence rates are 3.5 per 100 000. CE is also an

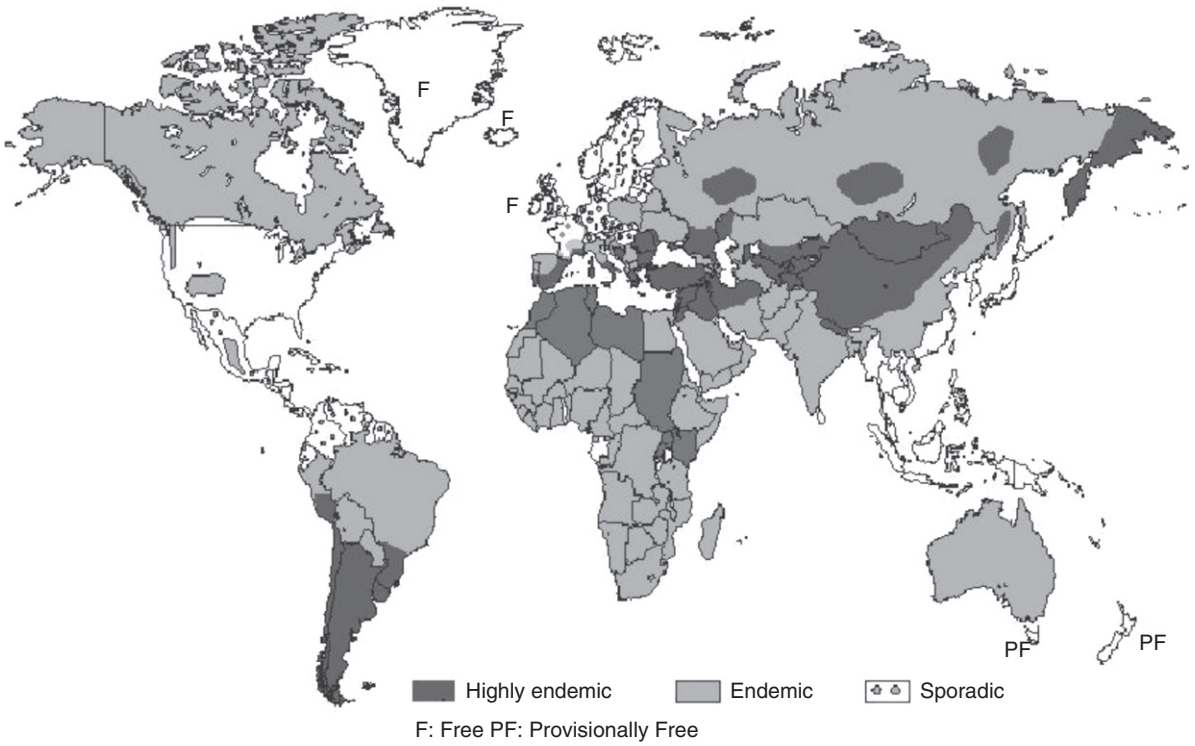

Figure 5 Approximate geographical distribution of the zoonotic strains of *E. granulosus*. Ireland is free of zoonotic *Echinococcus* spp., but is endemic for *E. equinus*. Reproduced from Eckert J, Conraths FJ, and Tackmann K (2000) Echinococcosis: an emerging or re-emerging zoonosis? *International Journal for Parasitology* 30: 1283–1294; Eckert J, Schantz PM, Gasser RB, *et al.* (2001) Geographic distribution and prevalence. In: *WHO/OIE Manual on Echinococcosis in Humans and Animals*, pp. 100–140. Geneva: WHO. © Institute für Parasitologie, Universität Zürich.

emerging problem in Greece, Bulgaria, and Romania where incidences of 3.3 per 100 000 per year have been recorded. There is also a small focus in Wales in the UK.

CE is a significant problem across much of the Middle East and North Africa. In Jordan the annual incidence is 2.9 per 100 000, in Tunisia 15 per 100 000, and in Turkey 0.67–6.6 per 100 000. In central Asia there has been a resurgence of CE following the collapse of the Soviet Union. This was due to poor funding of veterinary public health services, closure of centralized meat processing units and the privatization of large collectivized livestock enterprises. This enabled increased transmission of *E. granulosus* between dogs and livestock and from dogs to man. Consequently, surgical incidence rates are now commonly between 10 and 20 per 100 000 in much of central Asia. A similar pattern is also emerging in other former communist countries like Bulgaria.

Certain communities in Tibet have some of the highest incidences of CE. In some villages, US prevalences range between 5% and 10%. Similar disease burdens have also been recorded in transhumant pastoral communities in East Africa, such as the Turkana and Masai in Kenya and Tanzania, Toposa in Sudan, and the Dassanetch and Nyangatom in southern Ethiopia.

In Latin America, there are large endemic areas throughout the Andean regions of Peru, Argentina, Chile, Uruguay, southern Brazil, and sporadic cases being reported elsewhere such as Mexico.

In the US and Canada, CE tends to be sporadic and rare with cases occasionally being reported in certain groups of native Americans or particular ethnic groups.

In Australasia, CE was introduced with European colonisation and became a problem in large sheep rearing areas. Successful control programs have resulted in the elimination of the parasite from New Zealand and Tasmania. In continental Australia, the parasite has established a wild life cycle between macropod marsupials and dingoes. Therefore, prospects for elimination are now considered bleak. There are often descriptions of transmission within the domestic cycle, and human CE is frequently recorded.

Echinococcus multilocularis occurs in the northern hemisphere within a large belt stretching from the Arctic (80° N) southward to some regions approximately the 30° N latitude (**Figure 6**). The currently known endemic zone includes regions in Europe, Asia (extending eastward to Japan), and North America. More than 90% of human AE cases are in China where there is a heavily endemic region on the Tibetan plateau. In some communities 5% or more of the population may be infected. Elsewhere there are human cases reported from central and Eastern Europe, Turkey, much of Russia, central Asia, and Japan.

In western and central Europe, *E. multilocularis* is typically perpetuated in a wildlife cycle, involving red foxes (*Vulpes vulpes*) as definitive hosts and rodents (*Microtus arvalis, Arvicola terrestris, Myodes* [=*Clethrionomys*] *glareolus* and other species) as intermediate hosts. Prevalences of *E. multilocularis* in red foxes range from approximately 1% to more than 60% in various regions. In other regions such as China and central Asia, dogs are also infected as definitive hosts. This may increase the possibilities for transmission to man or contamination of food with parasite eggs.

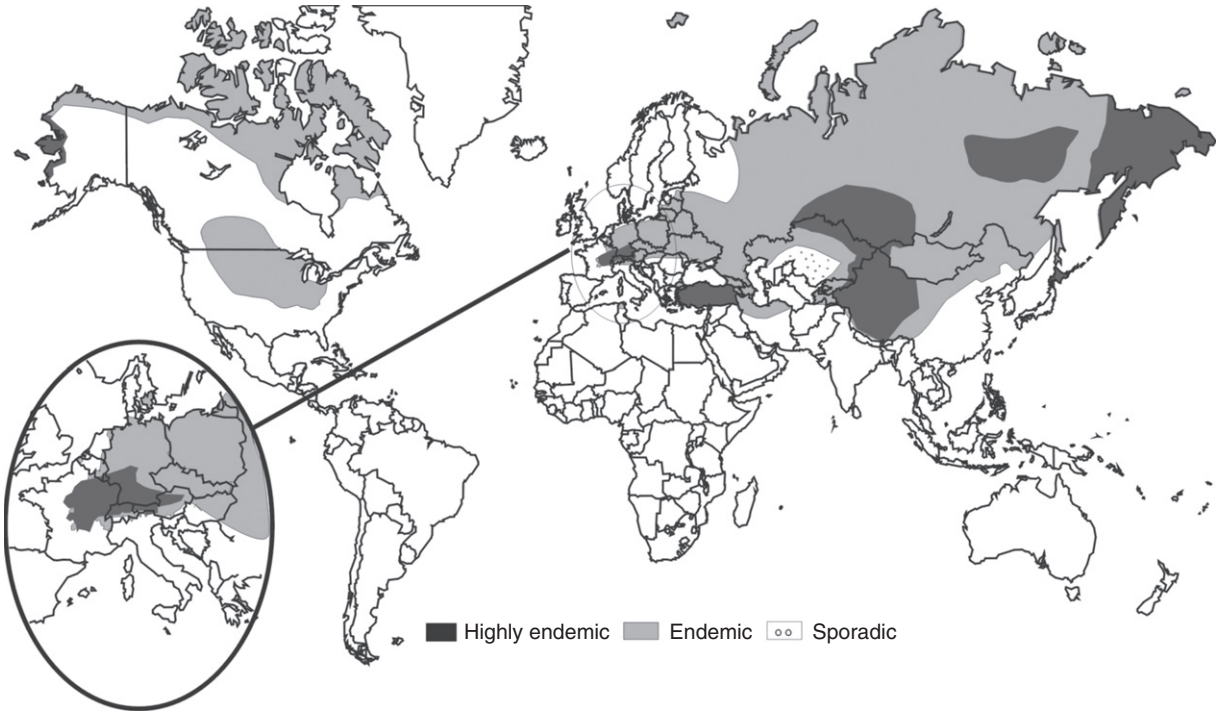

Figure 6 Global distribution of *E. multilocularis*. Image supplied by the Institute of Parasitology, Zurich.

Echinococcosis is not always associated with dog ownership or indeed contact with dogs or other carnivores. This may be because in some highly endemic areas dog ownership is universal and therefore cannot be used to discriminate between infected and noninfected subjects. Some groups such as Muslims regard dogs as unclean and therefore are unlikely to have close contact with them. Despite this CE infection amongst many of these people is evidence for indirect transmission of echinococcosis to man through contaminated food or water supplies. Epidemiological and experimental evidence has demonstrated that parasite eggs can be transmitted considerable distances by mechanical carriers such as insects. Thus, in highly endemic areas it is quite possible for individuals to contract CE even in the absence of dog contact.

Women are often reported to have a higher incidence of disease than men and this may be because they are more likely to tend to the household dogs and be involved with food preparation. In some populations men are found to have a higher incidence. This may reflect that in some societies men are more likely to be treated because they are more economically active, rather than an actual increased risk for men. Increasing age is also often reported as a risk factor with the peak age being 30–50 years. This is most likely due to continuous infection opportunities over time and the chronic and asymptomatic nature of abdominal CE.

Foodborne Transmission

Both cystic and alveolar echinococcosis can be transmitted to man through food. This is through contamination of food with parasite eggs and thus could occur where there is the possibility of contamination of food with dog or fox feces. Although not a consistent finding, there are studies that indicate an association of human infection with home grown vegetables, which presumably have been contaminated by dog feces. In addition, studies have shown an association with leaving food uncovered and thus available to flies. This is a potentially important means of human infection as flies have been shown to be capable of transmitting parasite eggs after they have fed on dog feces.

An unsafe water supply (such as from a stream) is also associated with infection with CE or AE in some studies and this may be due to water contamination with dog feces. This water can then contaminate food during food preparation.

With alveolar echinococcosis there is also a study linking the disease with eating wild fruit. This may be due to wild berries being contaminated with fox feces. However, a major issue that is difficult to resolve is source attribution for echinococcosis. This is because there is a long time lag, often of a number of years, between infection and the development of clinical signs, which makes it extremely difficult to identify the source of infection.

One recent study in Libya identified parasite eggs in vegetables and these could well include *Echinococcus* eggs. Tomato, cucumber, lettuce, and cress samples were examined for parasite eggs, and *Taenia*/*Echinococcus* eggs were found in 3%, 8%, 37%, and 33% of samples, respectively. This, therefore, provides strong evidence that inadequately washed and prepared salad vegetables are a potential source of infection.

An important point with regard to public health is animal offal that contains hydatid cysts (e.g., infected sheep liver). Such infected organs cannot directly infect humans even if consumed raw as the metacestode is not infectious to humans but must first infect a dog. Generally offal containing hydatid cysts would be condemned and removed from the food chain. This is for two reasons. First the organ would be regarded as

unwholesome and hence not suitable for human consumption. More importantly, the organ could be infectious to dogs and thus must be destroyed to prevent dogs becoming infected. A dog infected with *Echinococcus* is a substantial health hazard to its owner or indeed anyone coming in contact with this dog.

Economics and Societal Burden

CE presents a considerable societal and economic burden to a number of societies where *E. granulosus* is endemic. In terms of animal health the disease can lead to significant losses of production due to liver condemnations, lowered milk, meat and wool production, or decreased fertility in animals. This particularly impacts on societies with low socio-economic development, which have the highest prevalences in livestock.

A number of studies have estimated the economic costs of CE in various countries and it is often considerable. There is also a financial estimate of the global costs of CE, which suggests it could be as much as $3 billion annually if estimates for underreporting of the disease are accounted for.

A preliminary estimate of the global burden on echinococcosis has also been made, which indicates a loss of approximately one million DALYs. This is of a similar magnitude to the global burden of Trypanosomiosis or Schistosomiosis and considerably more than diseases such as Dengue or Leprosy. Similarly, the global burden of AE has been estimated to be approximately 600 000 DALYs with approximately 18 000 new cases annually.

Burden estimates present important methods in developing cost effective means of controlling this often neglected zoonosis. These estimates confirm that both CE and AE are major health problems in many parts of the world. However, what is less certain is the proportion of echinococcosis that is transmitted to man through the consumption of unsafe food that has been contaminated with *Echinococcus* eggs.

Prevention and Control

Control of CE has always involved a combination of routine anthelmintic treatment of dogs, control and reduction of stray dog populations, supervision of the slaughter of livestock and subsequent disposal of offal, and education of the public. A sheep vaccine has also recently been developed. This will prevent sheep becoming infected and hence break the cycle. Because this would then remove the source of infection for dogs, transmission to humans will be reduced or ceases. The various options for controlling CE are reviewed by Torgerson *et al*. in 2011. By implementing a carefully planned control strategy it is possible to eliminate *E. granulosus* and this has occurred in some Island nations such as New Zealand.

There is concern in Europe that fox populations are increasing and foxes are being found in greater numbers in the urban environment. This has led to an increase in the numbers of human AE cases in countries such as Switzerland. Control of AE is more problematic than CE as *E. multilocularis* has a wild life cycle. However, there has been some success by the distribution of praziquantel impregnated baits to foxes. In China, it is possible that dogs play an important role in the transmission of AE. Thus, periodic treatment of dogs with praziquantel may ameliorate transmission.

Conclusions

Echinococcosis can be a foodborne disease but the extent that it is foodborne is difficult to quantify. To prevent food becoming contaminated with *Echinococcus* eggs, dogs, and other carnivores must be totally excluded from any food preparation or storage areas. They should also be frequently treated with praziquantel. Dog feces should be properly disposed of and never used as a fertilizer for crops. Adequate cleaning and cooking of food should also minimize the risk of foodborne echinococcosis. Finally, food should not be accessible to flies as flies can carry *Echinococcus* eggs and thus act as a conduit of eggs from canine feces to food.

Taenia saginata and *Taenia solium*

RME Parkhouse, Instituto Gulbenkian de Ciencias, Oeiras, Portugal
LJS Harrison, Royal (Dick) School of Veterinary Science, Scotland, UK

Glossary

Cysticercus Tapeworm larva.
Cysticercosis Infection with tapeworm larvae.
Neurocysticercosis Cysticercosis located in the human brain.
Taeniasis Infection with the adult tapeworm.
Taeniid Adult tapeworm found in human intestine.

Introduction

Human taeniasis is caused by infection with the adult stage of the tapeworms *Taenia saginata* and *T. solium*, whereas human cysticercosis/neurocysticercosis results from infection with the larvae (cysticerci) of the latter species. Both of these parasites are zoonoses because the usual hosts for the cysticerci are cattle and swine respectively, from which humans become infected with the adult tapeworm. Food hygiene issues therefore arise if meat that is infected with viable cysticerci reaches the consumer or if food designed for human consumption is contaminated with eggs of *T. solium*. The worldwide prevalence of these parasites reflects inadequate socioeconomic conditions and inappropriate animal husbandry practices in the cattle and pig populations. A third, more recently identified taeniid, *T. asiatica* is also found in humans, cattle, and pigs but is restricted to Asia. As with the other two taeniids, humans are the definitive hosts, but in contrast both cattle and pigs can serve as intermediate hosts. Fortunately, humans do not act as intermediate hosts for *T. asiatica*. There is a continuing awareness in both the scientific community and the United Nations agencies of public health importance of human taeniasis and cysticercosis/neurocysticercosis, and of the economic importance of cysticercosis in cattle and pigs. The purpose of this article is to outline the history and biology of *T. saginata* and *T. solium*, their current medical/veterinary and economic importance, and to discuss in more detail the prospects for improving control by introducing new methods of treatment or animal management and by adopting a rational approach to the development of diagnostic assays and immunoprophylaxis. *Taenia asiatica* is considered for comparison, where appropriate.

History and Biology

Tapeworms were first documented as parasites of man *c.*1500 BC as the Ebers papyrus described worms that were probably species of *Taenia*, but it is likely that the existence of such large and obvious parasites was known well before that time. *Taenia asiatica* was identified in the 1980s. It is similar to *T. saginata* but is considered a unique species.

Parasites of the family Taeniidae have two mammalian hosts in their life cycle (Figure 1). The strobilated adult tapeworms inhabit the small intestine of the final host. The adult tapeworms of both *T. solium* and *T. saginata* are parasitic in man, causing human taeniasis. The larval cysticerci of these species were also known to man in ancient times. However, it was only in the eighteenth century the association of the larval cyst and adult tapeworm was suspected, and it was not until the following century that the life cycles of various taeniid species were fully demonstrated.

The morphological characteristics and life cycles of these parasites are well described in the literature. As with most taeniids *T. solium* bears a double row of hooks on its rostellum, whereas *T. saginata* does not have a rostellum or hooks. The gravid terminal segments of the adult tapeworms are either passed out in the feces or, in the case of *T. saginata*, can actively migrate out of the anus. The gravid segments of *T. saginata* and *T. solium* contain up to 80 000 and 40 000 eggs, respectively. The eggs released from these segments form the only free-living stage in the life cycle and are immediately infective for the intermediate host. Although the eggs of *T. saginata* can survive up to several months on pasture, *T. solium* eggs are generally not considered so resilient. After the eggs have been ingested by a suitable host, the six-hooked, hexacanth larvae or oncospheres hatch and activate in the small intestine before migrating to the development site, for example, the musculature or elsewhere, as is the case with *T. solium*, which can pass the blood–brain barrier via the lymphatics and blood stream. They then develop into the intermediate stage, termed cysticerci.

Cysticercosis is the term used to describe infection of the mammalian intermediate host by those taeniid cestodes, including both *T. solium* and *T. saginata*, whose larvae (metacestodes) are called cysticerci. They take the form of unilocular

 doi:10.1016/B978-0-12-378612-8.00148-7

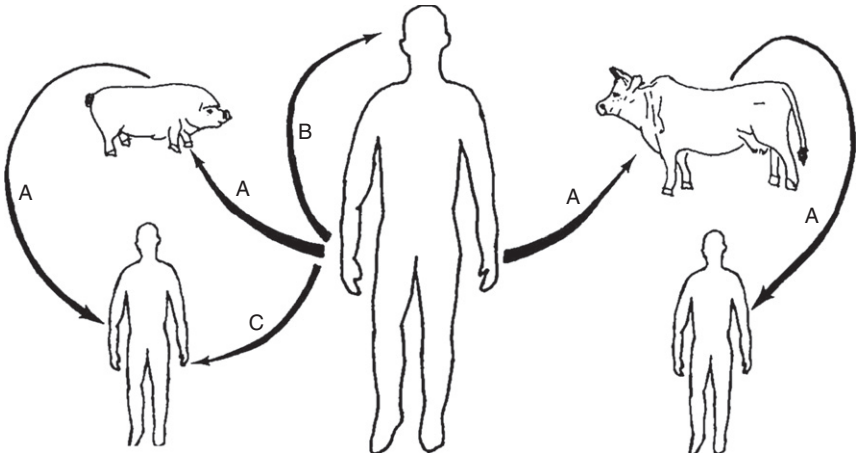

Figure 1 Diagram of the life cycles of *Taenia solium* (left) and *T. saginata* (right). The adult tapeworm of both species is located in the small intestine of the human host. When *T. solium* eggs are ingested by pigs or *T. saginata* eggs are ingested by cattle the eggs hatch and the larvae migrate to the tissues where they develop into cysticerci. Man becomes infected with either tapeworm when he consumes meat containing viable cysticerci (route A). However, *T. solium* cysticerci may develop in humans (routes B and C) including those already infected with the tapeworm.

cysts each containing a single scolex. The oncospheres of *T. saginata* and *T. solium* require at least 12 weeks but probably longer to develop to fully infective cysticerci, the characteristic bladder form may be identified within 2–4 weeks. The most common intermediate host for *T. solium* is the domestic pig. However, the cysticerci of this cestode can also infect a number of other mammalian hosts, including dogs and, unfortunately, man where generalized human cysticercosis can also occur with the cysticerci located in the musculature. In contrast, the cysticerci of *T. saginata* are more restricted in their host range and are usually only found in domestic cattle, both *Bos indicus* and *Bos taurus*. Mature cysticerci of *T. saginata* and *T. solium* are approximately 1-cm long and 0.75-cm wide but *T. solium* cysticerci can be larger.

Typical sites for the cysticerci of both species include the skeletal, cardiac, diaphragmatic, or lingual musculature but some cysts may develop in the liver of cattle and pigs and in other viscera. A strain of *T. saginata* has been reported in the Republic of Sudan, and Somalia, for which the predilection site is the liver, where unlike other geographical areas, large numbers of live cysts can be located. This is thought to be associated with a preference for the consumption of raw or very lightly cooked liver.

Unlike *T. saginata*, a characteristic of *T. solium* is that the parasite can cross the blood–brain barrier. Thus, in humans and pigs, the cysticerci of *T. solium* may be found in the brain or eye. It is this characteristic that is responsible for the major risk to human health caused by this parasite. Neurocysticercosis in man can cause severe symptoms including epilepsy and death.

Humans become infected with the tapeworm when they consume undercooked, raw, or rare meat containing viable cysticerci. If meat is well cooked until it is no longer pink then the cysticerci are killed and the transmission risk averted.

Epidemiology

The variations in the epidemiological patterns of taeniasis/cysticercosis are a reflection of the numbers and distribution of the human, cattle, and pig populations and also of the different management methods used with these domestic animals. Pigs are not commonly kept in Islamic countries. Their geographical distribution is thus more restricted than cattle but they are kept in large numbers in highly populous areas of the world such as Asia. In East Africa, because of the regulations governing the control of African swine fever, pigs tended to be maintained in tick-free commercial piggeries or if not should be kept tethered so that they cannot roam. Commercial piggeries are also found in west, central, and southern Africa but as with many countries in Latin America/Asia where intensive and semiintensive production systems are located, village-reared pigs or periurban pig production is becoming more common. Such pigs are often left to forage around human dwelling places, where, due to poor or nonexistent sanitary facilities they have access to human feces. This practice, combined with the omnivorous and coprophagous habits of pigs, accounts for the fact they are often found to have massive burdens of *T. solium* cysticerci. Cattle, being herbivorous, are usually taken to graze in areas away from direct contact with human dwellings, although they may still be in close contact with their herdsmen. Consequently, the intensity of infection in cattle is usually less than pigs.

Following a series of epidemiological studies, it was concluded that the difficulty in eradicating the large tapeworms such as *T. saginata* and to a lesser extent *T. solium* may lie in an interaction between their high biotic potential and the effective immunity acquired by their intermediate hosts. Thus, the balance between parasitic survival and attrition, on the one hand, and host immunity and fitness on the other hand, are the principal components in a complex system of interactions. For example, in areas of high prevalence of *T. saginata*, young cattle rapidly develop resistance to reinfection as a result of ingesting eggs from pasture and will retain that resistance because of the continual challenge. A result of this acquired resistance is that the numbers of cysticerci in the cattle when they are slaughtered are lower than would otherwise be expected from the high infection pressure. If the numbers of eggs on the pasture drops, perhaps as a result of the application of

control measures, young cattle may fail to acquire this resistance and remain susceptible to sporadic challenge. This is the situation that occurs in areas of low prevalence, where cattle involved in localized outbreaks may become heavily infected.

Naive cattle of all ages are susceptible to primary infection with *T. saginata*, however, they rapidly acquire a strong resistance to reinfection and will usually begin to destroy those cysts, which become established following the primary infection within 10–12 months. Thus, an explanation is needed for the fact that adult cattle of five or more years of age are commonly found to be carrying viable *T. saginata* cysticerci at slaughter in countries such as Kenya, where cattle often mature more slowly that the 18 months to slaughter as is common in say European countries. One possibility is that these cysticerci are those that have survived because their hosts were first infected very early in life, as it has been shown experimentally that cysticerci acquired during the neonatal period are able to survive in an otherwise resistant population. Although *T. solium* has a high biotic potential, it appears to be more susceptible to control by conventional means. This may be partly due to the relatively lower egg production of adult *T. solium* as compared with adult *T. saginata* and to the ease with which management practices for pigs can be modified.

Human and Animal Health Importance

Taeniasis causes various symptoms and signs, which probably depend very much on the psychological and physical characteristics of the host and are often not apparent but if they are they can include: abdominal pain, itchiness around the anus; appearance of active proglottids from the anus (especially in the case of *T. saginata* infection); and nausea. Some patients lose their appetite and thus lose weight, others experience increased appetite and gain weight, some patients tolerate the infection, whereas others do not. Other less common signs can include: diarrhea or constipation, dizziness, headache, vomiting, and weakness.

Taeniasis is known to cause pathomorphological changes in the jejunal mucosa and also functional disorders; reversible achlorhydria or lowered gastric secretion being found in 70% of patients. As a result of the reduced gastric acidity, bacterial or viral gastroenteritis is common, especially in those who are permanently exposed to various intestinal pathogens. Despite the relatively mild symptoms caused by the adult tapeworm, the infection is esthetically unacceptable. In addition, infection with adult *T. solium* is associated with the risk of an acute infection with the cysticerci. Infected persons require treatment, whereas the rest of the population requires protection from infection and the assurance that their beef and pork do not contain viable cysticerci of either parasite.

In humans, the symptoms of *T. solium* cysticercosis are also generally of minor importance, in the absence of nervous system involvement, being limited principally to muscular aches and pains. Neurocysticercosis is however a serious condition, often debilitating and sometimes fatal. The most frequent feature is epilepsy, in particular late onset epilepsy, but almost any focal neurological abnormality may occur. Locally acquired human neurocysticercosis continues to be a major cause of morbidity. It has been found to be the commonest identifiable cause of epilepsy in certain ethnic groups in South Africans, accounting for 32% of the epileptic patients in this population. However, the prevalence of human neurocysticercosis in most of Africa is not as well recorded as it is in other areas of the world such as Mexico, India, and China. An epidemiological survey carried out in northern Togo also pointed to a link between neurocysticercosis and epilepsy in that area with 38% of epileptic patients also found to have neurocysticercosis.

It has been commonly assumed that, cysticercosis per se is of little direct health importance in domestic animals, only causing occasional acute disease following rare massive infections or leading to esthetically unacceptable infections in pet dogs. However, there is some evidence that suggests that these parasites may not be totally innocuous. This is because, in common with many other parasites, such infections appear to be associated with general debilitation and some degree of suppression of their host's immune response. If this suppression results in the hosts being less able to control concurrent diseases or to respond adequately to vaccines, these parasites may be of greater general importance. Clearly, such considerations may also apply to human cysticercosis/neurocysticercosis patients.

Meat Inspection

Although most animals slaughtered under village conditions in some countries are not subjected to any form of meat inspection by qualified personnel, infected meat may be noted and rejected as unfit for consumption as was the case with carcasses of *T. solium* infected pigs 'measly pork' in Europe as early as the thirteenth century, well before the association with tapeworm infections was recognized.

The public health importance of larval taeniids in meat has led to the practice of condemnation or treatment – of infected organs or whole carcasses observed during meat inspection in centralized modern slaughter houses in an attempt to prevent completion of the parasitic life cycle. Research into the control of *T. saginata* taeniasis/cysticercosis was stimulated in Africa largely as a result of the desire by the beef producing nations to develop an export trade in beef to Europe and elsewhere. The presence of cysticerci in the meat would be a serious obstacle to meeting the import regulations of the recipient countries.

Studies were made by veterinary surgeons supervising meat inspection in abattoirs, who were primarily concerned with finding the most reliable routines for detecting the cysts in naturally infected carcasses by direct knife-and-eye inspection and also ways of handling such carcasses, usually by prolonged freezing or boiling, so as to eliminate the possibility of them transmitting the parasite to man. At the same time, the data obtained in abattoirs were used to assess the prevalence of cysticercosis in cattle and pigs in the catchment areas.

Meat inspection still relies exclusively on visual examination of the intact and cut surfaces of the carcass in the slaughter house by meat inspectors who follow officially laid down procedures. These vary from country to country and between the two parasitic infections. In the case of *T. saginata* the organs examined usually include the heart, diaphragm,

tongue, and cheek muscles, these being on the whole the less valuable parts of the carcass. Several of these are also the sites at which the cysts are concentrated in experimentally infected animals and may therefore be the optimal sites to examine in areas where the cattle have usually acquired the infection relatively recently. However, under production systems where cattle are matured relatively slowly, and where the infections are most commonly long-standing, the heart in particular is usually less heavily infected at slaughter. It was also shown some years ago that it is advantageous to include one or more cuts into the shoulder muscles of African cattle due presumably to the differing distribution of skeletal muscle between *B. taurus* and *B. indicus*.

Parasite burdens tend to be overdispersed, consequently light infections with *T. saginata* are relatively common. Only the more heavily infected carcasses can be reliably detected by these traditional methods of knife-and-eye inspection. Hence, it is recognized that existing procedures fail to detect many of the infected carcasses. Accordingly, meat inspection (even where it is routinely carried out) cannot be relied on to adequately control these parasites, although it may prevent the esthetically unacceptable heavily infected carcasses from appearing in the market place. Unfortunately, it is precisely these lightly infected carcasses, which usually escape detection during meat inspection, that are also most readily overlooked by consumers, so that the parasites in them are more likely to be eaten by humans and so infect those with a preference for raw or lightly cooked meat. Although heavily infected carcases tend to be condemned, more lightly infected carcases can in some circumstances either be chilled, frozen, or the meat processed, thus rendering it fit for human consumption. The value of such downgraded carcases is of course reduced and that combined with the cost of treatment results in an economic loss to the meat industry.

In the case of *T. solium* in pigs generalized infections are more common, and the cysticerci are larger so they are more easily detected at meat inspection. This may be another reason why this parasite has proved easier to control by conventional means.

Risk Factors Contributing to Transmission

Various practices and factors are of importance in maintaining a high prevalence level of *Taenia* infections in man and animals. From the life cycle of *Taenia* and the well-known transmission routes a series of possible risk factors can be anticipated. Many of these involve basic and food hygiene and can be summarized as follows:

- Risk factors for bovine cysticercosis (*T. saginata*/cysticercosis):
  - Application of human sewage slurry on pastures or highly permeable soils with possible contamination of water-bearing surface and drinking water.
  - Defecation of man in places frequented by cattle or in cattle feed production areas.
  - Tapeworm carrier on the farm.
  - Poor hygiene of stable personnel (e.g., handling of bovine feed or hand milking with egg-contaminated hands).
  - *Taenia* eggs in effluent water from sewage treatment plants.
- Risk factors for human taeniasis (*T. saginata* and *T. solium*):
  - Consumption of raw or undercooked meat, even when officially declared fit for consumption.
  - Consumption of uncontrolled meat.
- Risk factors for swine cysticercosis (*T. solium* cysticercosis):
  - Application of human slurry over pastures or human feces located within reach of free ranging pigs.
  - Tapeworm carrier on the farm, when swine have access to human feces.
  - Swine that are used as garbage collectors (including eating human feces).
- Risk factors for human cysticercosis/neurocysticercosis (*T. solium* cysticercosis):
  - Initially, man may have become infected with a *T. solium* tapeworm by consumption of raw or improperly cooked pork.
  - Poor personal hygiene (self-infection).
  - Consumption of food handled or prepared by infected persons.
  - Cohabitation and/or close contact with infected persons.

Public Health Measures

The consequences to man of infection with the cysticerci of *T. solium* together with the economic losses caused by the disease in man and animals have led to many national efforts to control or eradicate tapeworm diseases. In most developed countries, a combination of meat inspection and other factors, such as general improvements in sanitation and the availability of effective drug treatment for humans infected with tapeworms, have succeeded in almost or completely eradicating *T. solium*, but not *T. saginata*, in many countries. These measures have not so far been consistently applied in most of the less-developed countries. At present only a few such countries even have definite plans for controlling these parasites, although the large-scale use of praziquantel has proved useful in the control of *T. solium* taeniasis. It must therefore be expected that taeniasis/cysticercosis/neurocysticercosis will continue to be a problem for the foreseeable future.

Economic Impact and Assessment of Burden

Bovine and porcine cysticercosis both have an economic impact due to the losses incurred by infected carcasses, but because of the different public health/veterinary balance between the two parasites, the main driver for control of *T. saginata* is considered to be economic factors, whereas public health factors are the major concern with *T. solium*. The parasites can cause both severe illness and productivity losses in human and agricultural animal populations. Several recent studies indicate the extensive societal impacts on endemic areas. Estimates of burden provide essential, evidence-based, baseline data for conducting cost–benefit and cost–utility analyses. This information can be used to underpin calls for control and thus help secure political support, releasing the necessary financial and technical resources. To evaluate the

burden, the monetary and nonmonetary impacts of these zoonoses on human health, agriculture, and society must be considered across the board. Attempts to reduce the prevalence of *T. solium* and *T. saginata* in humans and their cysticerci in pigs and cattle may have a considerable impact on the economics of the meat production industries. This is particularly important where export industries are involved, because most importing countries have stringent regulations designed to prevent the importation of infected meat.

The costs can be broken down into those involved in treating human taeniasis and more importantly human cysticercosis; those incurred when pig and cattle carcasses are treated or condemned; and the costs involved in the inspection procedures themselves. Although there have been attempts to assess the economic burden caused by these parasites, in most countries there are no accurate data on any of these factors, especially in relation to *T. solium*. It was estimated that bovine cysticercosis was costing the economies of both Kenya and Botswana approximately UK £1 million each per annum. In the former country, this mainly arose from the loss of value that results in small abattoirs from boiling the meat to kill the cysts. In Botswana, a lower prevalence in fewer animals caused similar losses because of the reduced export potential. The losses will also vary with the prevalence.

Species Identification and Differentiation, Epidemiological and Other Diagnostic/Monitoring Tools

Taeniasis

It is particularly desirable to identify and treat *T. solium* infections in man because of the risk of either the host or his contacts developing *T. solium* cysticercosis. It is important, therefore, to be able to discriminate between *T. saginata* and *T. solium* tapeworm infection in humans. The morphological characteristics of the gravid proglottids such as their size and the number of uterine branches are usually used as the criteria for such identification. However, there can be considerable difficulty in distinguishing the two species because such features may overlap and accordingly many clinical reports refer only to '*Taenia* spp.'

Although the two species can be differentiated biochemically by differences in gene products, i.e., proteins or enzymes as the electrophoretic profiles of their proteins and their isoenzyme patterns differ. The samples required for use in these procedures are labile and must be either processed immediately or carefully frozen, preferably in liquid nitrogen. Fixatives such as alcohol or formalin cannot be used, so samples cannot easily be transported from one reference laboratory to another. Thus, this methodology proved of restricted value.

The application of species-specific deoxyribonucleic acid (DNA) probes to the identification of these tapeworm proglottides has immediate utility precisely, because DNA is very stable and samples can be stored in alcohol for transportation, before DNA extraction and analysis. In the clinical situation, it is important to have DNA probes, which will positively identify each individual sample. This is now feasible with the development of polymerase chain reaction (PCR) tools specific for *T. saginata*, *T. solium*, and *T. asiatica*, which allow the positive identification and differentiation of these parasites. Such tools can also make a major impact in epidemiological studies as specific reagents for the identification of discrete strains or geographical isolates of the parasite. Serological assays, based on polyclonal antibodies against adult tapeworm components, for the detection of taeniid worm antigen in the feces (coproantigen detection) are described in the literature, but a lack of species specificity limits their use.

Cysticercosis/neurocysticercosis

In contrast to adult tapeworm infections, where the proglottides or eggs may be found in the feces, the identification of hosts harboring cysticerci by direct parasitological examination poses problems. This is because the cysticerci are relatively small and widely disseminated in the tissues of the host. In humans *T. solium* cysticerci can sometimes be identified by biopsy of subcutaneous nodules, whereas in pigs it is often possible to observe them under the tongue, especially in relatively heavy infections. Cysticercosis is rarely diagnosed during life in cattle. The presence of dead calcified cysticerci can be detected by X-rays, but while this may be of some value in assisting the diagnosis of human cysticercosis, it is of little practical value in domestic animals. These reservations have stimulated a search for alternative methods of parasite detection.

Computerized tomography scanning and magnetic resonance imaging procedures provide a reliable diagnosis for neurocysticercosis in humans. These procedures are, however, neither cheap nor widely available in rural areas where *T. solium* persists. Nor is it practical to screen large numbers of people by these techniques.

An alternative diagnostic procedure is serodiagnosis, which allows the rapid screening of patients with neurological symptoms. Infected domestic animals might also be identified by antemortem serological screening and treated to kill the cysticerci, excluded from feedlot systems or subjected to close postmortem examination followed by treatment of the infected carcasses by freezing or cold storage.

All of these parasitological or clinical procedures require specially trained personnel and have the added disadvantage that each individual test is processed serially. Modern serology, through the widespread adoption of the enzyme-linked immunosorbent assay (ELISA) however, is rapid, cheap, may be automated and has the major logistic advantage that the samples are processed simultaneously with consequent decrease in turnover time.

Requirements for a serodiagnostic assay include levels of sensitivity, specificity and stability, and ease of performance, especially when used under tropical conditions. It is particularly important when diagnosing human neurocysticercosis that each infected patient is accurately identified. The criteria could perhaps be less stringent for herd animals, such as cattle, which can be treated on a group basis. Diagnostic assays for larval cestode infections should be directed toward the detection of those hosts harboring viable larvae. They should also provide an indication of the severity and progress of the infection, thus identifying those hosts that are suitable candidates for drug or surgical treatment. A highly

useful tool in the diagnosis of taeniid cysticercal infections is a serological test for the presence of viable parasites. This could be used to provide an immediate estimate of the prevalence of these infections in humans, cattle, or pigs and, as a rational indicator for clinical action for *T. solium* neurocysticercosis in man.

It has long been known that taeniids and other helminth parasites contain many cross reactive antigens, hence diagnostic assays based on the use of crude parasite extracts for antibody detection met with limited success. Problems included lack of specificity and sensitivity due to poor signal to background ratios. The problem is particularly serious in the diagnosis of helminth infections in domestic animals as they tend to be exposed to a large range of parasites. Also, although not generally the case with *T. solium* infection in pigs, *T. saginata* tends to be overdispersed in the cattle population with the majority of animals harboring only a small number of cysticerci so that they do not develop a strong serological response to infection. The reason why assays of an acceptable degree of sensitivity and specificity for the detection of *T. saginata* and *T. solium* infections were not developed was primarily a failure to identify sufficiently specific antigenic epitopes.

A detailed study at the molecular level of parasite antigens is a prerequisite for the logical design of serodiagnostic assays. This is particularly the case when dealing with complex metazoan parasites such as the taeniids. The application of modern analytical techniques such as molecular cloning, Western blotting and the direct or biosynthetic radiolabeling combined with sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE) analysis allowed the identification of those parasite products, which are of diagnostic potential. The detection of specific antibodies in is one diagnostic tool for suspected cases of neurocysticercosis in man. Attempts to improve the performance of serological tests by partial purification of antigen extracts have been superseded by the development of peptide and recombinant protein based assays. A monoclonal antibody ELISA capture assay is now available, which detect surface and excreted products of cysticerci in the serum of *T. saginata* infected bovines and, due to a convenient cross reaction, the assay also detected similar excretions/secretions of *T. solium* cysticerci in the serum and cerebrospinal fluid of humans with confirmed *T. solium* cysticercosis. Once a specific serodiagnostic system has been identified, the sensitivity of modern ELISA-based technology, notwithstanding the possibility of further refinements, such as the development of rapid (pen-side) or lateral flow assays, offers the necessary sensitivity and versatility for field use. Effective serodiagnosis will undoubtedly lead to an increased number of pigs or cattle identified as infected with *T. solium* or *T. saginata* because the direct knife-and-eye methods for detecting cysticerci are known to be inaccurate.

As with taeniasis, PCR tools are also now developed that allow both the positive identification of cysticerci obtained either at biopsy or autopsy and the differentiation of these lesions from other possible infections such as sarcocystis. It is also possible to employ PCR techniques to detect parasite DNA in body fluid such as cerebrospinal fluid in the case of human neurocysticercosis.

Chemotherapeutic Control

Treatment of infection with the adult tapeworms of *T. saginata* or *T. solium* is relatively easy with the appropriate dose of suitable chemotherapeutic drugs to kill the parasite and/or the use of purgatives to stimulate expulsion of the worm. The drugs of choice are niclosamide and praziquantel, which were introduced in the late 1970s. The drug has been used in wide-scale treatment programs for the control of *T. solium* tapeworm infections in humans. Until the beginning of the 1980s there was no effective treatment for cysticercosis in man other than surgical intervention to excise cysticerci or relieve hydrocephalus in neurocysticercosis. Praziquantel is not only an effective treatment for adult taeniids but will also destroy viable cerebral cysts of *T. solium*. Adverse effects are fortunately few, and inflammatory reactions due to dying cysticerci are treated with corticosteroids. Other drugs such as albendazole are also efficacious.

Chemotherapy has mainly been used in the experimental treatment of cysticercosis in pigs and cattle. Albendazole, which appeared to offer promise as a dual purpose drug already licensed for use in many countries as a nematocide in cattle and pigs, is not fully effective against the cysticerci of *T. saginata*. Another benzimidazole derivative, fenbendazole, is effective against the cysticerci of *T. solium* in pigs and high doses of fenbendazole have been reported effective against immature and mature cysticerci of *T. saginata*. Praziquantel kills *T. saginata* cysticerci in cattle at dose rates of 100 mg kg^{-1} and above but there is some controversy as to its efficacy against immature cysticerci. Unfortunately, praziquantel is still an expensive drug, and it is not generally economic to use it in cattle. However, alternative sources or analogs may become available, such as the Chinese pyquiton and another Chinese drug Mienang No. 5 also reportedly kills cysticerci.

Even when all the cysts have been killed by a suitable drug, any calcified residues derived from those cysts that were already dead or dying at the time of treatment remain detectable in the carcass for months. Meat inspectors would have to be fully informed that drug treatment has taken place and appreciate that such residues, although possibly unacceptable esthetically, are quite innocuous as regards the transmission of the parasite to man. This is of particular importance while meat inspection is relied on as the main means of postmortem diagnosis and control. It would clearly be preferable in the long term to seek means of preventing infection in the first place.

Immunoprophylaxis

Because of the importance of acquired immunity in regulating the intensity of infection with cysticerci of *T. saginata*, a vaccine would assist during a control program by replacing this natural immunity until the parasite is eradicated and thus reduce the risk of cysticercosis 'storms.' This may apply even if effective chemotherapy was introduced as an additional control measure.

The development of vaccines against *T. saginata* cysticercosis in cattle and *T. solium* cysticercosis in pigs was made feasible because taeniid larval infections can be prevented by

antibody-mediated immune mechanisms. Resistance to secondary infection can be produced either by primary infection with the parasite or by immunization using homologous or heterologous parasite extracts. The oncosphere, or material secreted or shed by the oncosphere, is one potent source of immunogens. Extracts of cysticerci were used to vaccinate pigs against *T. solium* infection, as have extracts of *T. saginata* proglottids to immunize cattle against *T. saginata* infection. More recently, work was conducted on the molecular characterization of the antigens involved.

A considerable amount of evidence pointed to the importance of humoral immunity in resistance to the early intermediate stages of taeniid parasites. Protection by passive transfer of immune sera from animals infected with cysticerci indicated that antibodies play a role in immunity and that it is the invasive larvae or oncospheres, which are most vulnerable to such attack. Although the invasive oncosphere is considered the prime 'target' of a protective immune response, components of the cysticercal stage also constitute possible 'targets' and cysticercal extracts have been used to vaccinate animals. Studies on *T. solium* have suggested that resistance against the older cysticerci may have a cellular component in particular involving eosinophils.

There would be clear advantages in having a vaccine, which was directed against both the early invasive and later developmental stages of the parasites. If any invasive parasites survived the first line of immune defense they could then be killed at a later stage in development but while the parasites were still small and their death unlikely to result in lesions in the meat. In addition, investigations into possible antigenic variation between different strains of these parasites should be initiated to ascertain if they have the same antigenic and genomic characteristics and to ensure that vaccines are directed toward uniformly available antigens.

Progress has been made on the application of genetic engineering to the development of vaccines against taeniids. Although there are many practical difficulties to be overcome in the production and large-scale testing of such vaccines, extending the application of these techniques to parasites such as *T. solium* and *T. saginata* could do much to overcome the problems encountered when trying to produce vaccines against a parasite, where the main source of parasitic material is man or cattle. The vaccination of cattle and pigs in endemic areas remains a long-term aim for control of *T. saginata* and *T. solium* infection.

Conclusions

Conventional approaches that can be taken for the control of cysticercosis in man and domestic animals, and taeniasis in man include improved standards of human hygiene, public health education, and a more realistic approach to management practices and efficacy of meat inspection. It would be rational to adopt the attitude that when any carcasses in a group, herd, or village are infected then all the animals from that group are presumed to be infected and treated accordingly by prolonged cold storage, freezing, or processing the meat by boiling and canning. These approaches may well-eliminate *T. solium* but only reduce the prevalence of *T. saginata*. Additional control methods such as immunoprophylaxis and wide-scale application of chemotherapy either in cattle, pig, or the human population would augment conventional methods, speed up control programs and possibly eliminate *T. saginata* from the cattle population. However, mass chemotherapy to reduce the human *T. solium* tapeworm population must be treated with a degree of caution due to the potential risk that humans may also suffer from neurocysticercosis, either symptomatic or asymptomatic. Chemotherapy to kill the adult tapeworm may damage the cysticerci resulting in undesirable inflammatory reactions.

Improvements in the accuracy of detection of infected animals or humans by the application of highly specific and sensitive PCR, recombinant protein, peptide antibody detection assays, or monoclonal antibody-based assays, which detect the characteristic products of metabolism of viable cysts in the circulation would be very advantageous. Such assay can feasibly be presented either as conventions ELISA or enzyme-linked immunoelectrotransfer blot (EITB) assays or as rapid (pen side) lateral flow assays which are quick and simple to use in the clinical or farm situation. This would allow the identification of human patients, young animals, or groups of animals, which require treatment or act as an incentive for farmers with an identified problem to instigate control measures as early in the production system as possible. The detection of those animals that present a genuine hazard to human health and the exclusion of animals that only contain dead cysts could be a major factor in rendering such serological screening acceptable to owners, butchers, and public health authorities.

Although the possibility of effective chemotherapy against cysticercosis has become a reality, praziquantel is still too expensive for routine use in animals, even though this situation may well change. There is a continuing need to develop commercially viable larvicidal cestocides suitable for treating both humans and animals. Indeed, in view of the appearance of resistance to previously highly effective anthelmintics by other helminths it would be preferable not to place total reliance on any one drug. However, the instigation of a control program involving the use of chemotherapy would probably need to be undertaken by government because such a program could not be properly coordinated if it was to rely solely on the initiative and action of individuals. It will be desirable, especially in hyperendemic areas, that cysticidal drugs should mainly be used in young animals to reduce treatment costs and allow time for complete reabsorption of dead cysts before slaughter. Control program could now potentially include effective and cost-effective vaccines. Such recombinant vaccines should possibly be incorporated in with other vaccines used in the same young stock.

Effective transmission control would naturally reduce the prevalence of both porcine and bovine cysticercosis and thus helps to eliminate the continued meat hygiene problem caused by these parasites, and the production losses ensuing from attempt to control transmission by inspection of animals very late in the production system.

HELMINTH–NEMATODE

Contents

Anisakid Nematodes

AJ Lymbery and JA Walters, Murdoch University, Murdoch, WA, Australia

Glossary

Accidental host Host that is not part of the normal life cycle of a parasite.
Anaphylaxis Exaggerated hypersensitivity reaction to antigen.
Anisakiasis Disease caused by infection with larval roundworms (or allergens from these worms) belonging to the family Anisakidae.
Definitive host Host in which an adult parasite lives and reproduces.
Intermediate host Host in which a parasite passes a larval stage and which is an obligatory part of the life cycle.
Sibling species Species that are morphologically similar, but reproductively isolated.
Urticaria Skin eruption characterized by transient, itchy wheals.

Background

Anisakiasis (anisakidosis) refers to infection with, or an allergic reaction to, larval stages of nematodes belonging to the family Anisakidae (and possibly also Raphidascaridae). These worms, commonly called anisakids, are found in the flesh, viscera, or body cavity of fishes or cephalopod molluscs. People contract anisakiasis by consuming infected fishes or cephalopods, or, more rarely, by exposure to allergens when handling fish products. The first case of anisakiasis was described by Van Thiel, Kuipers, and Roskam in the Netherlands in 1960, when they reported the presence of a larval anisakid in a patient suffering from acute abdominal pain. There has been a dramatic increase in the reported prevalence of anisakiasis throughout the world in the past two decades.

Characteristics

Taxonomy and Classification

Anisakid nematodes, broadly defined, are those members of the superfamily Ascaridoidea with an aquatic definitive host (fish, reptile, piscivorous bird, or mammal), whose transmission is dependent on water and usually involves aquatic invertebrate and fish intermediate hosts. More than 20 different genera of anisakids have been described. Although there is still some taxonomic uncertainty within the group, these genera are usually classified into one of the two families; Anisakidae or Raphidascarididae.

Cases of human infection have been reported with worms from a number of genera within these families. However, the two genera that are most often associated with anisakiasis are *Anisakis* and *Pseudoterranova*, both from the family Anisakidae. Historically, only two major zoonotic species were recognized; the 'herring worm' or 'whale worm' *Anisakis simplex* and the 'codworm' or 'seal worm' *Pseudoterranova decipiens*, both with an apparently cosmopolitan distribution. However, recent molecular genetic studies have found that both these morphospecies actually comprise a number of genetically differentiated sibling species, often with distinct host and geographic ranges.

Three different species have been described within the *A. simplex* complex; *A. simplex* (*sensu stricto*), *Anisakis pegreffi*, and *Anisakis simplex* C. In addition to these three sibling species, six other species of *Anisakis* have been confirmed using genetic

markers; *Anisakis typica*, *Anisakis physeteris*, *Anisakis brevispiculata*, *Anisakis zhiphidarum*, *Anisakis paggiae*, and *Anisakis nascetti*. Six different species have been described within the *P. decipiens* species complex; *P. decipiens* (*sensu stricto*), *Pseudoterranova krabbei*, *Pseudoterranova bulbosa*, *Pseudoterranova azarasi*, *P. decipiens* E, and *Pseudoterranova cattani*. In addition to these six sibling species, two other species of *Pseudoterranova* have been described on morphological criteria (*Pseudoterranova kogiae* and *Pseudoterranova ceticola*), although these species have not yet been confirmed genetically.

These species lists should not be regarded as definitive. Future systematic studies of the family using molecular genetic techniques are likely to uncover more species of anisakid nematodes and should be an urgent research priority. Molecular genetic analyses will also provide an essential tool for basic ecological studies of anisakids, providing us with a clearer understanding of geographic distribution, host range, and prevalence rates in definitive and intermediate hosts of different species within the family Anisakidae.

Life Cycle

Anisakids utilize aquatic mammals, piscivorous birds, aquatic reptiles, or fish as definitive hosts. Larval anisakids are found in aquatic invertebrates and fishes, although for most species, the precise details of the life cycle are uncertain and it is not clear whether the invertebrate and fish hosts are obligatory or whether the larval development occurs within them. For this reason, they have been referred to by different authors as both

Table 1 Forms of anisakiasis

Forms of anisakiasis	*Description*	*Pathology*
Noninvasive	Larvae do not penetrate mucosa	Usually asymptomatic
Invasive		
Oropharyngeal	Larvae penetrate the tissues of oropharyngeal cavity	Slight
Gastrointestinal	Larvae penetrate the gastric or intestinal mucosa	Slight–severe
Extra-alimentary	Larvae enter the body cavity	Severe
Gastroallergic	Allergic response to the larval antigens	Slight–severe

Source: Adapted from Lymbery and Cheah 2007.

intermediate and paratenic hosts; in this article, both invertebrates and fish are referred to as intermediate hosts, on the assumption that both of them are required for successful completion of the parasite's life cycle.

A generalized life cycle for species of *Anisakis* and *Pseudoterranova* is shown in Figure 1. Adults of *Anisakis* spp. are found in the alimentary tract (particularly the stomach) of cetaceans (dolphins, porpoises, and whales) and adults of *Pseudoterranova* spp. in the stomach of pinnipeds (seals, sea lions, and walrus), although the definitive host range of most species is still incompletely known. Eggs are shed in the feces and require an incubation period before hatching into free-living larvae. There is uncertainty over whether one or two molts occur within the egg and therefore whether the free-living larvae are in their second stage (L2) or third stage (L3). Free-living larvae are ingested by invertebrates, particularly crustaceans, such as copepods, amphipods, isopods, euphausiids, and decapods, where they grow within the hemocoel, perhaps undergoing one molt. Fishes and, at least for some species of *Anisakis*, cephalopod molluscs, such as squid and cuttlefish, become infected by eating crustaceans containing L3 larvae, which penetrate the intestine and invade the tissues, where they may continue to grow or become encapsulated. Fishes and cephalopods are referred to as primary hosts when they obtain their larval infection from crustaceans, and as secondary hosts when they become infected by eating other infected fishes or cephalopods. Definitive hosts are usually infected by eating fishes or cephalopods containing L3 larvae, which then develop to adults in the alimentary tract.

Infection of People

People may be accidental hosts in the life cycle of anisakids, becoming infected by eating intermediate hosts (usually fishes), which contain larvae. More than 90% of identified infections in people involve *A. simplex* (*sensu lato*), with most of the remainder involving *P. decipiens* (*sensu lato*), and other anisakid species, such as *A. physeteris* and *Contracaecum osculatum*, being found only rarely. Almost all reported cases of anisakiasis have involved L3 anisakid larvae, although L4 larvae have been identified in a small number of cases.

A very large number of fish species act as hosts for species of *Anisakis* and *Pseudoterranova*. Primary fish hosts are planktivores or predominantly planktivores, which acquire the parasite directly from crustacean invertebrate hosts. Secondary fish hosts are piscivores, which usually acquire the parasite from infected planktivorous fish. Prevalences and intensities of infection vary widely between fish hosts, both within and between anisakid species. These differences appear to be more related to geographic distribution, feeding habit, and growth rate of hosts than to behavioral or physiological host preferences of the parasites. Both prevalence and intensity of infection tend to increase with host age and size and are usually greater in secondary than in primary fish hosts.

As people usually become infected with anisakids by eating larvae contained within fish hosts, the distribution of larval nematodes within the tissues of fishes is epidemiologically important. After L3 larvae, contained within infected invertebrate or primary fish hosts, are ingested by a fish, they penetrate the intestinal wall. They may then remain within the body cavity, or migrate into the flesh or internal organs. Differences in relative abundance among these microhabitats may be affected by the species of parasite, the species and age of the infected fish, and the environmental conditions to which the fish are subjected after capture. Recent studies have suggested that the larvae of *A. simplex* (*sensu stricto*) are more likely to migrate into the flesh of fishes than the larvae of other species of *Anisakis*. Other studies have found that the larvae of *P. decipiens* (*sensu stricto*) are found more often in the flesh of young fishes than older fishes. In addition, there is evidence that larvae may migrate from the visceral organs to the flesh after death of their fish host, and that this migration may be enhanced by cold storage. The influence of all these factors is often difficult to disentangle; and at present, no general conclusions can be made concerning the risk factors for larvae being found in the flesh of fishes, where they are more likely to be eaten by people.

Clinical Manifestation

The disease associated with accidental infection or an allergic reaction to larval anisakid nematodes is usually called anisakiasis or anisakidosis. Clinically, human anisakiasis can take a number of forms, depending on the location and symptoms caused by the larvae (Table 1).

Noninvasive Anisakiasis

In noninvasive anisakiasis, often (but not exclusively) associated with infections with *Pseudoterranova* spp., larvae remain in the alimentary tract without penetrating the mucosal wall.

This often causes an asymptomatic infection, which may only be discovered when the worms are expelled by coughing, vomiting, or defecating hours, days, or even weeks after consuming a seafood meal. Occasionally, noninvasive infections give rise to a 'tingling throat syndrome,' which happens when worms migrate back up the esophagus into the oropharynx.

Invasive Anisakiasis

In invasive anisakiasis, larvae penetrate into or through the wall of the alimentary tract. Penetration of the buccal mucosa or pharyngeal mucosa occurs only rarely, and is usually associated with slight pain, feelings of discomfort, and difficulty in swallowing. Penetration of the gastric or intestinal mucosa is the most common form of invasive anisakiasis, with gastric anisakiasis more common than intestinal anisakiasis. Infections with *Anisakis* spp. are associated with both gastric and intestinal invasions, whereas infections by *Pseudoterranova* spp. are usually associated only with gastric invasions.

Symptoms of acute gastric anisakiasis appear 1–12 h after consumption of infected seafood, and include sudden stomach pain, nausea, and vomiting, with blood often found in gastric juices and stools. If acute cases are misdiagnosed, gastric anisakiasis may become a chronic disease, with clinical features very similar to peptic ulcer, gastric tumor, acute gastritis, and cholecystitis.

Intestinal anisakiasis usually manifests as an acute disease, occurring 5–7 days after seafood consumption. Clinical symptoms include nausea, vomiting, fever, bloody diarrhea, and severe lower abdominal pain, similar to acute abdominal syndromes, such as intestinal obstruction, appendicitis, or peritonitis.

Occasionally, anisakid larvae have been found to completely penetrate the wall of the alimentary tract and enter the body cavity. Larvae then usually lodge in the peritoneum or subcutaneous tissues, forming tumor-like, eosinophilic granulomas or abscesses. Associated symptoms include abdominal pain, vomiting, and bloody stools.

Gastroallergic Anisakiasis

Anisakiasis is often associated with a strong allergic response, mediated by immunoglobulin E and with clinical symptoms ranging from isolated swellings to urticaria and life-threatening anaphylactic shock. Allergic responses may occur with or without the gastrointestinal symptoms described above. The first signs of an allergic reaction usually occur within 2 h after eating infected seafood, although it may take up to 6 h to appear. Most cases of allergy reported to date have involved *A. simplex* (*sensu lato*). The allergens, which invoke a hypersensitivity reaction, appear to be highly resistant to heat and freezing, raising the prospect of an allergic response to parasitized seafood products, which have been prepared in a way that would normally kill nematode larvae. In addition, allergic symptoms have been found in fish processing workers, presumably from occupational exposure to contaminated fishes, and in people exposed to fishmeal or even to meat from chickens fed with a fishmeal-based diet. It is not yet clear whether the development of gastroallergic anisakiasis requires a prior, priming infection with live anisakid larvae or whether exposure to the anisakid allergens alone is sufficient to produce an allergic response.

Epidemiology

Prevalence and Geographic Distribution

Anisakiasis occurs throughout the world, with foci in North Asia and West Europe. More than 90% of the reported cases are from Japan, with the rest mostly from the Netherlands, France, and Spain. However, cases of anisakiasis have also been reported from many other areas of the world, including USA, Mexico, Canada, UK, Belgium, Egypt, Korea, Philippines, Chile, Australia, and New Zealand.

In the past 30 years, there has been a marked increase in the prevalence of anisakiasis throughout the world. This increase in reported cases of anisakiasis is probably due in large part to the use of new diagnostic techniques, particularly endoscopy. However, it is likely that the recent increased prevalence of anisakiasis is not solely due to the improved diagnostic methods, but also reflects a greater risk of contracting parasitic infections. As with other fish-borne parasitic diseases, the increasing global demand for seafood and a growing preference for raw or lightly cooked food, especially in many western countries, increase the risk of parasite exposure. It has also been suggested that the risk of exposure to anisakids has increased because greater regulatory controls over the exploitation of marine mammals has led to increasing population sizes of potential definitive hosts. However, evidence to support this view is mixed, and the relationship between definitive host and parasite population size is not straightforward for parasites, such as anisakid nematodes, which have a complex, multihost life cycle.

Risk Factors

The prevalence of anisakiasis and other fish-borne parasitic zoonoses is related to the traditions of consuming raw, lightly cooked, or marinated fish, such as Japanese sushi and sashimi, Dutch salted or smoked herring, Scandinavian gravlax (dry, cured salmon), Spanish boquerones en vinagre (pickled anchovies), Hawaiian lomi-lomi (raw salmon), Filipino kinilaw (chopped, marinated fish), and Latin American ceviche (raw fish seasoned with lemon juice). The risk of anisakid larvae in these dishes depends on the species of fish being used and may be enhanced if the fish are eaten whole (because worms are often found in the viscera rather than the flesh of the fish) or if the fish have been kept whole for some time after capture, rather than gutted immediately (because worms may migrate from the viscera to the flesh after death of the fish).

A major epidemiological issue which needs to be addressed is the reason why anisakiasis is most often associated with certain species of anisakid larvae. Almost all recorded cases involve infection with *A. simplex* (*sensu lato*) or *P. decipiens* (*sensu lato*). However, it is not clear to what extent this is a function of the geographic distribution of these parasitic species, their fish host range, their microhabitat distribution within fish, their propensity for postmortem migration, or

their invasive ability when ingested by humans. It is possible that all of these factors are involved, but determining their relative importance is essential because it will impact the advice that can be provided about the risk factors for anisakiasis.

Control

Preventive or control measures for anisakiasis focus on postharvest handling, storage, and cooking procedures for fish. However, consumption of live larvae in raw or undercooked fish is not the only way in which the parasite can cause disease and there is evidence that occupational exposure to fish products may be sufficient to trigger an allergic response to anisakid allergens. Furthermore, the allergens responsible for gastroallergic anisakiasis may be resistant to the freezing and cooking procedures recommended for killing anisakid larvae.

Postharvest Handling

In many countries with high prevalences of anisakid larvae in fish, fish are examined for infection at processing, with heavily infected fillets trimmed or discarded. The usual procedure is to examine fillets by candling on a light table. However, the candling procedure is very inefficient, often detecting as few as 33% of heavily infected fish (i.e., those with more than three worms per kg). Candling efficiency can be improved by slicing fillets longitudinally or by using different wavelengths of light and illumination sources to increase the contrast between the worm and flesh of the fish. Other approaches, such as laser candling, radiography, scanning laser acoustic microscope, pulse-echo technology, and electromagnetic detection have also been tested, but none of these are able to improve efficiency of detection to an extent that justifies increased processing costs or reduction in marketable fillet yield. Recent research has concentrated on molecular genetic approaches, with the development of primers for polymerase chain reaction amplification of anisakid gene sequences and the identification of restriction enzymes generating specific restriction profiles. Such techniques have demonstrated good specificity and sensitivity in experimental tests and have the advantage of being able to identify, if required, the species of anisakids present in fillets. They are likely to become the preferred methods for detecting anisakid larvae in fish flesh.

Freezing and Storage

Freezing kills nematode larvae, as long as the temperature is low enough and maintained for a sufficiently long period of time. Most health and food safety organizations recommend that the fish intended for raw or semiraw (marinated or partly cooked) consumption be frozen to at least $-20\ ^{\circ}C$ and stored at this temperature for 24 h or more. The available literature suggests that this is adequate to kill larval nematodes, although the US Food & Drug Administration provides more stringent recommendations, indicating that fish should be frozen to $-35\ ^{\circ}C$ or below for 15 h, or to $-20\ ^{\circ}C$ or below for a minimum of 7 days.

Preparation

Anisakid larvae are resistant to salting, smoke curing, and marinading. For home consumption, it is usually recommended that fish should be cooked by conventional means at 60 °C or higher, for at least 10 min. The effect of microwave cooking on anisakid larvae has not been well studied.

Ascaris

C Dold, Centre for Clinical Vaccinology and Tropical Medicine, Oxford, UK
CV Holland, Trinity College, Dublin, Ireland

Glossary

Bolus of worms An aggregation of entangled worms that tends to occur in hosts with a high infection intensity.
Disability adjusted life years (DALYs) The sum of the years of potential life lost due to premature mortality and the years of productive life lost due to disability.
Infection intensity Defines the number of parasites in an infected host. *Ascaris* infection intensity is defined by the concentration of eggs per gram (epg) of stool.
Oviposition Deposition of eggs in which the embryo develops outside the maternal body.
Patent infection An infection in which the infectious agent is shed from the host.

Characteristics of the Genus

Within the family Ascarididae, the genus *Ascaris* describes intestinal roundworms with a three-lipped mouth. While 13–16 species are known from mammalian hosts, two species, *Ascaris lumbricoides* (Linnaeus, 1758) and *Ascaris suum* (Goeze, 1782), are of the greatest medical importance and, therefore, are the best studied. *Ascaris lumbricoides* and *A. suum* infect humans and pigs, respectively.

Since the two species are morphologically indistinguishable, there has been considerable debate concerning the taxonomic status of human and pig *Ascaris*. Modern classifications are based on molecular methods, which have shown that *A. lumbricoides* and *A. suum* differ in the mitochondrial genome (mtDNA) sequence. Therefore, *A. suum* and *A. lumbricoides* are closely related at a phylogenetic level but have been conclusively shown to be correctly separated as two species in their own right.

While human and pig *Ascaris* typically infect their conventional hosts, experimental crosstransmission studies indicate that the two species can infect both hosts. Furthermore, infected human hosts in *A. lumbricoides* nonendemic areas in for example the Netherlands, North America, and Denmark harbor *A. suum*, indicating that pigs are a potential reservoir for the human population. Contrastingly, in *A. lumbricoides*-endemic regions of Guatemala and China, crossinfection between host species is low or absent. Despite low levels of crossinfection in certain areas, ascariasis is a zoonotic disease and cases of transmission from pigs to humans have been documented in Europe.

Life Cycle

Hosts contract *Ascaris* infection via the fecal–oral route (Figure 1). Infection is by the ingestion of embryonated infective ova. Larvae hatch in the small intestine and migrate to the cecum and proximal colon, where they penetrate the mucosa. The parasites migrate to the liver via the portal blood and later advance to the lungs, where they penetrate the alveolar space and ascend the bronchial tree to the throat. At this point, the helminths are swallowed and return to the small intestine. Larvae mature and reach sexual maturity in the small intestine. Mature male and female adult worms measure 15–25 cm and 20–35 cm, respectively. *A. suum* in pigs tend to have an affinity for the first three quarters of the small intestine but particularly the latter portion of the first half.

Adult worms may reside in the intestines for approximately 1–2 years. Worm copulation takes place in the host's small intestine and female worms are estimated to produce approximately 200 000 ova daily but production is known to be density dependent as the number of eggs decreases with worm load. Ova are shed via host feces into the environment. The time from infection to the presence of ova in stools is approximately 67–76 days and 6–8 weeks in humans and pigs, respectively.

Egg Development and Viability

Ascaris eggs are ellipse-shaped to round, golden brown, and vary in size (*A. suum*: 50–70 μm in length and 40–60 μm in width; *A. l7umbricoides*: 45–75 μm in length and 35–50 μm in width). Both unfertilized and fertilized eggs may be found in an infected host's feces. Fertilized eggs tend to have adhesive properties, which is a result of a cortical layer composed of mucopolysaccharide.

The further development of eggs in feces is dependent on environmental variables such as oxygen, moisture content, temperature, and shade. Optimal conditions for development and to maintain viability are moist, warm shaded soil. Embryonation rates are variable depending on temperature, but full development to the infective stage can occur within 10–14 days at $30 \pm 2\,^{\circ}C$. *Ascaris* eggs consist of four layers, making

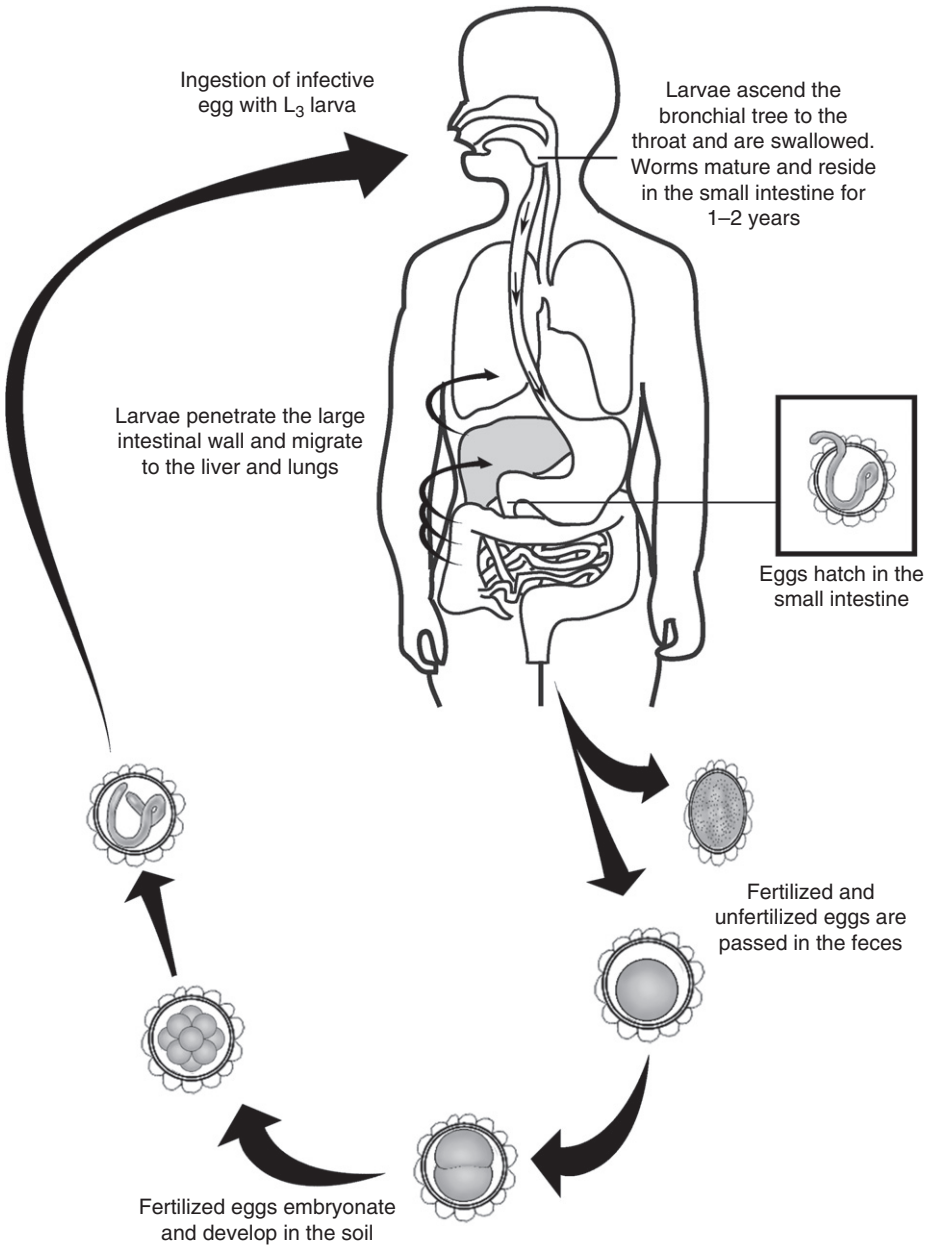

Figure 1 *Ascaris* life cycle.

them very resistant to adverse environmental conditions and while results vary, eggs can retain infectivity in the host environment for up to 15 years. The single-celled eggs that are shed in the feces develop into eggs containing third stage (L_3) larva, which have undergone two molts during development. The infective egg stage must be ingested to cause infection and eggs are triggered to hatch under intestinal conditions.

Infectivity

Epidemiological studies of *A. lumbricoides* infection in humans have shown that individuals tend to be reinfected with similar worm burdens as before treatment. The consistent observed heterogeneity in infection intensities between hosts is not fully understood but it has been calculated that a host genetic component accounts for 30–50% and 35–44% of variation in the worm load harbored in humans and pigs, respectively. Therefore, one cannot conclusively state an infective dose as it is largely dependent on the host individual. Despite this, the infectious dose is essentially low as each infective *Ascaris* egg is capable of developing into an adult parasite once ingested by its host.

High egg density inhibits embryonation and so stocks maintained for experimental studies should be diluted to ≤ 25 eggs μl^{-1} in order to maximize stock infectivity. Laboratory embryonated *A. suum* eggs can be maintained in 0.1 M sulfuric acid, for up to 5 years at room temperature. Many

experimental porcine studies are conducted since *A. suum* in the pig is a natural host parasite system and is therefore comparable to human infection. Coupled with this, rodent models have gained popularity since *Ascaris* undergoes a similar migratory route in both mice and pigs and thus humans. While adult worm infections cannot be studied in the mouse, this experimental host can provide information on the earlier stages of larval infection. Coupled with this, rodents are often infected in order to assess whether eggs are infective in studies focusing on egg embryonation and development. One can then isolate and enumerate the pulmonary larvae at approximately days 7 postinfection in mice. Therefore the experimental host provides a fast method for determining egg infectivity based on the infection intensities observed.

Health Consequences

The majority of hosts harbor few adult *Ascaris* worms and therefore tend to be asymptomatic. However, morbidity and mortality increase with burden and an estimated 60 000 people die annually from the infection. Migrating larvae are known to induce inflammatory reactions in the liver and lungs but the impact of *Ascaris* larval migration is less clearly understood than that of mature worms in the gut. The first symptoms evident in human infection are wheezing, coughing, and eosinophilia caused by pulmonary larval migration. The resultant respiratory distress is known as Loeffler's syndrome, but it is not evident until day 10–14 postegg ingestion. Characteristic symptoms of adult worm infections and chronic ascariasis include abdominal distension and pain, nausea, and diarrhea. In heavy infections, entangled worms can lead to mechanical intestinal obstruction, which is most commonly detected in children.

Ascaris infection is associated with appetite loss and impaired weight gain and therefore impacts on host nutrition. Intestinal malabsorption has been documented in *Ascaris*-infected children, which was attributed to infection-induced alterations in intestinal villi lengths. Studies have indicated that infection leads to reduced protein and fat absorption as well as vitamin A and C deficiency.

As discussed later (see Diagnosis of Infection), diagnostic techniques are dependent on detection and enumeration of worm eggs passed in host feces. Oviposition by the adult female occurs 2–3 months after infection is acquired, at which point hosts will have experienced acute symptoms (e.g., the Loefflers syndrome).

Epidemiology

It is currently estimated that 807 million people worldwide are infected with *A. lumbricoides*. Infection is most commonly documented in endemic developing countries but sporadic cases are reported in developed countries as a result of travel, consumption of contaminated imported crops, or zoonotic transmission from pigs. Prevalence in endemic countries varies and is generally low in countries with arid climates and high in those with consistent wet weather and warmth as embryonation and thus transmission are maintained throughout the year in latter conditions. Furthermore, the intestinal roundworm coexists with overpopulation, poor sanitation, and a high level of fecal contamination as well as inadequate sewage disposal, which plays an integral role in increasing transmission. The geographical distributions of *A. lumbricoides* and other helminth infections (*Trichuris trichiura* and hookworms) as well as malaria, tuberculosis, and HIV tend to overlap. Conflicting results of the effect of helminth infection on the 'big three' diseases indicate the need for further research as the full impact of large scale deworming programs is currently unknown.

The spectrum of disease associated with *Ascaris* infection is known as ascariasis. The majority of infected hosts are asymptomatic as morbidity tends to be associated with the worm burden harbored. Both human and porcine hosts experience acute lung inflammation and difficulty in breathing as a result of larval migration through the pulmonary tissue. Characteristic symptoms of chronic human ascariasis include abdominal distension and pain, nausea, and diarrhea. Entangled adult worms have also been documented as leading to mechanical intestinal obstruction in 0.005–2 per 1000 infections per year, which is the most common complication in human infections, with an associated mean case fatality rate of 5.7%. Combined with physical self-limiting symptoms, chronic infection can also lead to malaise, stunted growth, and malnutrition. Morbidity associated with *A. lumbricoides* infection is assessed as disability-adjusted life years (DALYs), which has been calculated at 10.5 million.

Foodborne Transmission

The infective agents of the helminths are the eggs, not the worms. Therefore, *Ascaris* infection is not acquired directly from consumption of infected porcine hosts. However, in *Ascaris*-endemic areas, human feces, raw sewage, and untreated wastewater are used as fertilizer to grow crops for human consumption. Therefore, many human infections can be attributed to the ingestion of polluted crops and contact with polluted feces or polluted wastewater. Furthermore, sludge is widely used as a fertilizer in agricultural fields; therefore it also poses the risk of dissemination of infection in *Ascaris*-endemic areas. Similarly, a high prevalence and intensity of *Ascaris* infection is observed in areas where human excreta are used as fertilizer for crops. The spread of these so-called 'nightsoils' maintains transmission and reinfection in endemic areas. Furthermore, transportation/exportation of food to developed countries can also increase the threat of contaminants in the importing countries.

Diagnosis of Infection

Detection in Feces

Diagnosis of ascariasis is generally dependent on the detection of *Ascaris* ova in the host's feces. The coprological diagnostic assays available are quantitative and, therefore, infection intensities can be determined based on a classification system provided by the WHO (Table 1). Originally devised to assess

Table 1 Classes of infection intensity according to *Ascaris* eggs detected per gram feces (WHO, 1998)

Eggs per gram feces	*Infection intensity*
1–4999	Light
5000–49 999	Moderate
≥50 000	Heavy

Schistosoma prevalence in Japan, the Kato–Katz method is the most commonly used diagnostic tool for intestinal helminth infections and involves examination of a thick smear of a approximately 50 mg stool sample. The long-term popularity of this WHO-recommended method is attributed to multiple factors such as its simplicity, relatively low cost, and suitability for rapid use under field conditions.

A further widely used diagnostic assay, the formol–ether-concentration method allows for concurrent diagnosis of intestinal protozoa as well as helminth infections. Samples are preserved in sodium acetate–acetic acid formalin (SAF) or dilute formalin, which is advantageous for large epidemiological surveys in which analysis is undertaken at later time points. The efficiency of detection is also increased in this method by the addition of ether, which removes fats and oils from the stool samples. Centrifugation results in a layered sample, from which the ether and formalin can be discarded, so that the remaining pellet containing the parasite ova can be examined.

A recently developed coprological method known as FLOTAC is based on the centrifugal flotation of a fecal sample suspension during which helminth eggs gather in the apical portion of the flotation column. This portion can be subsequently translated for viewing under a microscope. While this new method was originally designed for veterinary use, it has shown promising results for the detection of human parasites.

Sensitivity of Detection

A selection of studies has comprehensively assessed the relative diagnostic performance of the Kato–Katz and/or formol–ether-concentration methods along with the FLOTAC technique in order to determine the most reliable assay. The Kato–Katz method has a theoretical analytic sensitivity of 24 eggs per gram (epg) of stool, which can be increased by examining multiple thick smears prepared from the same stool sample or multiple stool samples. For example, one study reported an increase in sensitivity from 56.3% to 70.3% when one and three Kato–Katz smears were examined for *A. lumbricoides*. The FLOTAC technique requires a 24-fold higher amount of stool than a single Kato–Katz and consequently increases the likelihood of detecting ova. Therefore, the FLOTAC detects a higher number of *A. lumbricoides* infections in comparison to the Kato–Katz and especially formol–ether-concentration methods. The lower sensitivity of the Kato–Katz method tends to be a larger diagnostic issue for hookworm and *T. trichiura* since these helminths produce fewer ova than *A. lumbricoides*. However, the risk of misinterpretation increases when using the Kato–Katz method in assessing *A. lumbricoides* infections at low intensities. Despite lower sensitivities of Kato–Katz, this diagnostic method yields more accurate infection intensity results than FLOTAC. Therefore, the choice of diagnostic method should be based on the purpose of the study.

Alternative Methods

The routine diagnosis for ascariasis is primarily based on morphological identification of eggs or adult worms passed in the host's feces. However, there are alternative methods available based on detecting parasites through imaging techniques, *Ascaris*-specific nucleic acid markers, or antigens in host tissue or serum.

Imaging Diagnostic Techniques

The larval stage of *Ascaris* infection may also be diagnosed in the host's sputum by microscopy. Combined with this, imaging techniques such as chest radiography and high resolution CT show symptoms of pulmonary migration, including patchy alveolar infiltrate and alveolar hemorrhage. The use of radiography can also identify aggregations of adult *A. lumbricoides* worms as the parasites tend to form a bolus in the intestines of hosts, particularly children who present with abdominal pain. A further complication of *A. lumbricoides* infection, hepatobiliary ascariasis in which worms enter the common bile duct can be detected using imaging techniques. Ultrasonography can identify more than 85% of cases of biliary ascariasis. While scanning and imaging techniques are a tool useful for the detection of *Ascaris* infection, the availability of such diagnostic tools are limited in highly endemic areas and are not suitable for mass application.

Nucleic Acid Based Methods

The internal transcribed spacer (ITS) is the most common marker used to discriminate nematode species as it has highly variable nuclear loci. The first ITS (ITS-1) has been shown as a useful marker in identifying *Ascaris* in porcine liver and can therefore provide a useful tool for diagnosing infection at the early larval stages. However, much debate has arisen as to whether this approach can reliably differentiate between *A. suum* and *A. lumbricoides* infection. Determining host origin would be advantageous over existing microscopy diagnosis techniques. Since pig and human *Ascaris* are so closely related, significant similarity of the ITS region is observed between the two species. Even though some studies argue that the sequence difference is reproducible, others suggest that the use of this molecular marker in defining *Ascaris* sp. genotypes requires reconsideration. Therefore, while PCR methods would increase specificity and sensitivity in diagnosing *Ascaris* infection, such practices are yet to be adopted as standard protocol especially in endemic countries where there is a lack of available technologies.

Serological Analyses

Immunological methods can provide direct evidence that an infection is present. Researchers have undertaken enzyme-linked immunosorbent assays (ELISAs) in which *A. suum* antigens have been detected and therefore prove useful in herd examinations. The high level of sensitivity provided by antigen detection would overcome the problem of false negatives in cases of low *A. lumbricoides* intensities. However, such

techniques are unable to distinguish between current and past infections and therefore require further definition of assay performance prior to mass application.

Analytical Aspects

Detection and Treatment of *Ascaris* Eggs in Wastewater and Sludge

Ascaris is the most common helminth egg in wastewater and sludge and the WHO has cited helminth ova as one of the main targeted pathogens in its recent water reuse guidelines. While *Ascaris* eggs found in wastewater and sludge may not be infective, they may embryonate under suitable conditions once deposited through irrigation and fertilization of crops.

Assessment of *Ascaris* prevalence in communities with differing sanitation systems has shown that untreated wastewater is associated with increased helminth infection, particularly *A. lumbricoides* infection. The current WHO guidelines recommend treating wastewater so that ≤ 1 nematode egg l^{-1} remains prior to irrigation. This guideline is generally accepted as sufficient but some studies have suggested that a guideline of 0.1 egg l^{-1} is more appropriate when children are likely to be exposed. Increased *Ascaris* infection is associated with consumption of food items fertilized with nightsoils rather than with the act of spreading the human excreta. Treatment of human excreta with ovicides held in nightsoil tanks substantially reduces infection levels. Similarly to wastewater, the current guideline limit for sludge is ≤ 1 helminth ova g^{-1}. During wastewater treatment, the suspended solids are removed, thus removing all helminth ova. Therefore, while *Ascaris* eggs are removed from wastewater, they are later inactivated in sludge. Inactivation of *Ascaris* ova in sludge proves difficult due to their resistance to many chemicals and physical conditions.

In order to ensure that the prevalence of helminth ova is reduced to ≤ 1 helminth ova l^{-1} of wastewater or per gram of sludge, treatment techniques may need to be combined to increase efficiency. The removal of helminth ova in the suspended solids portion may be undertaken by sedimentation, filtration, or coagulation–flocculation. There are various treatment methods for inactivating helminth ova in sludge but in general the eggs are destroyed by raising the temperature, lowering moisture ($<5\%$), or adding certain disinfectants. Alkaline poststabilization is advantageous due to its low cost, yet has disadvantages such as the process' inability to destroy organic compounds that permit microbial regrowth. While *Ascaris* ova tend to show resistance to a range of chemicals, peracetic acid, for example enters the eggs and damages the nuclei, thus rendering them inactive. There are few studies on the effect of anaerobic digestion on the viability of helminth ova and the process is costly. However, a further step to this process involving thermal drying has been shown to inactivate the eggs. Studies differ in their outcome on the effectiveness of composting on inactivating helminth ova, yet it appears that this process in unable to produce sludge with <1 helminth ova per 4 g sludge. Similarly with the process of dehydration, there are contradictory results on its effectiveness in inactivating helminth ova. There is little information on the subject of sludge treatment to destroy helminth ova and therefore further research is required to assess the most efficient methods as well as the most cost-effective so that they can be implemented in endemic developing countries, where the prevalence of *Ascaris* of up to 85% in sludge has been recorded.

Since *Ascaris* ova are resistant to many treatments and have a high prevalence in raw sludge in endemic countries, these specimens are often used as indicator organisms in monitoring the efficiency of treatment. In order to assess the effectiveness of treatments, methods of detecting *Ascaris* eggs are undertaken. The US Environmental Protection Agency (EPA) describes a commonly used standard method to quantify the level of *Ascaris* ova contamination in wastewater, sludge, and compost. Samples are blended in water and surfactant and large particulates are removed by screening. The sediment is allowed to settle and the supernatant is subsequently decanted. Following density-gradient centrifugation using magnesium sulfate, a layer is formed, which will contain any helminth ova present. A further screening step is undertaken and followed by incubation for up to 4 weeks at 26 °C so that *Ascaris* eggs are fully embryonated, if viable, once microscopic examination takes place.

Standard methods in detecting *Ascaris* eggs in wastewater and sludge currently depend on labor-intensive and time-consuming identification by means of microscopy. Furthermore, such methods cannot identify the species of *Ascaris* or host of origin. The adoption of PCR can increase the specificity and sensitivity of detection as well as decreasing the time required. Current approaches require an incubation period of approximately 30 days in order to allow eggs to embryonate so that they can be identified. However, molecular methods can be undertaken within a day if only determination on total *Ascaris* eggs is required or 10 days if viability assessment is needed. A quantitative PCR (qPCR) approach has been developed in which one is able to detect the quantity and viability of the eggs in a given sample. Combined with this, since the nucleic target chosen (ITS-1 rDNA) differs between *A. lumbricoides* and *A. suum*, the eggs can be identified to species level (see Section Nucleic Acid Based Methods). Since ITS-1 rDNA increases as the eggs develop from the single-celled stage to a 600 cell infective larvae, this approach allows one to differentiate the stages of egg development, which is not always possible using microscopy.

Methods of Detection in Foods

While a standard method of detecting *Ascaris* eggs in food does not appear to be practiced, many protocols exist. In general, researchers assessing the quantity of *Ascaris* eggs on vegetables and fruit tend to firstly weigh the food item which then undergoes washing and sonication steps in a dilute detergent (e.g., 1% sodium dodecyl sulfate and 0.1% Tween 80). Centrifugation or sedimentation steps concentrate the parasite ova, which can then be examined by microscopy.

Importance to the Food and Water Industries

The use of untreated nightsoil, wastewater, and sludge all lead to higher levels of *Ascaris* infection by means of contaminating food. While these modes of transmission maintain infection,

it is difficult to assess the proportion of worms acquired solely through ingestion of contaminated foodstuffs especially in highly endemic areas. Imported crops have been implicated in cases of infection in nonendemic areas in the past but it is frequently difficult to associate outbreaks with a particular food item (e.g., Robertson and Gjerde, 2001). As discussed earlier (see Section Health Consequences), the first symptoms evident in human infection are not evident until day 10–14 postegg ingestion. Further to this, diagnosis does not generally occur until oviposition by the adult female 2–3 months after infection was acquired. As a result, retrospective inquiries are required in order to identify the source of infection. It is, therefore, likely that foodborne transmission, particularly in nonendemic regions, is underdetected.

Since *A. suum* infects humans, porcine waste is also an important vehicle for transmission. Studies in which *Ascaris* haplotypes have been identified have also shown that there is an association between the proximity of inhabitation to pig farms and human infection with *A. suum*. The increased interest in organic farming may exacerbate the potential of cross species infection especially since organic farms have a higher incidence of infection due to a lack of provision of anthelminthics.

Importance to the Consumer

Human infection is contracted after the ingestion of embryonated infective *A. lumbricoides* or *A. suum* eggs. Consumption of contaminated fruit and vegetables is a primary route of infection. Person-to-person transmission can also occur during food preparation if proper sanitation is not adhered to. While many studies undertaken vary in design and methodology, there is evidence that there is an effect of handwashing upon both prevalence and intensity of *Ascaris* infection and so personal hygiene plays a key role in transmission. As well as thorough washing or peeling of vegetables, cooking will decrease the potential spread of infection. Both *A. lumbricoides* and *A. suum* eggs have similar susceptibility to high temperatures. While results from studies vary, the majority of eggs are killed within 45–60 min at 50 °C and within 15 min at 55 °C. Contrastingly, *Ascaris* eggs are more resistant to low temperatures as unembryonated eggs can resume development after 40 days at −26 °C. Embryonated eggs however are less tolerant of colder temperatures; their viability is compromised within 20 days at −11 °C.

Since eggs are sticky (see Section Egg Development and Viability), they tend to adhere to many surfaces in the home, including food utensils. Therefore, sufficient washing of utensils are required prior to food preparation and consumption in order to reduce infection.

It is difficult to delineate the routes of transmission responsible for individual infections especially in highly endemic areas due to the number of possible routes of transmission and the length of time required for establishment of patent infection. Outbreaks in nonendemic countries can be avoided through appropriate hygiene and food preparation practices. It is unlikely that foodborne transmission in endemic countries will be eradicated, yet it can be minimized by the implementation of improved sanitation facilities, raw wastewater treatment combined with education and practice of improved consumer hygiene and food preparation practices.

Strategies for Control of *Ascaris*

The adequate treatment of wastewater and sludge, described above (see Detection and Treatment of *Ascaris* Eggs in Wastewater and Sludge), can successfully interrupt transmission of the parasite by reducing contamination of food items. Combined with this, the spread of helminth infection can be prevented through implementation of three major strategies: anthelmintic treatment, improvements in sanitation, and health education.

Anthelmintic Treatment

Treatment of *Ascaris* infection is an important means to prevent the transmission of the parasite as well as reduce morbidity. There are a range of drugs available for treatment of patent infection of *Ascaris* infection, which are also effective against other helminth infections. The most commonly administered anthelmintic drugs to treat *A. lumbricoides* are albendazole, levamisole, and mebendazole. Treatment leads to immobilization and expulsions of worms from the gut via the feces. The WHO aim to undertake anthelmintic drug treatment programs in order to reduce morbidity rather than eradicate helminths as control of these parasites is dependent on sanitation and interruption of transmission also. Since morbidity associated with helminth infection is the greatest in school-aged children, the WHO recommends regular administration of anthelminthics to at least 75% of this high risk group. Regular treatment is necessary due to high reinfection rates in endemic regions. For example, in one study conducted *A. lumbricoides* reached 55% of pretreatment rates within 11 months.

Improvements in Sanitation and Health Education

Improvements in sanitation interrupt transmission of infection by reducing the infiltration of eggs into the environment, which leads to the contamination of foodstuffs. Therefore, the long-term provision of improved sanitary facilities can gradually reduce worm loads and consequent morbidity. Health education programs also aim to reduce parasite burdens as they encourage the construction of improved sanitary facilities. Furthermore, health education focuses on behaviors related to food preparation as well as family hygiene (see Importance to the Consumer).

The multiple strategies implemented to control ascariasis each serve to interrupt different potential sources of infection. Anthelmintic treatment, health education, and improvements in sanitation prevent the dispersion of parasite eggs into the environment while wastewater and sludge treatment reduces the risk of food contamination. Furthermore, health education in the area of food preparation and hygiene prevents infection when crops are contaminated. The range of control strategies required in order to reduce the spread and intensity of *Ascaris* infection highlights the complexity of eradicating the ubiquitous parasitic nematode.

Capillaria hepatica and *Capillaria philippinensis*

VY Belizario Jr, National Institutes of Health and College of Public Health, University of the Philippines Manila, Manila, Philippines
FIG Totañes, National Institutes of Health, University of the Philippines Manila, Manila, Philippines

Glossary

Borborygmi Gurgling or rumbling stomach.
Embryonization The development of the helminth zygote into a larva within the egg.
Enzyme-linked immunosorbent assay An assay that relies on an enzymatic conversion reaction and is used to detect the presence of specific substances.
Intermediate host An animal wherein the asexual or larval stage of a parasite may reside during the parasite's life cycle.
Lagomorphs Members of taxonomic order that includes rabbits, hares, and pikas.
Larviparous Pertaining to laying live larvae.
Open defecation Evacuation of feces outside a latrine, often in open fields/natural environment.
Oviparous Pertaining to laying ova or eggs.
Relapse Recurrence of symptoms after an asymptomatic period, usually after treatment.
Zoonotic infection Infections that are transmitted between vertebrate animals and man.

Introduction

The genus *Capillaria* falls under the phylum Nematoda, order Trichurida, and family Trichinellidae. There are approximately 300 known species under the genus *Capillaria*, most of which infect animal species. Four species, *Capillaria aerophila*, *Capillaria hepatica*, *Capillaria philippinensis*, and *Capillaria plica*, have been reported to infect humans. Some species require intermediate hosts in their life cycle (i.e., *C. aerophila*, *C. philippinensis*), whereas some are directly transmitted (egg-to-egg cycle) and do not require an intermediate host (i.e., *C. hepatica*).

Capillaria hepatica

Rodents and lagomorphs are the natural hosts of *C. hepatica* (syn. *Calodium hepaticum*). Infection with *C. hepatica* involves the host's liver, resulting in fibrosis and parenchymal damage, and eventually death in some cases. Zoonotic infections in humans have been reported, although such cases are rare.

Parasite Biology

Hosts, including humans, are infected through the ingestion of embryonated eggs (i.e., mature, infective eggs) from contaminated food or water. The eggs hatch in the cecum, and the larvae penetrate the mucosal membrane, enter into the portal system, and migrate into the liver parenchyma. In about approximately 18 to 20 days postinfection, the larvae mature and female worms deposit fertilized unembryonated eggs in the surrounding parenchyma. Embryonation of helminth eggs occurs when the eggs reach the environment. The process takes approximately 5–7 weeks, depending on the temperature, humidity, and level of oxygen. In most cases, eggs are not passed out in the stool. Instead, eggs are released into and eventually exposed to the environment only after the death and disintegration of the host. In some cases, unembryonated eggs (i.e., immature, non-infective eggs) inside the host are ingested by and pass through the digestive system of carnivorous animals, and are eventually excreted (unchanged) through the feces into the environment where they embryonate. Embryonated eggs can stay infective for 25 months at room temperature.

Pathogenesis

The presence of larvae and adult worms, as well as the deposition of eggs in the liver parenchyma result in inflammatory reaction, granuloma formation, and focal necrosis. The reaction of hepatic tissue may result in clinical manifestations similar to that of acute hepatitis. The classic triad of persistent fever, hepatomegaly, and eosinophilia may be observed. Other findings may include abdominal pain, organomegaly involving the spleen or the kidneys, anemia, and weight loss. Death may occur in cases of severe liver damage and hepatic failure.

Epidemiology

The first reported case of hepatic capillariasis was on a British soldier who died in India in 1923. Postmortem examination revealed "an apparent suppurative condition of the liver with areas of spongy consistence." Large masses of eggs similar to

 doi:10.1016/B978-0-12-378612-8.00142-6

Hepaticola hepatica (*Capillaria hepatica*) eggs were observed on microscopic examination of liver samples. From 1924 to 1996, there were 37 reported cases of hepatic capillariasis from countries such as the former Czechoslovakia, USA, Mexico, Brazil, South Africa, Japan, and Korea. Three more cases were reported in Brazil in 1999, and one in India in 2007.

Prevention and Control

Preventive measures include thorough washing or cooking of vegetables and boiling of water in areas where the infection is endemic. Proper disposal of animal carcasses is also important to avoid contamination of food and water, as well as transmission to other animal hosts.

Capillaria philippinensis

History

In 1963, a 29-year-old male patient from Bacarra, Ilocos Norte, Philippines, was admitted at the Philippine General Hospital. The patient was reported to have diarrhea of 3 weeks duration and recurrent ascites. The patient appeared to be emaciated and cachectic, and died a week after admission. Autopsy findings revealed a large number of tiny worms recovered from the intestines. At that time, the species of the parasite was unknown, but it was later identified as a member of the genus *Capillaria*. Soon after, the new species was called *Capillaria philippinensis*. This patient was the first reported case of capillariasis philippinensis, although a number of people from Bacarra were also reported to have died following chronic gastroenteritis around the same year.

In 1965, an outbreak of chronic gastroenteritis occurred in Pudoc West, Ilocos Sur, Philippines, involving cases from all age groups. The disease resulted in death in a number of patients, most of whom were middle-aged men. An investigation in 1966 reported that cases presented with profuse diarrhea, abdominal pain, borborygmi, and wasting. Stool examination showed 'unusual' *Trichuris trichiura* ova, whereas autopsy of a fatal case revealed findings of intestinal worms similar to that found in the initial case from Bacarra. Soon after, the disease spread to the neighboring towns that resulted in more than 1000 cases and 77 deaths. It is believed that the spread of the disease during the epidemic may have been a result of washing fecally-contaminated bed sheets in lagoons in the Tagudin area of Ilocos Sur, exposing the freshwater fish to infective *Capillaria* eggs. During the outbreak, people in the area maintained their practice of eating raw or poorly-cooked fresh water fish which may have contributed to increased transmission of the disease.

Parasite Biology and Life Cycle

Capillaria philippinensis adult worm is characteristically filamentous at its anterior end, with a thicker and shorter posterior end. Females may be both oviparous and larviparous, and their uteri may contain thick- or thin-shelled ova, and larvae. *Capillaria philippinensis* may be regarded as a bridge between the genera *Trichuris* (oviparous) and *Trichinella* (larviparous). *Capillaria philippinensis* eggs are peanut- or barrel-shaped, with striated shells, flattened ends, and prominent bipolar mucoid plugs.

The complete lifecycle of *C. philippinensis* involves the passage of unembryonated eggs from the feces of infected definitive hosts. The eggs embryonate in the soil or water and are ingested by an intermediate fish host. The egg hatches in the intestines of the fish and develops into an infective larva. The larva enters a definitive host through ingestion of raw or poorly-cooked fish and develops in the small intestines into an adult worm. Larviparous females produce larvae resulting in autoinfection, whereas oviparous females produce eggs that are then released into the environment through the feces.

Pathogenesis and Clinical Manifestation

Although the incubation period is unknown, early symptoms observed in the cases from the Philippines usually manifested 3 weeks after consumption of raw or poorly-cooked fish. Persons with *C. philippinensis* infection usually develop symptoms as the helminth population increases, and present with abdominal pains and borborygmi. Patients initially experience intermittent diarrhea, which progresses to passing out 8–10 voluminous stools per day. After a few weeks, there is weight loss, malaise, anorexia, vomiting, and bipedal edema. Physical findings include pallor, muscle wasting, low blood pressure, distant heart sounds, gallop rhythm, pulsus alterans, abdominal distention and tenderness, edema, and hyporeflexia.

The parasites are responsible for micro-ulcers in the intestinal epithelium and the compressive degeneration and mechanical compression of epithelial cells. The ulcerative and degenerative lesions in the intestinal mucosa may account for malabsorption of fluid, fat, protein, and electrolytes. Laboratory findings may include low serum potassium, sodium, calcium, albumin, and total protein levels. Anemia with hypochromic and microcytic red blood cell morphology may be seen. Eosinophil ratios may be elevated. Histologically, the intestinal villi may appear flattened and denuded with dilated mucosal glands. The lamina propria is infiltrated with plasma cells, lymphocytes, macrophages, and neutrophils. Endoscopic finding may reveal nonspecific segmental erythematous inflammation with superficial erosions with exudation in the small intestines. Upper gastrointestinal series with barium may reveal mucosal thickening and segmentation in the small intestines suggestive of malabsorption syndrome.

Severe electrolyte loss, dehydration, and heart failure may occur in untreated cases, and may result in fatality. Necroscopy findings may show serous fluid in the abdominal, pleural, and pericardial cavities. Histological sections of the small intestines may reveal large numbers of worms in the glands, crypts of Lieberkuhn, and within the lamina propria. Villi may be denuded or completely destroyed, and glands may be dilated and filled with eosinophilic debris. Plasma cells, lymphocytes, macrophages, neutrophils, and eosinophils may be seen as infiltrations in the lamina propria.

Diagnosis and Treatment

Suspicion of capillariasis may be made based on symptoms of chronic diarrhea, borborygmi, abdominal pain, and weight loss in a patient with a history of travel to an endemic area and

a history of eating raw or poorly-cooked fresh- or brackish-water fish. A definitive diagnosis may be made based on finding characteristic eggs in the feces by direct smear or wet mount, or by stool concentration techniques. Various larval stages of the parasites as well as adult worms may be seen in the feces. The parasites can also be recovered from the small intestines by duodenal aspiration.

The use of sandwich enzyme-linked immunosorbent assay (ELISA) in the detection of coproantigen prepared from stool samples of infected patients has been demonstrated to have high specificity for the diagnosis of capillariasis. This technique did not show cross reaction with coproantigen from patients with *Fasciola gigantica* and *Schistosoma mansoni*. In another study done in Thailand, cross reaction of capillariasis patient antibodies with *Trichinella spiralis* antigen in immunoblot assay suggested the prospective use of *T. spiralis* antigen for the immunodiagnosis of capillariasis. ELISA using *T. spiralis* antigen was shown to have a sensitivity of 100% (43 positive cases) and a specificity of 100% (57 negative cases) in the diagnosis of capillariasis. Examination of fresh water fish may show *C. philippinensis* larvae although this is not routinely done.

The current drug of choice for the treatment of capillariasis is mebendazole given at 200 mg twice a day for 20 days, for both adult and pediatric patients. Albendazole is the alternative drug, given at 400 mg as a single dose or in two divided doses for a period of 10 days for both adult and pediatric patients. Cases of relapse, or the recurrence of capillariasis after a period of improvement, have been documented, and have been attributed to the inability of the anthelminthics to affect parasite larvae. Extended treatments allow maturation of larvae into drug-susceptible adults. Mebendazole 200 mg twice a day may be given for an additional 30 days in cases with relapse. Alternatively, albendazole 400 mg day^{-1} may be given for an additional 20 days. Supportive treatment with replacement of fluid and electrolytes, as well as high protein diet must also be considered. A repeat stool examination may be done after treatment to monitor the infection status of the patient after treatment.

Epidemiology

After reports of capillariasis in the Northern Philippines in 1966, sporadic cases were then seen in neighboring countries. The first case of capillariasis reported in Thailand was in an 18-month-old girl in 1973, whereas the first epidemic was reported in 1981. In Taiwan, a review of local hospital data throughout Taiwan since the report of its first case in 1983 revealed a total of 30 capillariasis cases (from 1983 to 2003), 21 of whom were from two major Taiwanese aboriginal tribes. Cases of capillariasis were later reported in Iran, Japan, Indonesia, United Arab Emirates, South Korea, India, Egypt, and Lao People's Democratic Republic.

In the Philippines, nearly 2000 cases have been reported from the Northern Luzon provinces from 1967 to 1990. Cases have also been documented in Zambales, in Central Luzon, and Southern Leyte in the Visayas region. In Monkayo, Compostela Valley Province in Southern Philippines, an outbreak described as a 'mystery disease' in 1998 resulted in the death of villagers due to misdiagnosis. Intestinal capillariasis was diagnosed in 17% of the cases presenting with chronic diarrhea. Poor sanitation and defecation in fields and rivers were also reported. A more recently described endemic area in the Philippines includes Zamboanga del Norte, where 4.9% of those examined were confirmed to have capillariasis. Residents in the area have reported consumption of raw freshwater fish.

Disease Control and Prevention

Early diagnosis and treatment can greatly contribute to a decrease in mortality caused by capillariasis. Health service providers, especially in endemic areas, must be made aware of the common signs and symptoms of capillariasis, and should be familiar with the treatment regimens for the disease. Microscopists must also be trained in identifying *C. philippinensis* ova in stool to increase sensitivity of diagnosis. This can also contribute to more accurate disease surveillance in the community. Improvements in environmental sanitation may help reduce disease transmission. Discouraging indiscriminate or open defecation and consumption of raw or poorly cooked fish through health education may also contribute to disease prevention and control.

Gnathostoma spinigerum

P Dekumyoy, D Watthanakulpanich, and J Waikagul, Mahidol University, Bangkok, Thailand

Glossary

Copro-DNA technique A method used to detect the DNA of parasitic agents, especially intestinal parasites in the fecal samples of human or animal hosts.
Immunoblotting A sero-test for examining specific antibody; the results normally show a specific diagnostic band for an infection.
Intermediate host An animal in which a parasite can develop into a further developmental stage, but not an adult stage.
Migratory swelling A specific technical term for the symptom caused by a gnathostome worm migrating under the superficial layers of the skin.
Paratenic host An animal in which a parasite larva can live with suspended development.
Xanthochromic Pale blood-colored cerebrospinal fluid.

Background

Larvae of the nematode *Gnathostoma spinigerum* cause migratory swelling syndrome in humans. Superficial infections are painful and irritating, but the impact of deep infection is more devastating. If the infected organ is the brain, the person affected may be paralyzed or die. Infection is usually acquired by eating raw or insufficiently cooked fish, the second intermediate host; however, infection is also possible by direct penetration of actively moving larvae. Gnathostomiasis spinigerum is distributed mainly in Asia, and has recently appeared in countries where the disease was previously nonendemic, among travelers returning from endemic areas in Asia.

Characteristics and Transmission

The gnathostome nematode has a body and head-bulb covered with rows of spines. The number of rows, and the number and shapes of the spines are diagnostic characteristics of *Gnathostoma* species. There are 13 species in the genus *Gnathostoma*; among them, five species have been reported in humans (*Gnathostoma binucleatum, Gnathostoma doloresi, Gnathostoma hispidum, Gnathostoma nipponicum,* and *Gnathostoma spinigerum*), and one possible infection with another species, *Gnathostoma malaysiae*. *G. spinigerum* is the main causative agent of infection in humans in Asia, and its close relative, *G. binucleatum*, is mainly distributed in Latin America. *G. spinigerum* AL3 (Figure 1) can be distinguished from other species by the shape and number of hooklets in the head-bulb and the number of nuclei of the intestinal epithelial cell (Table 1).

Gnathostoma spinigerum has a complicated life cycle, involving many species of animals as first, second, paratenic, and final hosts. Adult males and females live in a tumor in the stomach wall of their feline and canine definitive hosts. Eggs are released by gravid females, and pass out of the host with the feces, entering natural water resources. Second-stage larvae hatch out and swim freely in the water, then develop into early third-stage larvae after being eaten by copepods (*Cyclops* spp.), the first intermediate host. Infected copepods are eaten by fish, the second intermediate host, and advanced third-stage larvae (AL3) develop and encyst in the liver and muscles of their fish host. AL3 can survive in many species of fish, amphibians,

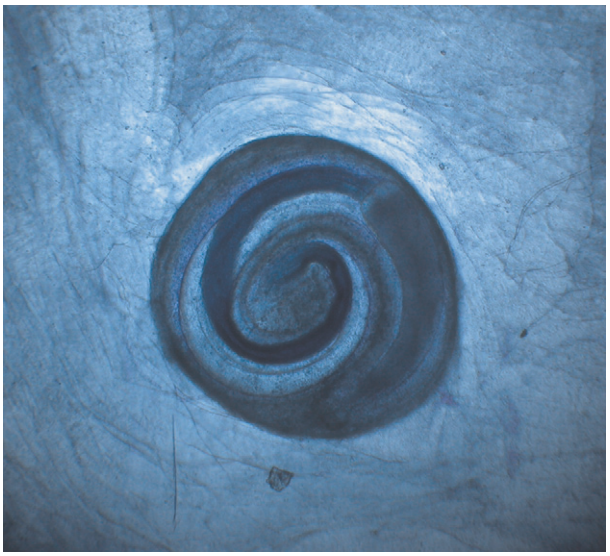

Figure 1 Advanced third-stage *G. spinigerum* larva encysted in frog's muscle.

 doi:10.1016/B978-0-12-378612-8.00144-X

Table 1 Specific characteristics of advanced third-stage *G. spinigerum* larvae

- Body approximately 4.0 mm in length
- Head-bulb armed with four rows, and in each row there are 43, 44, 45, and 49 hooklets
- Head-bulb hooklets are oblongated
- Intestinal epithelial cell has 3–7 nuclei (those that morphologically closely resemble the species *G. binucleatum* has 2–5 nuclei)[a]

[a]Akahane *et al.* (1994) A morphological observation of the advanced third-stage larvae of Mexican *Gnathostom. Japanese Journal of Parasitology* 43(1): 18–22.

Table 2 Transmission routes of advanced third-stage *G. spinigerum* larvae (AL3) to humans (Daengsvang, 1980)[a]

- Ingestion of encysted or excysted AL3 in meat of fish and other animals – second intermediate hosts and paratenic hosts
- Ingestion of early third-stage larvae in copepods (first intermediate host) – *Cyclops* spp.
- Direct penetration of AL3 into human skin during preparing food (infected meat)
- Migration of AL3 via placenta (transplacenta) from infected pregnant mother to embryo in uterus

[a]Daengsvang S (1980) *A Monograph on the Genus Gnathostoma and Gnathostomiasis in Thailand*, pp. 1–87. Tokyo: SEAMIC/IMFJ.

reptiles, and birds without further development among these prey–predator cycles. This characteristic makes the gnathostome a unique nematode, as transmission can occur in several ways (Table 2). The most common route of infection is the ingestion of raw fish containing AL3. However, other intermediate and paratenic hosts also play important roles in parasite transmission. Freshwater fish are a common food source, and are prepared differently in several countries. Several local dishes are reported and commonly prepared, such as the fish dishes *som fak*, *pla raa*, *pla jom*, *koi pla*, and small amphibians, in Thailand; *ceviche* and *callos* in Latin America; *sashimi* and *sushi* in Japan; *naniura* (fish) in Indonesia; roast eel in Vietnam; raw bream in Zambia; and raw catfish in Tanzania. Rural inhabitants and the urban residents of some Asian countries eat the meat, viscera, and blood of paratenic hosts, such as snakes and aquatic snails. Visitors who encounter/enjoy eating local and exotic foods find these dishes interesting. Gnathostome infection may occur by skin penetration when handling infected fish with bare hands, while preparing food at home, and preparing home and industrial products using fish materials. While rare, the consumption of infected copepods with early-stage *Gnathostoma* larvae from water resources may cause accidental infection. Another possibility, the local application of reptile or amphibian flesh to a wound, may cause the penetration of larvae from raw meat.

Clinical Manifestations

Gnathostoma larvae are likely to migrate randomly throughout the body of paratenic hosts, including humans. The disease has been divided into two main categories, external or cutaneous gnathostomiasis, and internal or visceral gnathostomiasis, depending on the site of larval migration and the organs affected. The clinical features can be cutaneous, ocular, neurologic, or a combination of all, and presentation varies from 24–48 h to 1–2 years after ingestion of infected-stage larvae. Symptoms can vary widely, and may include fever and malaise, depending on the migration of the worm. The most helpful manifestation in establishing a diagnosis is localized, intermittent, migratory swelling in the superficial layers of the skin, depending on the depth of the skin affected; for example, the hands, arms, shoulders, face, feet, or trunk (especially the abdomen), or even sometimes in more fragile areas, such as the eye, the brain, or the spinal cord. Cutaneous swelling varies in size, with signs of inflammation, redness, indurated erythematous plaques, and pain with itching, which might be the cause of migrating panniculitis, eruptions, and pseudofurunculosis. In addition, the swelling is hard and nonpitting, and lasts for various lengths of time before it subsides. Reappearance of the swelling in another spot can occur after a symptom-free interval of 1 week to several months. Some symptoms of pleura-pulmonary involvement are frequent coughing with or without exudates or hemoptysis, chest pain, dyspnea, and pneumothorax due to effects on the respiratory system. Patients may suffer from epigastric pain, nausea, or vomiting, which are presumably due to penetration of the gastric wall by the ingested larvae; granuloma may form in the peritoneal cavity. Hematuria may occur, with or without pain, or irritation of the kidneys. Serious symptoms, such as paralysis, seizures, or coma, may occur, depending on the location of the worm in the central nervous system (CNS). Ocular involvement also occurs, probably by migration of the worm via the optic nerves, and causes pain, uveitis, iritis, intraocular pressure and hemorrhage, retinal scarring, detachment, deteriorated visual acuity, and blindness. Clinical findings on physical examination depend on the area of the body into which the worms migrate, and vary among causative *Gnathostoma* species. In *G. spinigerum* and *G. binucleatum* infection, the disease persists with relapse for over several years in a relative deeper part of the skin of the peripheral part of the human body. In *G. hispidum*, *G. nipponicum*, and *G. doloresi* infections, where migration is close to the body surface of the trunk with skin lesions, the disease may spontaneously disappear within 3 months, even without treatment.

Pathogenesis

The primary cause of infection is the consumption of third-stage *G. spinigerum* larvae from infected intermediate hosts.

Larvae can penetrate the stomach wall and migrate randomly to many parts of the human host, to continue causing lesions, such as destruction of the liver parenchyma, hemorrhage, granulation, and cicatrization. Infection results in initial nonspecific symptoms such as fever, arthralgias, myalgias, malaise, anorexia, nausea, vomiting, and abdominal pain, followed by skin lesions, which probably result from hepatic disorder. The migrating worm causes mechanical and chemical damage to the tissues, including the production and action of several kinds of secretions with inflammatory and allergic reactions by the host. The pathologic picture of the swelling and track-like necrosis comprises marked inflammation in both acute and chronic stages, necrotic changes, fibrogranulomatous formation, intense cellular infiltration with neutrophils, small mononuclear cells, plasma cells, and massive numbers of eosinophils. Leukocytosis with marked hypereosinophilia occurs in the peripheral blood, but does not correlate with clinical severity, and may also be associated with numerous other diseases. The parasite can also migrate into the ocular system and CNS, resulting in decreased visual acuity, blindness, and neurological symptoms, such as eosinophilic meningitis or meningoencephalitis and subarachnoid, as well as intracerebral and intraventricular hemorrhage. In cerebral gnathostomiasis, the cerebrospinal fluid (CSF) is usually bloody or xanthochromic, and a pleocytosis with increased white blood cells and prominent eosinophils.

Diagnosis and Analytical Methods

Patient diagnosis can first be performed using clinical symptoms, and confirmed by indirect antibody detection using serological methods, especially the immunoblotting technique. Stool examinations of the definitive canine/feline hosts for the presence of gnathostome eggs can confirm the disease transmission area and species of gnathostome nematode. Inspection of food materials and foodstuffs from intermediate and paratenic hosts must be conducted for food-safety precautions. Several species of fresh- and brackish-water fish, amphibians, crustaceans, reptiles, avians, and mammals have been reported as hosts harboring gnathostome worms. Several techniques have been used to detect parasites.

The current diagnosis of gnathostomiasis utilizes one technique or a combination of techniques, such as the detection of worms from a skin lesion or clinical manifestations and sero-testing the suspected case for specific antibody to *Gnathostoma*. Sero-detection is now routine practice, and the current sero-tests include the skin test, immunofluorescent test, ELISA, and immunoblot. Different antigen preparations from *G. spinigerum* have been used in these tests, such as crude extracts or sectioned samples, excretory–secretory products from infective larvae, and adult worms. DNA recombinant antigens have been developed and are being analyzed for their specificity to gnathostomiasis sera. Until now, native antigens have been used in sero-tests. Immunoblot using 24 kDa antigen from *G. spinigerum* infective larvae to serum IgG has shown 100% sensitivity (all worm-proven *G. spinigerum* cases) and an excellent specificity is determined by no reaction with 28 different diseases (not yet published). *G. hispidum* and *G. binucleatum* have been used as sources of antigens for ELISA and immunoblot. Immunoblot was used in the detection of IgG rather than IgG subclasses. For indirect ELISA, it is recommended that IgG1 and IgG2 subclasses yield higher sensitivity and specificity than total IgG for screening gnathostomiasis sera. However, the excellent sensitivity and specificity of these tests are based on the number samples of homologous and heterologous diseases used as reference.

The compression and digestion methods are commonly used for detecting and collecting gnathostome larvae in intermediate/paratenic host tissues. The compression technique is simple but tedious; *Gnathostoma* larvae are observed in host tissue samples pressed between two glass plates under a stereo-microscope. The tissue sample should be thin enough to observe larvae in encysted or unencysted forms. Gnathostome larvae are easily seen as red or pink spots in fish flesh or livers; sometimes, they appear pale yellow, which may cause detection difficulties, particularly for inexperienced laboratory staff.

The digestion method uses artificial gastric juice (1% HCl–1% pepsin) solution and activates the digestion at 37 °C in a shaking water bath or by stirring with a glass rod. Other protocols include the use of 0.6% pepsin in 0.08% HCl and incubation at 37 °C for 2–3 h, or 1.5% pepsin in water, adjusted to pH 2.0 with 1 M HCl, digestion at 37 °C for 4 h, or concentrated pineapple juice at 37 °C for 4 h. Pepsin digestion may be replaced with acid–trypsin digestion, but it is less efficient than pepsin. However, trypsin is cheaper than pepsin. This method is useful for digesting chopped tissues and tissue connected with pieces of host bone.

Control/Prevention Measures

It is recommended that meat be cooked using sufficient heat and time to kill the parasite before consumption. The physical and chemical methods used to preserve meat products, with the appropriate concentrations and times for killing gnathostome larvae, are summarized in Table 3. A protocol on methods for cooking meat and killing gnathostome larvae should be developed and distributed on media that are accessible to the public and the food industry. Offal of raw meat of intermediate/paratenic hosts must be segregated and not fed to the definitive hosts – dogs and cats – to prevent completion of the organism's life cycle.

Travelers entering endemic areas should be informed about gnathostomiasis, and how to prevent infection, by avoiding eating raw or improperly cooked freshwater fish, frogs, snakes, or even birds and chicken. Drinking water directly from natural water sources – especially ponds or lakes – should be avoided to prevent accidental intake of copepods infected with gnathostomes.

Information on gnathostomiasis and its prevention should be provided to the general public.

Research Needs

There is a need for further investigation of the epidemiology of gnathostomiases and *Gnathostoma* in many countries

Table 3 Estimated survival times for gnathostome larvae exposed to chemicals and other conditions

Condition	*Exposure time*	*Effect*
Temperature[abc]		
−4 °C	22 days	Encysted larvae survive
−9 °C	9 days	Encysted larvae survive
−20 °C	3–5 days	Encysted larvae survive
65 °C	5 h	Encysted larvae survive
Water at >70 °C	5 min	Killed encysted larvae
Boiling water	>5 min	Killed larva at 1 cm depth in muscle of fish
Boiling water and steaming	Few minutes	Killed encysted larva at 2 cm depth in fish
Salinity[ac]		
Soy	12 h	Killed encysted larva
Fish sauce (23% NaCl)	18 h	Encysted larvae survive
Salt (30%)	20 h	Encysted larvae survive
Physiological saline (0.9%)	12 days	Encysted larvae survive
Acid[abcd]		
Vinegar	6 h	Killed encysted larva
Vinegar (4% acetic acid)	5.5 h	Killed larva at 1 cm deep in muscle of fish
Vinegar (4% acetic acid)	8 days	Encysted larvae survive
Lime juice	5 days	Encysted larvae survive
Lime juice	5 days	Larvae survive
Lime juice containing 7.74% citric acid	7 days	Killed encysted larvae at 2–4 mm deep in the flesh of fish and frog
Others[c]		
Syrup (20% sugar)	6 days	Encysted larvae survive
28% ethyl alcohol	8 days	Encysted larvae survive
35% ethyl alcohol	9 days	Encysted larvae survive
Desiccation at room temperature	3 h	Encysted larvae survive
Minced meat salad	>8 days	Encysted larvae survive
De-chlorinated tap water	6 days	Encysted larvae survive
Radiation[e]		
Cobalt-60 gamma at 8 kGy	Not mentioned	Stop infectivity

where information is lacking. *Gnathostoma* worms may exist in the same geographical region and similar environmental settings. Though gnathostomiasis may not occur in these countries, and the inhabitants do not consume raw fish, there is still a risk for travelers who consume raw fish.

A commercial kit needs to be developed for the diagnosis of gnathostomiasis and the improvement of larva-detection methods in intermediate/paratenic host meat. There is also a need for a copro-DNA technique to detect gnathostome eggs in fecal samples of definitive hosts, for epidemiological surveys to identify new endemic areas.

At present, the available treatment of gnathostomiasis is a long-term regimen (10–21 days) of 400 mg albendazole. In some reports, albendazole was administered in combination with praziquantel or ivermectin. A better treatment with either shorter-term regimen of a new drug, or a new combination of anthelmintic, is needed. More in-depth research on the genetic/biology of worms and factors inducing clinical involvement, using multidisciplinary advanced technologies, would create new findings to enrich our knowledge of *Gnathostoma* and gnathostomiasis. A research network for *Gnathostoma* and gnathostomiasis has been developed between Mexico and Thailand, and other international collaborators are welcome.

Haplorchis

JH Clausen and D Murrell, University of Copenhagen, Frederiksberg, Denmark

Glossary

Cercaria The free-living larval stage produced by the intra-snail cycle of asexual multiplication in the life cycle of the parasite; the cercariae escape and swim from the snail, seeking the next host.

Intermediate host Fishborne trematodes (e.g., *Haplorchis*) have two intermediate hosts in their life cycle: an aquatic snail in which asexual multiplication of the larval trematode occurs, and fish the second intermediate host in which the metacercaria encysts.

Metacercaria The encysted resting or maturing stage of a trematode parasite in the tissues of an intermediate host. This is the trematode stage that is infective to the definitive host (in which the trematode parasite develops to the adult, sexually reproducing stage). For fishborne trematodes, the fish harbors the metacercaria.

Praziquantel An anthelmintic drug used for treatment of a wide spectrum of helminth infections, including almost all species of trematodes and many species of cestodes.

Background

Foodborne intestinal trematodes (flukes) are currently estimated by the World Health Organization (WHO) to infect 40–50 million people worldwide, and probably half of them acquired the parasites from fish. Belonging to the Heterophyidae family of helminth parasites, species of *Haplorchis* predominate among fishborne zoonotic parasites. *Haplorchis* is a common parasite of fish-eating birds and mammals in Africa, Eurasia, and Australia. Three species of *Haplorchis*, *Haplorchis pumilio*, *Haplorchis taichui*, and *Haplorchis yokogawai* are especially common in humans in these regions. Looss first described *H. pumilio* from pelicans and kites in Egypt in 1899, and it was recovered from humans in Taiwan by Nishigori in 1924. Also in 1924 in Taiwan, Chen recovered *H. taichui* from humans, and in 1932 Katsuta reported human infections with *H. yokgawai*. Since then, one or more of these species are frequently reported from China, Taiwan, Vietnam, the Philippines, Laos, Thailand, Malaysia, Indonesia, and Egypt. The genus *Haplorchis* has a very wide intermediate and definitive host range. As discussed below, the wide host range and human fondness for raw or lightly prepared fish foods are main factors for the wide geographic distribution of the haplorchids. For example, the number of species of fish (second intermediate host) reported to be susceptible to the infection with metacercariae (infective stage for mammals and birds) is more than 70. The number of fish-eating birds (including migratory species) and mammal species that are susceptible is also large.

Although *Haplorchis* has been recognized as potentially zoonotic for nearly a century, it is only during the past 20 years that recognition of it as a very common fishborne zoonosis has emerged, especially in the countries of South East Asia. In terms of infection intensity, it has been frequently shown to be the dominant intestinal fluke. This belated recognition is undoubtedly due to diagnostic confusion in routine fecal exams for parasite eggs (the primary detection procedure). It is very difficult to discriminate between the eggs of heterophyids ('minute trematodes') and those of other trematodes, especially those of the liver flukes. This has resulted in under reporting of intestinal flukes such as *Haplorchis* (until recently poorly known), and the over reporting of *Clonorchis sinensis* and *Opisthorchis* spp., which have long been recognized as important fishborne liver flukes. However, the increasing inclusion of worm expulsion methods in epidemiological studies, which yield adult stages for morphological and molecular analysis, is allowing more definitive species identification, and the resulting data are altering the human parasite diversity profiles in many regions and underscoring the poor specificity of fecal exams for small trematode eggs.

Characteristics

Taxonomy and Morphology

Adult *Haplorchis* trematodes are parasites of fish-eating birds and mammals, including humans and their domestic animals such as dogs, cats, and pigs which are important epidemiologically as reservoir hosts.

The *Haplorchis* genus is a member of the subfamily Haplochorinae, which is distinguished from other members of the Heterophyidae family by certain morphological features of the ventrogenital complex (Figure 1, adults). The Haplorchinae are characterized by the presence of a genital pore, gonotyle, and ventral sucker, which are sunk below the ventral surface in a single, common invagination, termed the ventro-genital sac; there is only a single opening on the ventral surface. Within the subfamily, *Haplorchis* is differentiated from other genera by

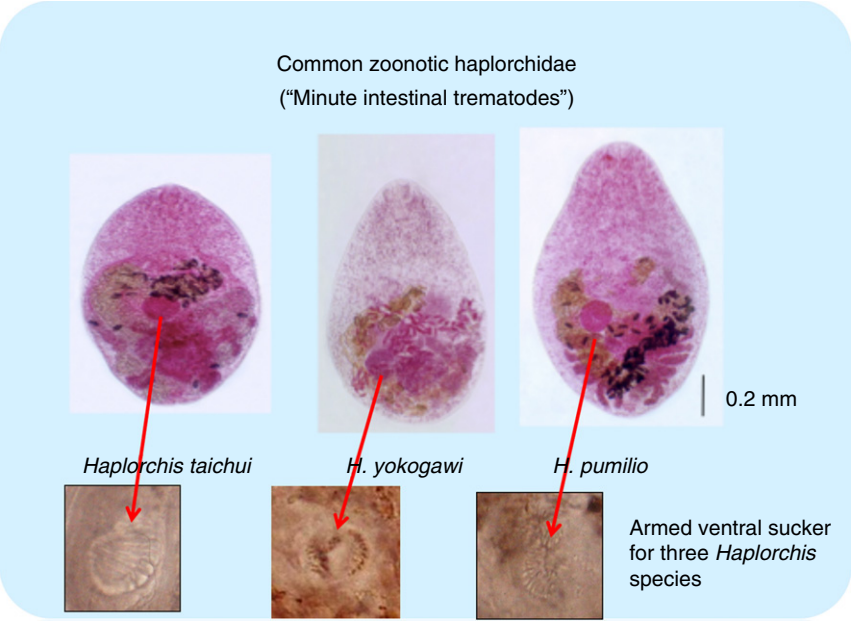

Figure 1 The difference in the number of spines around the ventral sucker between three species of *Haplorchis*, namely *H. taichui*, *H. yokogawi*, and *H. pumillio*, is shown. Ventral sucker of *H. taichui* armed with 12–16 spines, ventral sucker of *H. yokogawi* with apex comprising a large ventral lobe armed with numerous tiny spines and a larger variable but characteristic pair of sclerites ventro dextrally, and the ventral sucker of *H. pumilio* with 32–40 spines (Photos provided by Dr NT Lan Anh, National Institute of Veterinary Research, and Dr Do Dung, National Institute of Malariology, Parasitology and Entomology).

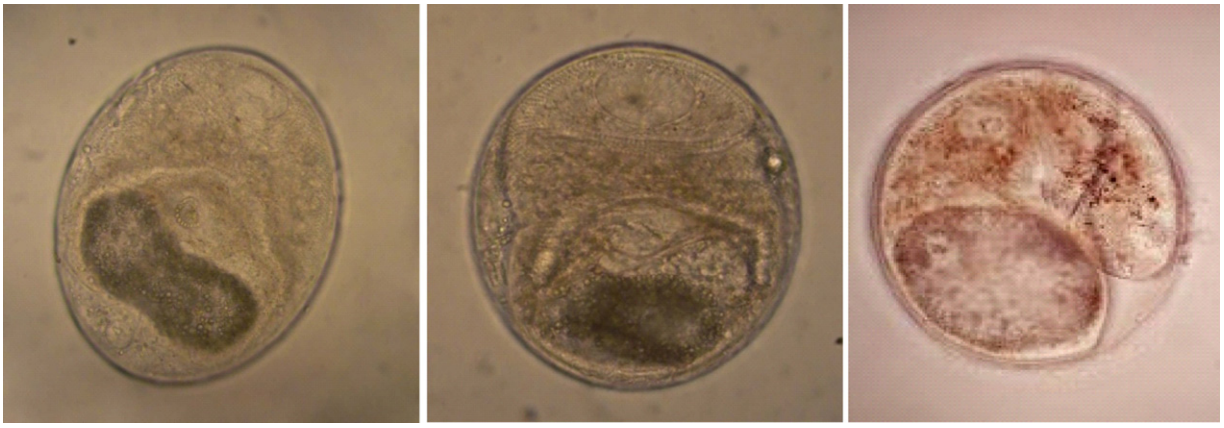

Figure 2 Metacercaria isolated from fish muscle seen through stereomicroscope (Photos of *H. taichui* and *H. pumillio* by Mr Jakob Skov and *H. yokogawi* by Dr Woon-Mok Sohn).

having a single testis and no gonotyle. The infective larval stage (metacercariae) for these hosts occurs in fish belonging especially to the Cyprinidae, Siluridae, and Cobitidae. Because the haplorchids are quite small, typically 30×18 μm in size, their species diagnosis can be difficult, especially in the metacercarial stage (Figure 2).

However, for the three most commonly encountered species in human infections, *H. pumilio*, *H. taichui*, and *H. yokogawai*, the number, size, and arrangement of spines on the ventral sucker are diagnostic (Figure 1). Recently, molecular methods have been developed which have promise for distinguishing the adult, metacercaria, and cercaria stages of *Haplorchis* spp.

Life Cycle

The life cycle of all *Haplorchis* species is similar and is characteristic of members of the family Heterophyidae (e.g., *Heterophyes* and *Metagonimus*). A schematic life cycle of Haplorchis is shown in Figure 3.

The adult worms residing in the small intestine of the definitive host shed eggs (typically less than 30 μm in length)

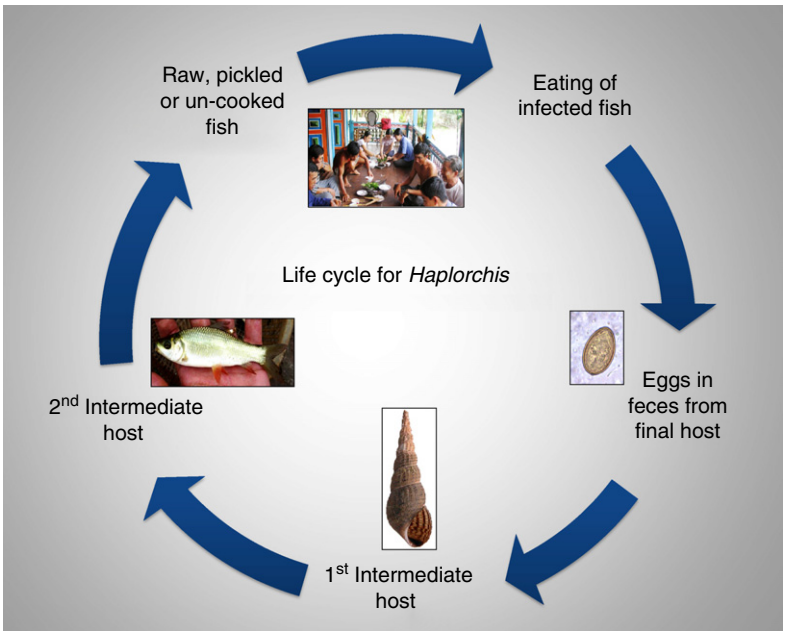

Figure 3 Schematic illustration of the life cycle for *Haplorchis* (Photos by Henry Madsen, Jesper Clausen, Darwin Murrell, FIBOZOPA).

which are voided with the feces. If deposited into water bodies they may be ingested by certain snails (for *Haplorchis*, snails belonging to the genera *Melanoides* and *Melania* are important vectors). In the snail the egg hatches releasing a miracidium, which invades the snail organs and metamorphoses to a sporocyst, in which, through asexual multiplication, daughter redial stages develop. In these, a second cycle of asexual multiplication occurs, producing large numbers of pleurolophocerus cercariae, which escape and swim from the snail. Attracted by fish, the cercariae penetrate under the fish's scales, or into the gills, muscle, and skin. Within a few days the cercariae develop into an encysted metacercarial stage which is infective to the definitive host. The life cycle is completed when the infected fish, or fish parts, is eaten by a bird or mammal, in which the metacercariae develop to the egg-producing adult stage within 4–5 days.

Virulence Factors

The pathology caused by intestinal infection has received little attention. However, it seems certain that because the adult worms insert themselves intimately with the intestinal villi the amount of damage to that layer is proportional to number of worms present. It is also not known if the adult worms secrete enzymes or other chemicals to facilitate their adherence and invasion of intestinal tissues; secretory products are not uncommon among other helminth parasites, such as *Trichinella*. These questions are only now beginning to be investigated.

Resistance Factors Facilitating Survival in the Intestine

There is little information on the longevity of adult *Haplorchis* in humans. In experimental infections in mice, a reduction of worm populations can be seen after 1 week of infection, however, infections in chickens have been reported to persist for up to 48 days. The earlier expulsion of worms from mice may be immune mediated because there is evidence that this 'self-cure' is density dependent. Long-term studies in suitable experimental models are needed to characterize the population dynamics of adult *Haplorchis* in infections in which metacercarial exposure is similar to the natural exposure doses and frequency experienced by humans.

Clinical Manifestations

Disease caused by minute flukes of the Heterophyidae family is called heterophyidiasis. Infections are less associated with mortality than other groups of parasites; however, cases with heavy infections of some well-studied heterophyid species (e.g., *Heterophyes* and *Metagonimus*) are often associated with diarrhea, mucus-rich feces, catarrhal inflammation, abdominal pain, dyspepsia, anorexia, nausea, and vomiting, the most prominent symptoms being malabsorption and diarrhea.

Because halporchid infections have only recently been recognized, it is not possible yet to assess their overall health impact. However, a recent report on *H. taichui* in Thailand indicates that mucosal ulceration, mucosal and submucosal hemorrhages, fusion and shortening of villi, chronic inflammation, and fibrosis of the submucosa can occur. A recent investigation on intestinal pathology caused by experimental infections of the rat with *Centrocestus armatus*, a close heterophyid relative of *Haplorchis*, is also suggestive. In the intestine the stroma of villi around the fluke became edematous and infiltrated by inflammatory cells such as lymphocytes, plasma cells, and eosinophils. The crypt became mildly hyperplastic and villi were moderately atrophied at 4 days postinfection. The intestinal lesion produced was confined to the areas around the

fluke, and the pathologic findings were not significantly different between infections with 1000 and 5000 flukes.

Epidemiology and Preharvest Control of Fish Infections

The geographical distribution of *Haplorchis* spp. is not well described in the literature, but it is likely very common in South East Asia, South Asia, the Middle East, and Africa. They are particularly endemic in the Philippines, Malaysia, Indonesia, Thailand, Lao People's Democratic Republic, Vietnam, People's Republic of China, and Egypt. Fish sources of infection include both wild caught and farmed fish.

The eating of raw, undercooked, or pickled fish is a key risk factor for humans to acquire infection. In South Asia and South East Asia especially, there are long traditions of eating raw, pickled, or undercooked fish. A good example is the tradition of eating different varieties of sour fermented fish in Thailand, Laos, and Cambodia. The raw fish is fermented giving it its sour taste and is considered a delicacy, especially in rural areas of North Eastern and Central Thailand, where it is called *Pla Som* It is known as *Pla Hok* in Cambodia and *Pa Som* in Laos. Other traditional ways of preparing fish are mixing it with raw crab meat spiced with soy sauce (ke-jang) in the Republic of Korea, and the eating of raw grass carp dishes in China and Vietnam. During food preparation, cross-contamination arising from using the same knife and chopping board for raw fish and other food products in kitchens and in restaurants may also be an important risk. Fish for these traditional raw, pickled, and uncooked dishes are normally obtained from fresh water reservoirs, lakes, rivers, or aquaculture ponds. The source of fish is also a risk factor for humans. Studies have shown that wild caught fish have a higher prevalence and intensity of *Haplorchis* metacercariae than fish reared in aquaculture ponds. Infection rates in pond fish appear to be influenced by the stocking density-at high densities metacercarial intensity can be nearly as high as in fish that are wild caught. As discussed in the Section on Clinical Manifestations, infections with *Haplorchis* are increasingly being reported. One important factor for this apparent emergence may be due to improvements in diagnosis (see Detection/Diagnosis Methods). Another possible explanation is that humans in endemic areas are increasing their consumption of fish.

Owing to an increased production of aquacultured fish more fish are available for consumption. The main production of aquaculture is being done in the Asian region, a region with many countries well known as endemic areas for fishborne zoonotic trematodes (FZTs). This increases the risk of exposure for consumers. However, the environments inside the aquaculture ponds, pens, or cages are often more controlled and manageable compared to natural environments. This increased level of control gives a unique opportunity to prevent FZTs from entering the cultured environment. Integrated control programs in fish nurseries and fish grow-out ponds have, therefore, been designed to lower the prevalence and intensity of metacercaria in fish being raised. The management practices of aquaculture can, therefore, be an important factor in controlling outbreaks and the spread of the parasite. Based on the risk-assessment studies that have been carried out in aquaculture systems, the following interventions should be included in a control program:

1. Because domestic animals such as pigs, cats, chickens, ducks, and dogs can act as alternative reservoir hosts, these domestic animals play a major role in the epidemiology of FZTs in aquaculture systems. Therefore, prevention of FZT infections in domestic animals must be included in aquaculture-management practices. This can be done by regular deworming of the animals and restricting their access to fish.
2. Humans residing and working on fish farms should also have regular parasite exams and be treated if infected.
3. Pond management must also include efforts to reduce the habitat conditions that promote snail invasion and multiplication (e.g., removing snails and mud from drained ponds when preparations are underway to prepare for new fish stocking). Control of run-off water to ponds and diversion of latrine drains (both from farm animals and from human facilities) are important interventions.
4. Education of fish farmers, fishermen, and the general public on the nature and consequences of eating raw or improperly prepared fish is also necessary.

Detection/Diagnosis Methods

The minute intestinal flukes can be detected in the three stages of their lifecycle: at the egg stage, the metacercaria stage, and the adult stage.

The metacercaria stage located in fish flesh or under the scales of the fish is the most important stage from a food-safety diagnosis perspective. To isolate the metacercaria from infected fish, two techniques are commonly used: the tissue compression technique and the digestion technique. Both techniques have their own advantages and it is up to the researcher or the analyst to choose the right method for the given task.

The compression technique is done by compressing fish flesh between two glass slides and examining the slides under a microscope. The advantage of this is that the analyst will know exactly where on the fish the sample is taken. The method is inexpensive and does not require chemical reagents.

The digestion technique is performed by subjecting either a whole fish or sections of a fish to pepsin enzymatic to liberate metacercariae. The advantages are that a large number of samples can be dealt with at the same time, and it is more efficient in recovery of any metacercariae present in the fish; the compression method is more likely to miss metacercariae in lightly infected fish. The metacercaria liberated from the flesh of the fish can then be easily isolated, identified microscopically, and utilized for either experimental infections or fixed for molecular or staining work.

To diagnose the potential infections of heterophyid intestinal flukes in humans (including *Haplorchis)*, a fecal sample from a host (human or animal) is processed and examined using simple techniques identifying the eggs. The most widely used methods are the Kato-Katz smear and formalin–ethyl–acetate techniques, because of their high sensitivity and because they allow for quantification of infection intensity.

Identification of adult flukes is done morphologically as the adults are easily recognizable compared to eggs and metaceraria stages. The major features and diagnostic characters of *H. taichui*, *H. yokogawi*, and *H. pumillio* metacercaria are shown in Figure 2. Some PCR-based methods have been developed in recent years to detect DNA from eggs and metacercaria in stool samples or from metacercaria which offer high sensitivity and specificity. However, molecular-based diagnostics are still expensive and it is considered unlikely at this current stage that they will become a standard tool for routine diagnosis.

Control and Prevention Measures

Postharvest control and prevention of the minute intestinal flukes are similar to the control measure for the liver flukes. There are reports that heating fish (e.g., sweet fish) for 10–15 min at 70 °C would be sufficient to inactivate metacercariae; however, the extent of research and available data are insufficient to determine the exact time–temperature treatment required. A review by WHO in 1995 of available data on processing conditions identified some parameters for heating, pickling, salting, freezing, and irradiating fish for the inactivation of parasites. Similar treatment conditions are also expressed in regulatory requirements of the US and the EU. For example, according to the US FDA, freezing and storing at –4 °F (− 20 °C) or below for 7 days (total time), or freezing at − 31 °F (− 35 °C) or below until solid and storing at –31 °F (− 35 °C) or below for 15 h, or freezing at –31 °F (− 35 °C) or below until solid and storing at –4 °F (− 20 °C) or below for 24 h is sufficient to kill parasites. FDA's Food Code recommends these freezing conditions to retailers who provide fish intended for raw consumption. Further, the heating of fish flesh to a temperature sufficient to kill bacteria is considered adequate for parasites.

Although brining and pickling of fish may reduce the risk, they do necessarily minimize it to an acceptable level. For example, some zoonotic trematode metacercariae require up to 8 days in 30% brine to be killed. Smoking to a temperature of 65 °C is considered to be effective for parasitic nematodes in fish, but there has been little research done on this process for intestinal trematodes.

Research Needs

Research is needed to better understand the importance of *Haplorchis* spp. and its public health impact on humans. Also needed are effective and sustainable aquaculture management practices to prevent infection in farmed fish. The rapid expansion of aquaculture in many areas of the world and the increasing demand for greater food safety and quality will only increase the need to control zoonotic parasites in fish. Although rapid and sensitive inspection procedures for use in fish processing would be helpful, much of the fish produced in less-developed countries do not pass a processing plant before being purchased by the consumer. However, postharvest inspection for exported and commercially high-value fish is feasible. Much more research would be needed, however, to develop cost-effective treatment technologies to render the product safe. Climate changes may be associated with an increase in snail habitats due to changed pattern of water flow. Snails are a key risk factor in the life cycle of fishborne zoonotic parasites and as a result of more snails, more people will potentially be at risk of getting infected with *Haplorchis* spp. Although the health and economic impact of many foodborne zoonoes in general has been at least partially estimated, this is not the case for recently emerged parasites such as *Haplorchis*. Impact evaluations of intestinal flukes on the health and economies of the countries with high endemicity are needed if these zoonoses are to be assigned their appropriate national priority for prevention and control resources. An integrated hazard analysis and critical control points (HACCP)-based approach including measures to prevent and control pollution with animal and human parasite eggs, the animal and snail intermediate hosts, and better aquaculture management practices is needed for a sustainable control of fishborne zoonotic parasites. The economic investment that will be required for poor and middle-income countries to develop sustainable control programs is difficult to project, but will probably be substantial, especially for fish export production systems. However, it is likely that the cost of not addressing the emerging risk of these flukes will be higher than the cost of taking action now.

Trichinella spiralis and Other *Trichinella* Species

HR Gamble, National Research Council, Washington, DC, USA

Glossary

Encapsulated Contained within a single muscle cell.
Muscle larvae First stage larvae of the genus *Trichinella* that are found encysted, or free, in host muscle tissue.
Newborn larvae First stage larvae of the genus *Trichinella* that are released by adult worms in the host intestine and migrate to muscle tissue.
Preharvest All processes of animal production that precede slaughtering.
Sylvatic That part of the transmission cycle of a disease or parasite that circulates in wildlife; opposite of domestic.

Background

The nematode parasite *Trichinella*, which people most commonly associate with pork, has historically been a serious cause for concern as a foodborne pathogen. It is distributed worldwide and has been found in virtually all carnivorous and omnivorous animals as well as less commonly in certain herbivores. *Trichinella spiralis* was first observed in 1835 by Paget, a British medical student, in the muscles of a man during postmortem dissection. The newly discovered worm was further described and named *Trichina spiralis* by Owen (1835). The name change to *Trichinella spiralis* was made in 1896 by Railliet because the genus *Trichina* had previously been attributed to a group of small flies.

A landmark in the history of clinical trichinellosis was Zenker's demonstration in 1860 that encapsulated larvae in the arm muscle caused the illness and death of a young woman. His subsequent collaboration with Leukart and Virchow confirmed the life history of the parasite by describing the various life cycle stages. Zenker's further investigations, using prior knowledge of the observation of *Trichinella* in pork, led him to identify pork as the source of human infection.

With the recognition of trichinellosis as an important foodborne disease, reports of its occurrence increased dramatically, with thousands of cases reported each year in Europe. As a result, mandatory testing programs for pork began as early as 1863 in Prussia and Germany and quickly spread to other countries in Europe. Although testing was not completely effective, it did remove the most heavily infected animals and greatly reduced the rate of human exposure. Some countries that did not adopt slaughter testing for *Trichinella*, most notably the US, relied on cooking and further processing methods to avoid human exposure. Over time, pig infections in most developed countries have been dramatically reduced due to improved management systems, including biosecure housing and the banning of waste feeding. However, pigs raised outdoors, under poor sanitary conditions and those exposed to wildlife, remain at risk. Further, due to the cosmopolitan distribution of *Trichinella* spp., human infection can result from eating meat from a wide variety of wild and domesticated animals.

Characteristics

Life Cycle

Trichinella spp. completes its entire life cycle in a single host (Figure 1). The infective stage is the first stage (L1) larva which is found in striated muscle cells of a wide range of hosts. On ingestion of *Trichinella*-infected muscle tissue by a new host, larvae are released by the host digestive processes. Larvae then enter the small intestine and burrow into the lamina propria of the villi in the jejunum and ileum where they undergo four molts to reach the adult stage. Adult male and female worms mate and produce newborn larvae. Adult female worms in the small intestine continue to produce larvae in most hosts for several weeks before they are expelled. Each female worm bears approximately 1500 newborn larvae, but this varies based on *Trichinella* species and host.

Newborn larvae leave the intestine and migrate, via the circulatory system, to the striated muscle tissue. During migration, the larvae are known to enter many tissues, including those of the myocardium, brain, and other sites, but here they either are destroyed or reenter the bloodstream. Generally, only larvae that reach striated muscles are able to continue development. They penetrate the sarcolemma of the fibers, where they mature. They become coiled within

 doi:10.1016/B978-0-12-378612-8.00145-1

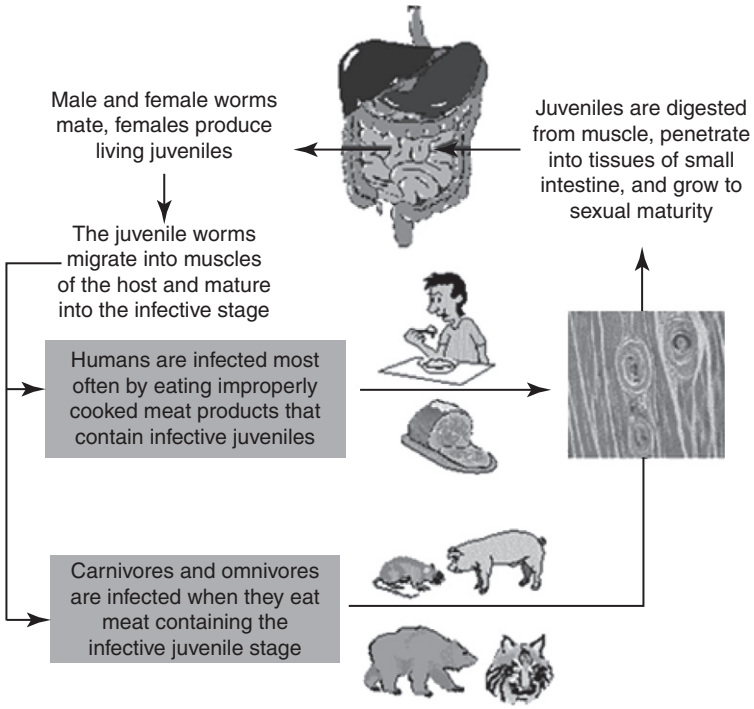

Figure 1 The life cycle of *Trichinella spiralis*.

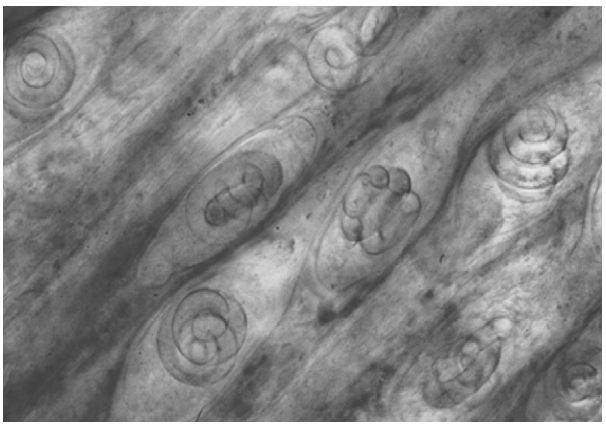

Figure 2 *Trichinella spiralis* larvae encapsulated in muscle tissue.

the fibers and, in the case of some of the species, are encapsulated as a result of the host's cellular response (Figure 2). This host–parasite complex, called the nurse cell, is capable of supporting the infective larvae for months or even years. An increased vascular supply to the nurse cell provides nutrients and oxygen vital to the parasite's survival. The encapsulated cyst eventually becomes calcified and as a result the larva dies.

The time required for complete development takes from 17 to 21 days (time from exposure to appearance and encystment of larvae in musculature). Once adult worms are expelled and migrating larvae reach and encyst in muscle tissue, no further increase in the number of worms can occur. An animal that is infected with *Trichinella* is at least partially refractory to a subsequent infection due to a strong and persistent immunity.

Morphology

The size of *Trichinella* larvae and adult stages varies by species and genotype. Muscle larvae (mature L1 stage) range in size from approximately 0.70–1.10 mm in length to 0.25–40 mm in width. Adult worms range in size from 0.60–1.60 mm in length to 0.25–0.35 mm in width for males and 1.25–3.35 mm in length and 0.30–0.40 mm in width for females. Newborn larvae (immature L1 stage) are approximately 110 μm in length and 7 μm in width. A distinguishing feature of the morphology of *Trichinella* spp. is the discoid shaped stichosome, which occupies the anterior third of the body. The secreted contents of these cells are important for serological detection of infection and also contain antigens which confer protective resistance to the host.

Taxonomy

For many years, the genus *Trichinella* was thought to be monospecific. Although the taxonomy of the genus continues to evolve, based on the findings using molecular tools, eight species and three genotypes of *Trichinella* are currently recognized. Of these, five species and three genotypes are found encapsulated in the host, whereas three species are non-encapsulating. All species and genotypes cause disease in humans.

Trichinella spiralis (also called T-1) is distributed in temperate regions worldwide and is most commonly associated

with a domestic pig cycle. It is the primary species found in pigs, wild boar, horses, and synanthropic rats, but may also be found in wildlife, especially in the vicinity of pig farms where transmission is ongoing. This species is highly infective for pigs, mice, and rats.

Trichinella nativa (T-2) is a cold climate adapted species. It has very limited infectivity for pigs, is found most commonly in wild canids, bear, and walrus. It is further distinguished by its resistance to freezing. *Trichinella nativa* causes human disease in arctic and subarctic regions.

Trichinella britovi (T-3) is found predominantly in wild animals, although it may occasionally be found in pigs or horses. It is widespread in temperate regions of Europe and Asia and has been associated with human disease resulting from the ingestion of undercooked game meats.

Trichinella murrelli (T-5) has been reported in wild animals from the US and parts of Canada. It has not been reported in domestic pigs, but has been reported in a horse; human infections have resulted from the ingestion of undercooked game meats.

Trichinella nelsoni (T-7) has been isolated sporadically from wildlife in Africa. It is characterized by greater resistance to elevated temperatures (2–3 °C higher) as compared with other species of *Trichinella*.

Three genotypes of encapsulating *Trichinella*, designated T-6, T-8, and T-9 have also been described. T-6 is found in carnivores in North America and parts of Canada. It is similar to *T. nativa* in its resistance to freezing in animal tissues, but does not extend as far north in its range. It is distinguished from *T. nativa* by both biochemical and molecular characters. *Trichinella* T-8 has only been reported in Africa. It is similar to *T. britovi*, but again, may be distinguished by both biochemical and molecular characters. *Trichinella* T-9 occurs in Japanese wildlife and may be differentiated from *T. britovi* by molecular methods. No human cases have been attributed to infection with *Trichinella* T-8 or T-9.

Three species of *Trichinella* do not form capsules in the host (Figure 3). These are *Trichinella pseudospiralis*, *Trichinella papuae*, and *Trichinella zimbabwensis*. *Trichinella pseudospiralis* has been recovered from raptorial birds, wild carnivores including wild boar, rats, and marsupials in Europe, Asia, North America, and the Australian subcontinent. Several human outbreaks due to *T. pseudospiralis* have been reported. *T. papuae* has been found in domestic and wild pigs as well as saltwater crocodiles (fed pig meat) in Papua New Guinea. Owing to its ability to infect reptiles, it is the suspected agent of human trichinellosis resulting from the ingestion of turtle and lizard meat. *Trichinella zimbabwensis* is similar to *T. papuae* in its ability to infect reptiles and wild carnivores. It has been reported in several parts of Africa but has not been implicated in human disease.

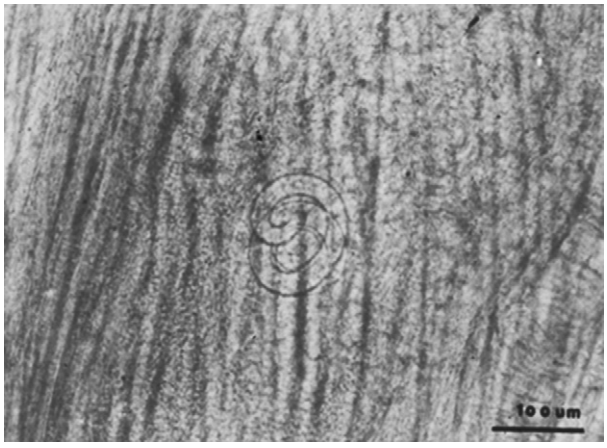

Figure 3 *Trichinella pseudospiralis* larva in muscle tissue. The larva is not encapsulated (compare to Figure 2).

Clinical Manifestations

Trichinellosis (the disease caused by *Trichinella* in humans) is manifested by symptoms associated with worms developing in the intestine (enteral phase) and in the musculature (parenteral phase). The occurrence of symptoms varies depending on the infecting dose, the susceptibility of the individual and possibly the species of *Trichinella*. In heavy infections, intestinal symptoms may develop as early as 1 week following ingestion of infective larvae. Intestinal symptoms, caused by worms invading and growing in the intestinal villi, typically include abdominal discomfort and diarrhea. The enteral phase generally only lasts a few days, but prolonged diarrhea has been observed in outbreaks in Arctic regions where *T. nativa* is the etiological agent, suggesting some clinical differences in the infecting species.

The onset of symptoms in the parenteral phase may occur within 1–2 weeks following infection or may be much later (4–6 weeks) as larger numbers of worms migrate and accumulate in the musculature. The clinical picture of the parenteral phase is much better defined although no signs or symptoms are pathognomonic. Symptoms include facial, and especially periorbital, edema, myalgia, headache, fever, and in some cases a macropapular rash. Conjunctival and subungual hemorrhages are also frequently observed. Complications principally include myocarditis and encephalitis which result from larvae migrating with heart musculature or the central nervous system.

The most common laboratory findings in trichinellosis are high eosinophil counts and increased levels of muscle enzymes including creatine phosphokinase and lactate dehydrogenase. Eosinophil counts may reach 10 000 cell mm^{-3} and elevated levels may persist for several weeks to several months following infection. Muscle enzymes in serum typically increase several fold during active infection (larval migration and muscle cell penetration).

Direct and indirect tests may be used to support the diagnosis of trichinellosis. Muscle biopsy is the only method for the direct verification of infection with *Trichinella* spp. A biopsy of 0.5–1.0 g of muscle from the deltoid or gastrocnemius may be compressed between glass slides and examined microscopically for the presence of larvae. Alternatively, the muscle sample may be digested in acidified pepsin and larvae recovered for enumeration. Muscle larvae may be detected approximately 2 weeks after infection and in numbers of larvae found in the musculature will increase over a period of several weeks. Microscopic detection of larvae in muscle biopsy compressions is more difficult when the infection is due to nonencapsulating species of *Trichinella* and therefore digestion of biopsy samples is the preferred method.

Detection of antibodies to *Trichinella* spp. is useful in confirming infection. The most commonly used test is the enzyme-linked immunoassay (ELISA), with an excretory-secretory antigen. This test is available in commercial kits or may be performed according to various published protocols.

The case definition for trichinellosis, including classification of suspected, probable, or confirmed cases, is based on a combination of signs and symptoms, laboratory findings, including biopsy (if performed), and epidemiological criteria. Several rubrics for case definition have been developed (see Dupouy-Camet *et al*. in Further Reading).

The severity of disease depends on the size of the infecting dose, whether the ingested meat was raw or partially cooked (affecting larval viability), the species of *Trichinella* involved, and the susceptibility of the person infected, including their immune status. It is generally believed that a dose of 1 larva per gram (LPG) of meat consumed in a typical meal (i.e., 150 larvae total) is sufficient to cause clinical disease. Although knowledge of the infecting species on the course of the disease is not well understood, in general it is believed that *T. spiralis* causes more severe disease than *T. britovi* and infection with *T. pseudospiralis* causes a more prolonged clinical disease.

Trichinellosis has been broken into categories of severity including: severe, moderate, mild or benign, and asymptomatic. In severe trichinellosis most or all the signs and symptoms are displayed. Hospitalization is often required and complications are frequently observed. Moderate disease is also characterized by expression of most signs and symptoms, but recovery is more rapid (5–7 weeks). Hospitalization is often not necessary and complications are less likely to occur. In mild disease, signs and symptoms are transient and recovery is rapid (3 weeks or less). Asymptomatic trichinellosis is only identified by a history of exposure and positive serology or biopsy.

Misdiagnosis and subclinical infections contribute to a dramatic underreporting of human trichinellosis. Misdiagnosis results from the general nature of the symptoms and the relatively rare occurrence of the disease in many countries. Patients from group outbreaks are more easily identified as compared to isolated cases. As an example of underreporting, autopsy studies in the US published in 1943 found 16.1% of the US population to be infected, whereas only approximately 400 clinical cases were reported each year between 1947 and 1950.

Treatment of trichinellosis depends on the severity of the disease and may include the administration of anthelmintics (typically mebendazole or albendazole) to kill worms in combination with glucocorticosteroids to reduce inflammation. If the disease is detected early, a primary goal of treatment is to eliminate adult worms in the intestine and thus reduce further accumulation of muscle larvae. For this purpose, anthelmintic treatment is recommended up to 4–6 weeks after exposure. Although anthelmintics also have some efficacy against *Trichinella* larvae in muscle tissue, the resulting inflammation caused by dying worms often creates allergic reactions due to the release of worm antigens. Thus, patients receiving anthelmintics to kill muscle larvae should also be treated with anti-inflammatory drugs (glucocorticosteroids) and monitored during treatment. Recovery is often complete, although muscle pain and weakness may persist. For prolonged muscle pain, glucocorticosteroids may be used for short periods of time to reduce discomfort.

Epidemiology

Prevalence in Humans

Humans acquire infection by ingesting raw or undercooked meat containing infective stages of the parasite. Human infections with *Trichinella* spp. have been reported from numerous countries on five continents – North and South America, Europe, Asia, and Africa. Human infections have not been reported from the mainland of Australia, but have been reported from Papua New Guinea and New Zealand.

As reported by Pozio (2007), the average yearly incidence of the disease in humans worldwide is probably close to 10 000 cases, but with a low mortality rate (approximately 0.2%). It is likely that only a fraction of actual cases are reported due to the nonspecific symptoms exhibited by this disease, as well as a lack of appropriate serological tests and a lack of knowledge of the disease on the part of physicians.

The prevalence of *Trichinella* infection in humans and the source of these infections vary greatly from country to country. Where pork production is tightly regulated and testing of pork for *Trichinella* infection has been required for many years, infections from pork are not found.

However, in countries where pigs are raised by traditional methods (outdoors), human infections occur regularly. Human trichinellosis linked to consumption of infected pork occurs in Central (Mexico) and South America (Argentina and Chile), in Asia (the People's Republic of China, Laos, Myanmar, Thailand, and Vietnam), and Europe (Bosnia-Herzegovina, Bulgaria, Byelorussia, Croatia, Georgia, Latvia, Lithuania, Poland, Romania, Russia, Serbia, and the Ukraine).

Even in countries where *Trichinella* infection has been absent from the domestic pork supply for many years, human infections may still occur from imported meat products which have not been properly inspected. For example, more than a dozen large outbreaks involving more than 3000 people occurred in France and Italy between 1975 and 2005, resulting from the consumption of horsemeat imported from East European and North American countries.

Game animals remain an important source of exposure to *Trichinella* spp. in all countries because infection cannot be controlled in wildlife. For this reason, hunters and consumers of game meats should either assure the safety of the meat through inspection methods, or prepare meat by methods that are known to inactivate the parasites.

Prevalence in Pigs

Trichinella prevalence in pigs varies from country to country, and regionally within countries. The lowest prevalence rates in domestic swine are found in countries where meat inspection programs have been in place for many years (including, in particular, countries of the European Union (EU)). In some instances, countries with long-standing inspection programs consider themselves free from *Trichinella* in domestic swine. In

countries of eastern Europe, higher prevalence rates of *Trichinella* have been reported in pigs and this is supported by higher numbers of cases of human trichinellosis. Increased prevalence of *Trichinella* infection in pigs in some of the Balkan countries is the result of changes from large government run farms to small holdings where pigs are raised outdoors. In the US, no formal inspection programs have been used to control *Trichinella* in pigs. However, changes in the pork industry which focus on confinement housing and other measures of biosecurity have essentially eliminated this infection from the domestic pork supply.

Only sporadic information is available on the prevalence of trichinellosis in South America, Africa, and Asia, but these limited reports suggest high infection rates occur in pigs in some countries. For example, in rural areas of China where pigs are raised outdoors in uncontrolled environments, pig infection rates can be 50% or higher.

Prevalence in Horses

Most evidence for infection in horses comes from the implication of horsemeat in human disease outbreaks. Despite widespread testing, detection of natural infections in horses has been rare – only a few naturally infected horses have been identified, from Mexico, Romania, the former Yugoslavia, and Poland. However, due to the habit of eating horsemeat without thorough cooking, a single infected horse can cause a large outbreak in humans. Horses implicated in human infections have generally been imported from countries where high infection rates occur in pigs. Further, epidemiological studies suggest that horses may be deliberately fed pork scraps or other meat scraps (from wild animals) to increase their weight before sale.

Prevalence in Wild Animals

Trichinella infection in wildlife varies tremendously from region to region, but it is safe to say that no area in nature is completely free from this parasite. The highest rates of infection are found in foxes, wolves, and bear, where infection rates can reach 85–90% of the population. It should be noted that infection rates in wildlife tend to increase in colder climates. In the domestic pig cycle, rats, skunks, raccoons, and other small mammals play an important role and are often found to have high infection rates.

Transmission of *Trichinella* in the Domestic and Sylvatic Cycles

Transmission patterns of *Trichinella* spp. may be grouped loosely into a domestic cycle and a sylvatic cycle (Figure 4). The domestic cycle involves primarily pigs and rats, whereas in the sylvatic cycle *Trichinella* spp. infection may be found in more than 100 species of mammals, as well as several species of birds (*T. pseudospiralis*) and reptiles (*T. zimbabwensis* and *T. papuae*). Although *T. spiralis* is the most common species found in domestic pigs, *T. britovi*, *T. murrelli*, and all three nonencapsulating species have also been reported from domestic pigs. Other species (*T. nativa*, *Trichinella* T-6) have extremely low infectivity for pigs and are not considered a risk for transmission to domestic pigs.

The geographic distribution of the various species is only partially documented due to lack of research in some areas of the globe. It is known that *T. spiralis* is cosmopolitan and this species has been widely reported from North and South America, Europe, and Asia, with localized reports from Africa (Egypt) and New Zealand. Other species have a more restricted distribution, in some cases based on certain

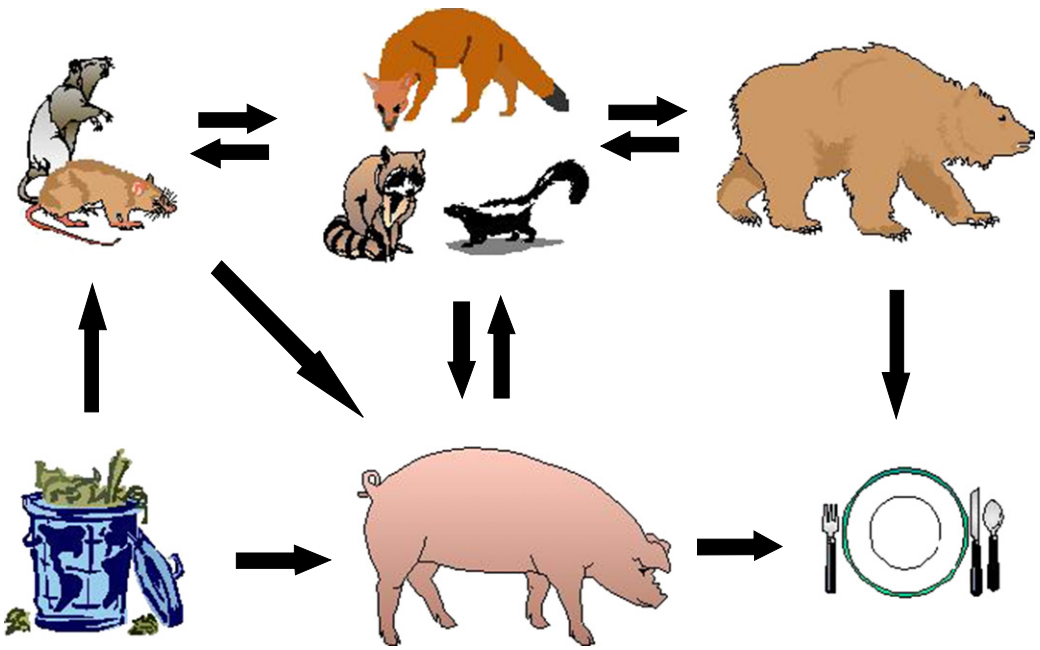

Figure 4 Transmission patterns of *Trichinella* spp. in the domestic and sylvatic (wildlife) cycles.

adaptations. The freeze resistant species (notably *T. nativa* and *Trichinella* T-6) are restricted to arctic and subarctic regions in the northern hemisphere and North America, respectively. *Trichinella britovi* occurs in temperate regions of Europe and Asia and in western Africa, whereas *T. murrelli* occurs in temperate regions of North America. These species overlap in range with *T. nativa* and *Trichinella* T-6. *T. nelsoni* and *Trichinella* T-8 have only been reported from Africa, whereas *Trichinella* T-9 has only been reported from Japan. Among the nonencapsulating species, *T. pseudospiralis* is cosmopolitan in distribution, whereas *T. papuae* is only currently known in Papua New Guinea and *T. zimbabwensis* has only been reported in East Africa.

Transmission of *Trichinella* in the domestic cycles is primarily influenced by animal management practices involving pigs. Exposure of domestic pigs to *Trichinella* spp. is limited to a few possibilities including: (1) feeding of animal waste products or other feed contaminated with parasites; (2) exposure to rodents or other wildlife infected with *Trichinella*; or (3) cannibalism within an infected herd. The use of good production/management practices for swine husbandry will preclude most risks for exposure to *Trichinella* in the environment.

Transmission of *Trichinella* in the sylvatic (wildlife) cycle relies on predation and carrion feeding. Generally, prevalence rates among carnivores increase up through the food chain. Sylvatic *Trichinella* infection affects public health in two ways. As a direct source, game meats pose a significant risk for human exposure to this parasite. Sources of documented human infection include wild boar, bear, walrus, fox, and cougar. Reducing exposure to *Trichinella* from these sources relies on education of hunters regarding the risks associated with eating raw or undercooked game meats. Sylvatic *Trichinella* infection also poses a risk as a source of infection to pigs. This is particularly true for *T. spiralis* and other species/genotypes which can infect pigs. Limiting the contact of pigs with wildlife is part of an overall risk reduction program for control of *Trichinella* infection in the domestic pig cycle.

Human Outbreaks

Human exposure to *Trichinella* spp. can only occur by ingestion of raw or undercooked meat containing infective larvae. Although pork has been the historical source of human infection, and continues to be an important source in some countries, in many countries effective control programs have dramatically reduced or eliminated pork as a risk for exposure. However, a variety of game meats continue to be a potential risk to humans if not prepared properly. These sources commonly include, bear and other carnivores that are high in the food chain (e.g., fox, cougar), feral pig/wild boar, and walrus, and less commonly, smaller mammals (e.g., opossum, badger, and squirrel), turtles, and lizards. Hunter/consumer education and inspection of these game meats are necessary to prevent infection from these sources. Other sources of infection include horses, for outbreaks in France and Italy, and dogs, for outbreaks in China, Russia, and elsewhere.

Because trichinellosis is not a frequent diagnosis in most countries, common source outbreaks are the most recognized occurrence of this disease. Outbreaks often occur during group events – holidays, weddings, etc. – where special or traditional dishes may be prepared that are not thoroughly cooked. Common source outbreaks also occur when *Trichinella*-infected game meats are distributed among a number of people and insufficiently cooked before being eaten. In common source outbreaks, identifying the meat which caused the infection may be used to confirm the presence of *Trichinella* larvae. Additional cases may then be identified from information on those exposed to the infected source meat.

Analytical Methods

Trichinella spp. may be identified by direct or indirect methods. The oldest method of direct detection of *Trichinella*, and one which is still frequently used, is the compression method. Small pieces of pork, or tissue from other animals, collected from the pillars (crus muscle) of the diaphragm, or alternative sites, are compressed between two thick glass slides (a compressorium) and examined microscopically. A minimum of 1 g must be examined to allow a theoretical sensitivity of 1 LPG (a number frequently cited as the threshold of infection posing a public health risk). In practice, the compression method has an approximate sensitivity of >3 LPG of tissue. The compression method is suitable for testing small numbers of samples and should be used to test carcasses of wild carnivores destined for human consumption.

An improvement in direct testing methods for *Trichinella* infection is the digestion method. Samples of tissue collected from sites of parasite predilection (diaphragm, cheek muscle, and tongue) are subjected to digestion in acidified pepsin. Larvae, freed from their muscle cell capsules, are recovered by a series of sedimentation steps, then visualized and enumerated under a microscope. Requirements for performing the digestion test are found in the Directives of the European Union (SANCO 2075/2005), in the US Code of Federal Regulations (9CFR 318.10), and in the OIE Manual of Standards for Diagnostic Tests and Vaccines.

Using methods of inspection testing as practiced on pig carcasses, the sensitivity of the digestion method is approximately 3 LPG. This level of detection is considered effective for identifying pork that poses a significant public health risk. Although there is insufficient information to determine the exact number of larvae which are necessary to cause clinical human disease (and these figures will be affected by the type of *Trichinella*, the amount of meat eaten, and the health of the individual), it is generally considered that infections >1 LPG are a public health risk. Thus, most infections which could cause clinical human disease would be detected by currently employed direct testing methods.

Trichinella spp. infection can also be detected by the presence of antibodies to the parasites in serum, blood, or tissue fluid samples. The ELISA has been used extensively for testing in both pre- and postslaughter applications. Based on the use of an excretory-secretory antigen collected from short-term *in vitro* cultivation of *T. spiralis*, the ELISA has proven to be highly sensitive and specific; no known cross-reactions occur using this test. Because the ELISA is not in widespread use for the detection of *Trichinella* in pigs at slaughter, the reader is referred to the OIE Manual of Standards for Diagnostic Test and Vaccines for specific methodologies involving this test.

Control and Prevention

Many countries require that pigs (and horses) sold as food animals be tested for *Trichinella* infection. These requirements are in the form of regulations governing slaughter inspection. The EU outlines these requirements in SANCO 2075/2005. Other countries have similar regulations and the proof of freedom from *Trichinella* infection must accompany products sold for interstate commerce. As stated in the OIE Terrestrial Animal Health Code, importing countries should mandate that an international health certificate accompany imported pork products. The sanitary certificate should attest that the product has: (1) been tested for *Trichinella* infection at slaughter and was shown to be negative; (2) originated from a *Trichinella*-free country or territory; or (3) been processed to ensure destruction of *Trichinella* larvae. In the same document, it is specified that horsemeat sold for human consumption should be submitted to slaughter inspection or be processed by methods known to kill *Trichinella* larvae.

Some countries, including the US, have relied primarily on further processing (cooking, freezing, and curing) of ready-to-eat pork products and advice to consumers regarding the safe preparation of fresh pork. Commercial processing methods which have been proven experimentally to render pork free from infective *Trichinella* larvae are described in the US Code of Federal Regulations (9CFR 318.10). Pork meat must be heated to 58 °C or frozen at one of several time temperature combinations. For flash freezing, *Trichinella* larvae are killed instantaneously at −35 °C. The effectiveness of curing depends on a combination of salt concentration, temperature, and time. Each method should be tested experimentally to determine effectiveness as no model for curing conditions has been devised. Consumers of fresh product are advised to cook pork, and other meat products that might serve as a source of *Trichinella*, to an internal temperature of 63 °C.

Preharvest Prevention of *Trichinella* Infection in Pigs

Prevention of exposure of domestic pigs to *Trichinella*, requires the implementation of sanitary management practices which: (1) prohibit feeding of animal products (without proper cooking); and (2) preventing exposure to rodents or other potentially infected mammals either directly, or through contamination of feed. Production practices which are free from risk or have minimal risk for exposure to *Trichinella* should be monitored periodically (by testing blood samples from live animals or by sampling slaughtered animals) to verify the absence of infection.

Several regulations support programs for certifying pigs free from risk of exposure to *Trichinella* including, SANCO 2075/2005 in the EU and, the National Trichinae Herd Certification Program in the US.

The OIE Terrestrial Animal Health Code specifies that absence of *Trichinella* infection in pigs can be documented by declaring a country or territory as '*Trichinella*-free' based on certain criteria. These criteria include: (1) the disease is compulsorily notifiable; (2) waste food feeding is officially regulated; (3) a surveillance program is in place to detect *Trichinella* infection at a very low prevalence in the disease free area; (4) surveillance is intensified where infection was last reported; and (5) any outbreaks of infection in swine or humans are fully investigated to determine the source. Establishing a country or region as free from *Trichinella* is difficult because the parasite circulates in so many species of wildlife.

Trichuris trichiura

J Horton, Tropical Projects, Hitchin, UK

Glossary

Embryonation Development process of the ova from a disorganized mass when laid to a fully developed larva.
Nematodes Worms of the phylum Nematoda, both free living or parasitic in almost all vertebrate and nonvertebrate animal species.
Operculum Openings in the ova through which the larvae escape.
Preventive chemotherapy Mass drug administration to the whole community irrespective of the infection status to reduce the prevalence and intensity of infections.
Soil-transmitted nematodes Generally considered to be whipworm (*Trichuris*), roundworm (*Ascaris*), and the two human hookworms, all of which are transmitted in a fecally contaminated environment (also known as geohelminths).
Trichuriasis Disease caused by infection with *Trichuris trichiura*.

Background

Nematodes (roundworms) of the genus *Trichuris* are found as parasites of vertebrates, including many domestic and wild mammals and have a global distribution. The human whipworm, *Trichuris trichiura*, only affects humans and primates, and has a direct life cycle without intermediate hosts. Infection in humans with closely related species such as *Trichuris suis* (from pigs) or *Trichuris muris* (from mice) may occur, but the infection is short lived and self-curing, and the parasites are unable to complete their life cycle. The World Health Organization estimates that more than 700 million people are infected worldwide, the majority being in Asia, although all tropical and subtropical regions are endemic. Evidence of human infection dates back to prehistoric times, with the demonstration of *Trichuris* eggs at archeological sites and in mummified human remains. The Alpine 'ice man' (approximately 3300 BC) had *Trichuris* eggs in his rectum. Morgani (1740) provided the first written evidence of infection in the human colon, and Roedere and Wagler (1761) gave a complete description and drawings from which Linnaeus derived its taxonomic classification in 1771 and originally called it *Ascaris trichiura*, the current name being finalized in a monograph by Stiles in 1901.

Characteristics

The genus *Trichuris* belongs to the family Trichuridae (syn. Trichocephaloidea), order Enoplida, class Secernentea (formerly Phasmidia) and phylum Nematoda. It is more correctly known as *Trichocephalus*, but the 1941 Committee on Nomenclature of the American Society of Parasitologists opted for *Trichuris* as the commonly accepted name at the time. More than 70 *Trichuris* species have been described; many are from small rodents, but the most important are those of domestic animals, such as *T. suis* (pig); *Trichuris vulpis* (dog); *T. muris* (mouse), *Trichuris ovis* (cattle); and *Trichuris felis*, *Trichuris campanula*, and *Trichuris serrata* (cats). However, *T. trichiura* has only been described from humans and some primates, such as chimpanzees and rhesus and colobus monkeys. *Trichuris suis* was at one time thought to be the same species, being indistinguishable on morphological grounds but has recently been shown to be genetically distinct, and is unable to develop in the human intestine and produce viable eggs. Infections with *T. vulpis* have been described rarely in humans, but again it is doubtful whether they are able to complete their life cycle.

Trichuris trichiura has a simple, direct, life cycle, which does not involve any intermediate hosts (Figure 1). Both male (30–45 mm) and female (30–50 mm) adults inhabit the cecum and much of the large intestine. They have a characteristic narrow anterior portion (hence the popular name of whipworm), which is inserted into the mucosa of the intestine, and a thicker posterior portion, which contains the intestine and the reproductive organs. Adults feed on the host's body fluids, which are obtained through the mouth at the extreme anterior of the worm. Adult females release between 3000 and 10 000 unembryonated ova a day into the feces. The ova are barrel shaped with plugs at the either ends measuring approximately 55 μm × 25 μm and gain a brownish coloration from bile impregnation as they pass through the intestine. They are passed in the stool and require 2–4 weeks to develop into the first-stage larva under optimal conditions in warm damp soil. Development rate is dependent on temperature and humidity (4–6 months at 15 °C, 3–4 weeks at

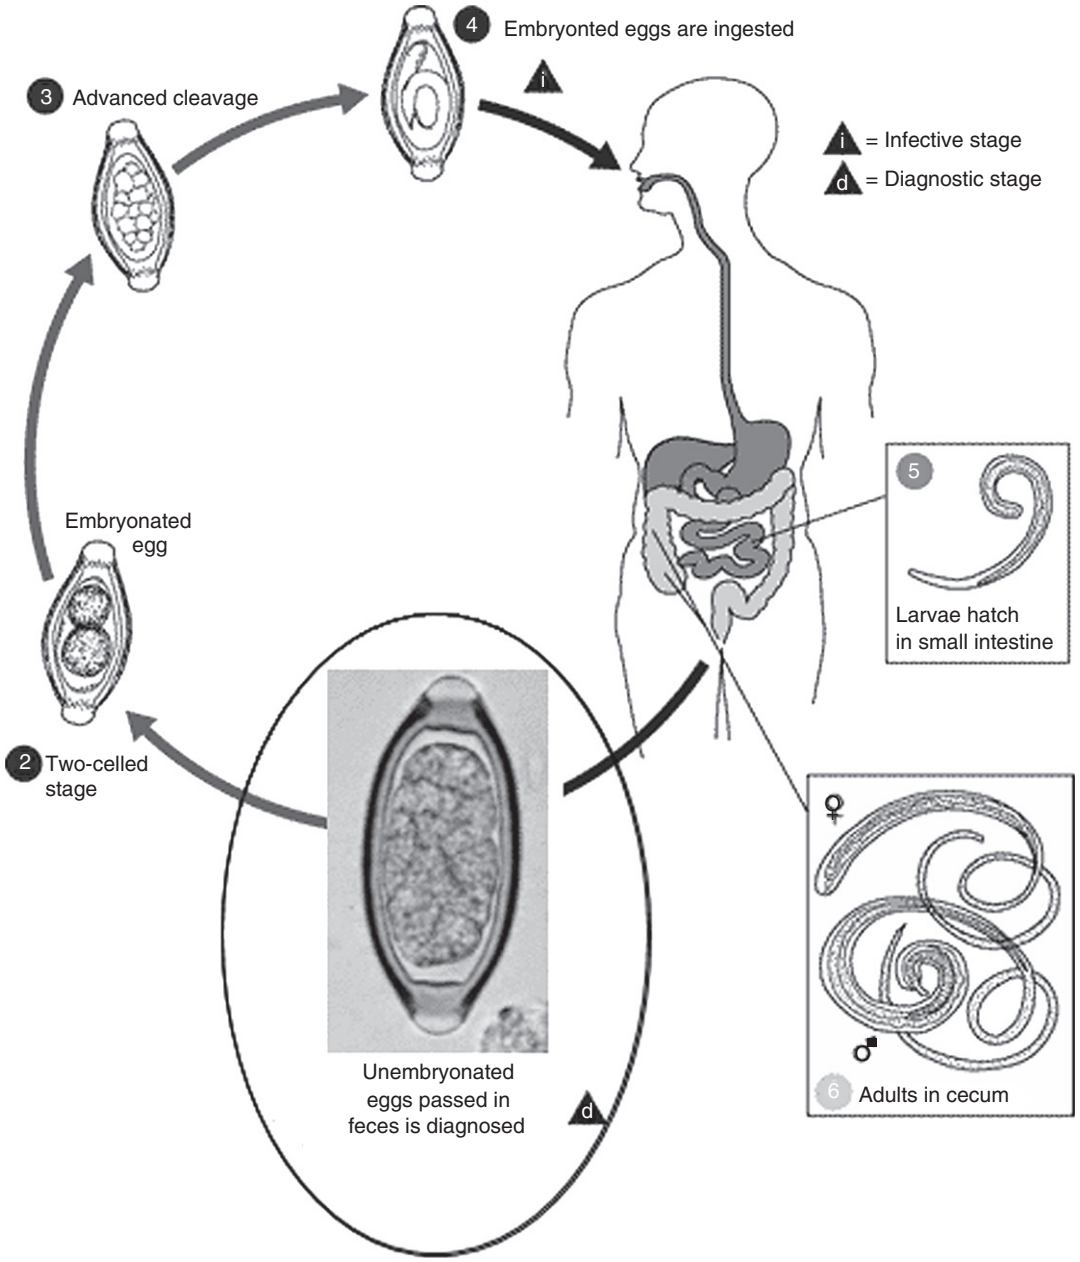

Figure 1 Life cycle of *Trichuris trichiura*. (1) Unembryonated eggs are shed in the feces. Their presence is the principal method of diagnosis. (2 and 3) Eggs develop in the soil. (4) Fully developed eggs containing larvae are ingested with food. (5) Eggs hatch in the intestine and undergo four molts to become adults. (6) Male and female adults are found in the large intestine, from the cecum to the rectum. Adults may be detected on colonoscopy/proctoscopy. www.dpd.cdc.gov/dpdx/images/ParasiteImages/S-Z/Trichuriasis/Trichuris_LifeCycle.gif

26 °C, 17 days at 30 °C, and 11 days at 35 °C). Ova may remain dormant in the soil for up to 5 years and are infective for at least 2 years. Embryonated ova containing infective larvae may subsequently be ingested from contaminated soil, food, or water. After ingestion, the ova wall is weakened, and the first-stage larva hatches and attaches to the intestinal wall, where it undergoes four molts to become an adult after 2–3 months, residing in the large intestine for 1–2 years. Copulation between male and female worms occurs in the intestine, giving rise to fertile females who begin to release ova.

Clinical Manifestations

In areas where *T. trichiura* is endemic, a large proportion of the population may be infected. Coinfection with other soil-transmitted nematodes, such as *Ascaris lumbricoides* and the hookworms *Necator americanus* and *Ancylostoma duodenale*, is common. Significant infections occur in infancy, with prevalence peaking in school-age and teenage children, and reducing in adult life. In most cases (at least 90% of those infected), infections are light and cause little or no obvious

symptoms other than mild abdominal discomfort and other vague symptoms. However, in heavily infected persons, especially children, significant symptoms may be present. Diarrhea, often with blood and mucus with cramping abdominal pains is a sign of the *Trichuris* dysentery syndrome, which when left untreated, may last for 6 months or more and mimics other forms of inflammatory bowel disease. Especially in children, this may be accompanied by rectal prolapse, which can be massive, with 10 cm or more of the rectum being exposed and adult worms visible on its surface. Rectal prolapse usually corrects itself once the underlying infection is treated. As a result of the chronic diarrhea, there is associated anorexia and weight loss, and a microcytic iron-deficiency anemia is also commonly seen in heavier infections. Such severe symptoms result in growth retardation and stunting, with growth rates well below the normal rate. Heavily infected children may look several years smaller than their peers and undergo a massive growth spurt when the infection is removed. In studies of such children, linear growth rates in excess of those seen using growth hormone replacement in deficient children have been seen.

Despite the apparent mild nature of the symptoms in all but a minority, it may be thought that trichuriasis is a minor problem. However, recent studies of children with mild-to-moderate infection have shown that, even in these, there is evidence of an effect on growth, physical fitness, and, more importantly, on cognitive ability. It has been shown that although it is difficult to measure the effects of mild infection directly, there is ample evidence of accelerated growth, improved physical fitness, and improvements in cognition scores following treatment of these mild infections. Thus, although it is a generally mild disease and does not account for much mortality in those affected, it does cause considerable low-level morbidity that affects the individual's functioning and inhibits community social and economic development.

Treatment is with a benzimidazole anthelmintic, such as albendazole (Zentel – GSK) 400 mg as a single dose, although a daily dose for 3 days is probably more effective, or mebendazole (Vermox – J&J) 500 mg daily for 3 days. Neither is fully effective, at least for heavy infections and further treatment may be necessary based on diagnostic stool tests. The addition of ivermectin (Mectizan – Merck) has been shown to increase cure rates.

Epidemiology

Trichuris trichiura has a worldwide distribution, principally within the tropical and subtropical zones, although it may have been more widely distributed in the past. However, with improvements in sanitation and public health in the richer countries, it has been largely eliminated from areas such as Southern USA, Japan, and much of the Mediterranean basin. Nonetheless, global prevalence has been estimated as at least 700 million infections by the World Health Organization and possibly as many as 1000 million by others. Alongside the other soil-transmitted nematodes, it is therefore one of the commonest parasitic infections on the planet. Before the advent of preventive chemotherapy programs with anthelmintics, the infection rates were estimated to be 25% in South and Central America, 31% in Africa, 12% in the Middle East, 36% in Bangladesh, and 58% in Southeast Asia. In Japan where the infection rates were similar historically, they have been reduced to 0.01%. It is likely that the current prevalence is much lower globally due to the effect of preventive chemotherapy, but accurate figures are almost impossible to obtain.

Transmission is direct through contamination of the environment as a result of promiscuous defecation around the living and work areas. Trichuriasis is therefore commonest in areas of poverty where there is little or no sanitation, and there is a tendency for heavier infection to cluster within families. Whether this is due to specific susceptibility factors within families or merely due to high levels of recurrent exposure to the contaminated environment is unknown. An additional factor encouraging higher levels of infection is the practice of using 'night soil' for fertilizing fields, thus directly contaminating foodstuffs. Although this is a practice seen throughout the world, it was a particular problem in the rice growing areas of Southeast Asia and probably drove the high prevalence there. Unfortunately, composting of night soil, effective for many other intestinal pathogens, does not destroy *Trichuris* ova. Children become infected at an early stage by playing in infected areas, and heavy infections are particularly noted in regions where there are micronutrient deficiencies leading to pica (soil eating) in children. Water sources may also be contaminated and add to general infection. In adults, infection, or reinfection, comes chiefly through the consumption of contaminated vegetables. The role of pigs as a potential source of infection, although often quoted, can now be discounted following the demonstration of the genetic differences between the human (primate) *T. trichiura* and the pig species *T. suis*.

Diagnosis

The principal method of diagnosis of infection is by examination of stool samples under the microscope, looking for the typical double plugged ova of *T. trichiura*. This appearance is clearly different from the ova of *Ascaris* and other soil-transmitted nematodes that are often present at the same time in coendemic areas. There are a number of techniques employed, all of which use small samples of stool that are treated and then applied to a slide for examination. The simplest approach is the iodine-stained smear, which can identify heavy infections, but it is hampered by the presence of food debris in lighter infections. The most commonly employed method is the Kato–Katz test, which uses a measured sample stained with malachite green that stains the ova of all soil-transmitted nematodes and provides a semiquantitative measure of the intensity of infection. An alternative is to use one of the flotation and concentration techniques that remove much of the fecal debris and both allow identification of very-low intensity infections and provide a measure of infection intensity. These latter tests are useful for the follow-up of treated individuals because of their sensitivity. Blood tests do not reveal much, other than anemia in chronically infected individuals and an eosinophilia, which may be found in any

case of heavy helminth infection. As has been noted for cases of rectal prolapse, the adult worms may be visualized on the prolapsed mucosa. In the absence of prolapse, adults may occasionally be seen on proctoscopy or colonoscopy when used for the investigation of chronic cases. The identification of adults by these methods is a rarity, but if a parasitologist confirms their identity, it is pathognomonic.

Because only *T. trichiura* commonly infects humans, and the stool identification techniques have proved their worth over many decades, it has not been necessary to resort to molecular techniques. However, comparative analysis of the *Trichuris ITS1* gene has been useful in differentiating *T. trichiura* of primates from *T. suis* of pigs, thus removing the potential of pigs as a reservoir host. As further work is done in this field, it is possible that such analysis may ultimately show that accidental infection with other specific animal species does occur. Of particular interest in this respect is the recent use of laboratory strains of both *T. suis* and *T. muris* as treatment for chronic inflammatory bowel conditions, such as Crohn's disease. In both cases, the infections are only established for a short time (a few weeks at most), which suggests that, for these species at least, sustainable human infection is unlikely.

Control and Prevention

Because of the mode of transmission, it is clear that the principal approach to prevention is sanitary improvement, both at personal and community level. It also applies to all the soil-transmitted nematodes, rather than just to *Trichuris*, although in some cases, other measures, such as wearing shoes, to prevent hookworm infection are also relevant. Education plays a part in ensuring that there is an understanding of the risks of eating potentially contaminated food and explaining the importance of proper personal hygiene for all members of the households. Hand washing, washing of salad vegetables in clean water, and adequate cooking of other vegetables are all important for the prevention of primary infection and reinfection in endemic communities. However, because it is the contamination of the environment with infected fecal material by promiscuous defecation, the proper use of toilets and pit latrines for disposal of feces is of paramount importance. In many areas where trichuriasis is a public health problem, clean water through deep tube wells has been provided, whereas the provision of adequate toilet facilities lags far behind. However, it is not only important to provide good deep pit latrines (or flush toilets where effluent can be treated) but also to ensure that these are used all the time. The main problem here is providing sufficient educational backup to support change in behavior. In endemic communities, chemotherapy with anthelmintic drugs should be considered to reduce the prevalence in the community, and thereby the risk of reinfection. This has been shown to be effective in controlled studies in the Caribbean and elsewhere, and in more extended mass treatment programs involving whole communities or even countries. Preventive chemotherapy can be effectively delivered to schoolchildren through their schools or in high prevalence areas by mass treatment campaigns. However, reducing community infection levels and thus the risk to individuals will take time and requires the combined intervention of chemotherapy, sanitary improvement, and behavioral change through education. The reduction in prevalence or disappearance of infection as a result of improved sanitation alone took many years to achieve in countries such as Japan or Italy.

Conclusion and Future Perspectives

Trichuriasis, alongside the other soil-transmitted nematodes, will remain a public health issue for many years to come, purely as a result of the massive scale of the problem. Within the broad tropical and subtropical belt, infection and reinfection will continue despite large-scale public health programs. Therefore, the key preventive measures to protect the individual is educating them to ensure proper hygiene and food cleaning and handling together with improvements in disposal of fecal material. It is hoped that the use of night soil as a fertilizer will ultimately be eliminated as this was the reason for the extreme prevalence seen in Southeast Asia. Identification and treatment of infected individuals is an impossible task, but effective reductions can be achieved by preventive chemotherapy. Currently, the drugs available are only partially effective for individual treatments, and it is hoped that newer drugs or combinations may become available that can produce a complete cure. This is of particular importance because hundreds of millions of doses of anthelmintic drugs are being used every year in the areas endemic for *Trichuris* and the other soil-transmitted nematodes, thus raising the threat of drug resistance.

Clonorchis sinensis

S-J Hong, Chung-Ang University College of Medicine, Seoul, Korea

Glossary

Cellophane-thick smear Fecal sample is spread on a slide glass and covered with a sheet of cellophane presoaked in glycerol.
Cercaria A larval form with a long tail, swimming in water and transforming into metacercaria.
Cholangi Denote bile duct.
Jaundice Yellowish coloring of the eyes and skin due to pigmentation of bilirubin.
Metacercaria A larval form occurring in fresh water fish and infective to human.
Reservoir host Animals that have parasites which also infect human and act as source of human infection.
Sashimi Thin slice or fillet of fish meat.

Background

Clonorchis sinensis was first discovered in a Chinese patient in 1875 and accepted as a new species of liver fluke in 1907. *Clonorchis sinensis* is a member of the family Opisthorchiidae. Its morphological characters are a spatula-like shape, thin, and translucent body, revealing internal organs, a convoluted uterus in middle of its body, and branched testes. Freshwater fish were identified as its second intermediate host in 1911 and a freshwater snail as its first intermediate host in 1917. Clonorchiasis, human infection caused by *C. sinensis* adults, is prevalent in southeastern and northeastern China, Korea, and northern Vietnam.

Geographical Distribution

Globally, it has been estimated 15–20 million people are infected with *C. sinensis*, and that more than 200 million people are at risk of infection. *Clonorchis sinensis* is distributed in East Asia including China, Korea, eastern Russia, northern Vietnam, and Taiwan. Formerly prevalent in Japan, it has been under control since 1960. In China, Guangdong Province has the highest infection rate, followed by Guangxi, Heilongjiang, and Sichuan provinces. Sporadic foci of high prevalence were reported from Hunan, Jilin, and Liaoning provinces. It has been estimated that 12.5–15 million of the Chinese population are infected with *C. sinensis*. In Korea, clonorchiasis is endemic in river basins in southern areas and 1.3 million people are estimated to be infected. In Russia, clonorchiasis is endemic in the Amur River basin, infecting one million people. In Vietnam, two human liver fluke species have been identified, *C. sinensis* in northern Vietnam and *Opisthorchis viverrini* in the south; approximately one million people are believed to be infected with *C. sinensis*.

Morphology and Life Cycle

Adult Fluke

When live encysted metacercariae infecting fish are ingested by humans, they excyst in the duodenum and migrate under bile-chemotaxis to the intrahepatic bile ducts. Juvenile worms grow

 doi:10.1016/B978-0-12-378612-8.00150-5

to the adult form and produce eggs in the human bile duct 4 weeks after infection.

The adult *C. sinensis* is dorsoventrally flat, elongated, translucent, with a yellowish color due to the presence of lipofuscin pigments (Figure 1). The adult fluke measures 10–25 mm long and 1.5–4 mm wide. Its oral sucker is subterminal anteriorly and its ventral sucker is located at the anterior one-fourth of the body. The oral sucker serves as a mouth which connects a globular pharynx and a short esophagus that bifurcates into two intestinal branches that

extend to the posterior end of the body, terminating blindly. The two testes, branch-like and deeply lobulated, lie tandem in the posterior one-third of the body. The small lobular ovary is at the mid-median anterior to the anterior testis. A large sac-shapes seminal receptacle lies behind the ovary at the equator level. The uterus, full of eggs, convolutes up between the intestines and opens in front of the ventral sucker. The vitelline follicles occupy both sides lateral to the uterus and the intestines (Figure 1).

Egg and Larval Development in the First Intermediate Snail Host

The eggs of *C. sinensis* escape the infected human in the feces (Figure 2). They are ellipsoid, yellowish brown in color, more pointed at one end, and operculate. They measure 26–30 μm in length and 14–15 μm in breadth, and have a wrinkled surface reminiscent of that of a muskmelon. The egg contains the initial larval stage of the parasite, a miracidium.

Miracidia hatch out of egg after ingestion by a suitable aquatic snail host, in which the parasite undergoes several asexual multiplication stages. Among freshwater snail species, *Parafossarulus manchuricus* is the most widely distributed species. Other potential host species are *P. anomalospiralis*, *Alocinma longicornis*, *Bithynia fushiana*, *Bithynia misella*, *Melanoides tuberculata*, *Assiminea lutea*, and *Thiara granifera*. The snails are found in water bodies that have poor flow or are stagnant with a stratum composed of mud rich in organic materials and water vegetation. In southern South Korea, snails appear in water bodies in April, achieve a peak population density in June, and disappear from water in November.

In the snails gastrointestinal tract, the miracidium penetrates the intestinal wall and then develops into sporocysts in peri-intestinal tissues and organs. The sporocysts are sac-like and contain several developing rediae. The rediae eventually yield the cercariae. Mature cercaria posses a body and a long tail. The cercaria, because of unique morphological features, is called a pleurolophocercous cercaria. In the snail host, a single

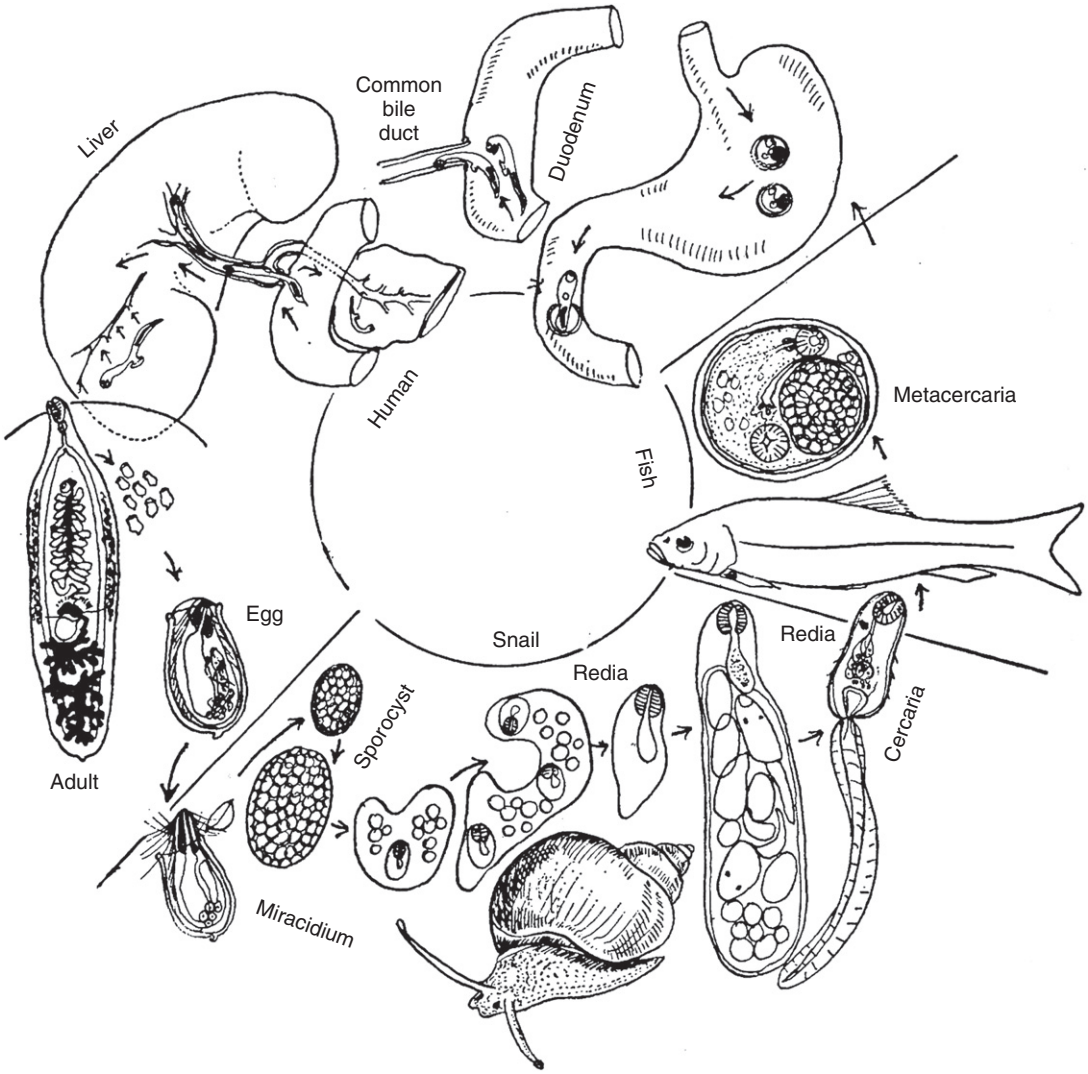

Figure 2 Life cycle of *Clonorchis sinensis* (Courtesy of Dr. J.Y. Chai).

miracidium can, because of this asexual multiplication, yield 3200–10 000 cercariae. The cercariae emerge from snails and swim in fresh water seeking a fish host; although very active for the first 12 h, they lose this swimming activity after 72 h if they do not find a fish host (Figure 2).

Metacercaria and the Second Intermediate Hosts

When cercariae find a suitable fish host, they attach and penetrate the skin between scales to enter subcutaneous tissues in 15–20 min. In the fish tissue, the cercarial body secrets cystogenic materials from its cystogenous glands and become encysted to form metacercaria within 24 h. The metacercaria is round to oval and measures 135–145 μm by 90–100 μm. The cyst wall is thin and clear. The cysts are surrounded by a capsule formed by a local tissue reaction in the fish host. After 10–15 days, the metacercariae have a ventral sucker larger than the oral sucker, an excretory vesicle full of dark excretory granules, and no eyespots (Figure 3). The metacercariae in freshwater fish attain infectivity to rabbits and rats 23–30 days after cercarial infection. The fish hosts of *C. sinensis* include numerous species of freshwater fish, predominantly of the family Cyprinidae. Metacercariae remain viable and infective to definitive hosts in the flesh of freshwater fish for approximately 1.5 years, but some die as early as 30 days after invasion.

When ingested by the final hosts, including man, the metacercariae excyst in the duodenum and migrate to the bile ducts (Figure 2).

Definitive and Reservoir Hosts

Man is the most suitable definitive host of *C. sinensis*, though in endemic areas dogs, cats, rats, pigs, buffaloes, weasels, and foxes have been reported to be animal reservoir hosts. Laboratory animals, rabbits, guinea pigs, hamsters, gerbils, and mice are susceptible to *C. sinensis*. In China, dogs and cats are considered major sources of *C. sinensis* eggs and these contaminate bodies of freshwater, such as ponds, puddles, streams, wetlands, rivers, lakes, and canals. These animals are free to roam in villages and are usually not restrained as pets in homes, and thus, they have access to raw or undercooked foods in household waste. In some endemic areas, cats are reported to have a high infection rate and high intensity infections. In Korea, feral cats and stray dogs infected with *C. sinensis* are considered important sources of the eggs that contaminate the environment. Reservoir hosts play an important role in the *C. sinensis* ecosystem, as a source of *C. sinensis* eggs, which when they contaminate, bodies of freshwater infect the freshwater snail hosts.

Pathology and Clinical Symptoms

Infection with *C. sinensis* provokes cholangitis in the hepatobiliary system of infected animals. During the early infection stage, juvenile worms cause proliferation and inflammation of biliary epithelium, and during late stage of infection, they provoke desquamation, glandular proliferation, and

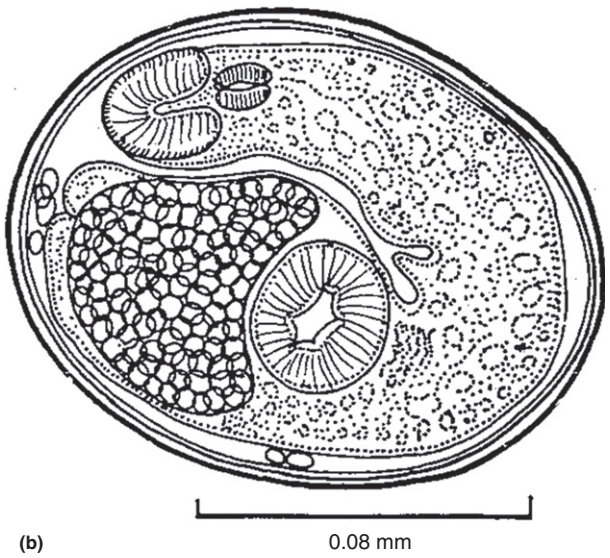

Figure 3 Metacercaria of *Clonorchis sinensis*. (a) A metacercaria isolated from a freshwater fish. (b) Drawing of a metacercaria (Courtesy of Dr. J.Y. Chai).

adenomatous hyperplasia in biliary epithelium (Figure 4), which exhibits high levels of goblet cells. In cases of heavy infection, periductal fibrosis develops and extends to bile capillaries
and the portal area, and the bile duct wall is infiltrated by lymphocytes, plasma cells, and eosinophils. In cases of chronic infection, hepatobiliary changes frequently progress to biliary cirrhosis. Pathologic changes in the biliary system progress chronically in clinical cases with a heavy worm burden due to the fluke accumulation caused by repeated infection.

Incidence of cholangiocarcinoma is higher in clonorchiasis endemic areas. In experimental animals, *C. sinensis* infection has been shown to provoke the production of reactive oxygen radicals and nitrosocompounds, to damage cellular DNA, and

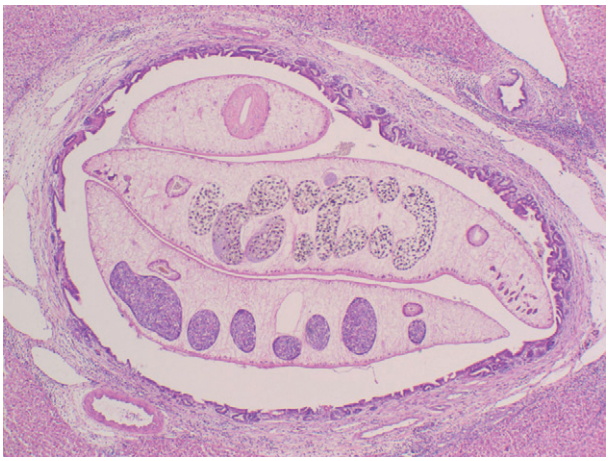

Figure 4 Histopathology of a rabbit liver 2 months after infection with *C. sinensis*. Hematoxylin-eosin stained (original magnification, 100 ×).

to progress to cholangiocarcinoma. In fact, *C. sinensis* infection is recognized to present a high risk of cholangiocarcinoma, and *C. sinensis* was classified as a Group 1 biological carcinogenic agent by the International Agency for Research on Cancer in 2009.

During early stage disease, *C. sinensis* causes mild cholangitis, and infected humans exhibit symptoms (if present) such as mild fever, epigastric tenderness, abdominal discomfort, malaise, and anorexia. In chronic infections with a heavy worm burden, the symptoms manifested are obstructive jaundice, fever, epigastric pain and tenderness, hepatomegaly, diarrhea, and ascites. Peripheral blood exhibits mild eosinophilia and IgG and IgE antibodies.

Diagnosis and Treatment of Human Infections

Human infections are diagnosed by the microscopic detection of eggs in fecal specimens. *Clonorchis sinensis* eggs are differentiated from those of heterophyid flukes by morphological features, such as shouldering around the operculum, wrinkles on the outer surface, and an abopercular knob. However, it is difficult to differentiate *C. sinensis* eggs from those of *Opisthorchis* spp. under a microscope. A cellophane-thick smear method (the Kato–Katz method) is widely employed in the field and the formalin-ether centrifugal sedimentation method is used with higher sensitivity and accuracy in clinical laboratories. Diagnosis can be made by detecting the DNA or proteins of *C. sinensis* in feces using specialized diagnostic kits. Enzyme-linked immunosorbent assay is a common serodiagnostic method for clonorchiasis. The antigen used is a crude antigenic preparation such as a soluble extract of adult *C. sinensis*.

Praziquantel is a potent anthelmintic for clonorchiasis, and at 75 $mgkg^{-1}$ of body weight provides high cure and egg reduction rates. Furthermore, praziquantel is well tolerated; its subjective side effects are mild or transient dizziness, headache, abdominal distress, and nausea.

Epidemiology of the Parasite

Susceptibility of the Fish Hosts

In *Pseudorasbora parva*, *C. sinensis* metacercarial infection and density show substantial seasonal fluctuations, that is, infections are maintained from May to September, but are relatively low from November to April. Freshwater fish become infected during spring and summer, because *P. manchuricus* sheds cercariae at this time. Furthermore, *C. sinensis* metacercariae in *P. parva* survive in cold water during winter, accumulate, and maintain viability until the summer.

The susceptibility of freshwater fish to metacercariae, in terms of infection rate and metacercarial burden, varies widely between species and from water body to water body – even within species. In China, small fish such as *P. parva* and *Parapelecus argenteus* are wild-caught, not raised in aquaculture systems, and show high infection rates and heavy metacercarial burdens. However, large fish, such as *Cyprinus carpio*, *Hypophthalmichthys molitrix*, and *Parabramis pekinesis*, are farmed in ponds and aquaculture systems and exhibit low intensity of metacercarial infections. The difference of the metacercarial infection statuses of large and small fish is understandable from the ecological point of view, as metacercarial infection of small fish is synchronized with the development of snails and of the parasite in a given ecosystem, but large fish in an aquaculture system have a narrow exposure window to cercarial infection.

The occurrence of clavate cells in the epidermis of freshwater fish is believed to be closely related to their susceptibilities to *C. sinensis* cercarial infection. Clavate cells are found in the epidermis of freshwater fish and are characterized by Oxner's dark halo around the nucleus. Small fish, such as *P. parva*, *Zacco platypus*, *Microphysgobio koreensis*, *Gnathopogon majimae*, *Acheilognathus signifier*, *Rhodeus ocellatus*, and *Sarcocheilichthys sinensis*, have no clavate cells in the skin and exhibit moderate to heavy *C. sinensis* metacercarial infection intensities, perhaps reflecting a greater susceptibility to metacercarial infection.

Research has also shown that mucus on the epidermis contains substances that adversely affect invading *C. sinensis* cercariae in large fish. An important cercariacidal substance is an ethyl ester of an unsaturated fatty acid, possibly linoleic acid. Furthermore, it has been reported that concentrations of linoleic acid in mucus vary between freshwater fish species and modulate susceptibility to *C. sinensis* cercariae.

Freshwater Fish as Sources of Human Infection

The Cyprinoid freshwater fish, which constitute approximately 11 families, play a role as second intermediate hosts for *C. sinensis*. Most of the fish species belong to the family Cyprinidae. In clonorchiasis endemic areas, *P. parva* (a small freshwater fish of weight 0.5–1.5 g) is the most common second intermediate host. Small fish, such as *P. parva*, are not raised in aquaculture systems but are caught in the wild, and small fish in the wild tend to show high infection rate and heavy burdens of *C. sinensis* metacercariae. However, large fish, such as the common carp *Cyprinus carpio*, the silver carp *Hypophthalmichthys molitrix*, the goldfish *Carassius auratus*, and

Vietnam	*H. molitrix*

P. pekinensis, are usually raised in aquaculture systems, and thus, have lower metacercarial infection rates and intensities. Thus, people who eat raw large fish become infected with fewer *C. sinensis* adults than those who eat small fish. However, those who routinely eat raw freshwater fish accumulate adult *C. sinensis* in the bile duct, which can lead to chronic infection and a heavy worm burden (Table 1).

In mid and southern China, large freshwater fish, such as the common and silver carp and *P. pekinensis*, are farmed in aquaculture systems and supplied to fish markets, and these fish have a light metacercarial burden. The grass carp (*Ctenopharyngodon idellus*) weighs 2–5 kg and is commonly sold in fish markets, and thus, is considered a species of public health importance. This fish has been reported to be infected with *C. sinensis* metacercariae in endemic areas in several Chinese provinces. Small freshwater fish, such as *P. parva*, *Oryzias latipes*, and *Abbottina sinensis*, are recognized as important fish hosts of the metacercariae and act as major sources of human clonorchiasis in northern endemic Chinese provinces. Other small fish, such as *Parapelecus argenteus* and *Gnathopogon imberbis*, have been reported to exhibit high *C. sinensis* metacercariae infection rates in Anhui, Hubei, Hunan, and Sichuan provinces in central China, which are moderately endemic areas (Table 1).

In Korea, most fish hosts belong to the family Cyprinidae and some to the families Bagridae and Clupeidae. The small freshwater fish, *P. parva* and *Pungtungia herzi*, have been reported to be heavily infected by *C. sinensis* metacercariae, whereas other small fish, such as *Pseudogobius esocinus*, *Hemibarbus labeo*, *Acheilognathus intermedia*, and *Zacco* spp., show high metacercarial infection rates but low infection intensities. However, large fish, such as *C. carpio* and *C. carassius*, which are frequently eaten raw, have low infection rates.

In northern Vietnam, seven species of freshwater fish have been reported to act as second intermediate hosts for *C. sinensis* and *H. molitrix* has been found to be the most infected with *C. sinensis* metacercariae.

The major mode of human clonorchiasis infection is the eating of raw or undercooked freshwater fish or crustaceans. In *C. sinensis* endemic areas, typically, more than 70% of inhabitants have eaten raw freshwater fish and in some endemic areas in East Asia, freshwater fish are served as raw fish congee or as 'sushi.' Consumers believe that raw fish is an excellent health food that is free of contamination. Large freshwater fish are favored for raw consumption in restaurants. In fact, in restaurants, small freshwater fish have been replaced by larger species, such as *C. carpio*, *C. capio nudus*, and *Ct. idellus*. Although large fish are less frequently and lightly infected with *C. sinensis* metacercariae, adult *C. sinensis* accumulate in the human bile duct for more than 10 years, and thus, the routine consumption of freshwater fish leads to the accumulation of adult flukes in the liver and heavy infections. However, although small fish like *P. parva* are infected heavily with *C. sinensis* metacercaria, they are rarely consumed raw, and thus are of little medical or public health importance in endemic areas.

In endemic areas, *C. sinensis* metacercariae can contaminate utensils used to prepare raw freshwater fish. Thus, in households where only men eat raw freshwater fish, women and children can become infected due to the contamination of utensils. Furthermore, hands accidentally contaminated with metacercariae, by not washing properly after preparing food or after catching freshwater fish can cause infections.

Detection of Metacercariae in Fish

Microscopy

In small freshwater fish, almost all metacercariae encyst in the flesh of the trunk, and more metacercariae encyst in supraspinal than in infraspinal flesh. In some heavily infected fish, the metacercariae are found in gill and scales, and rarely in viscera.

Clonorchis sinensis metacercariae can be directly detected in the flesh of freshwater fish, as follows. First, prepare thin slices of fish muscle, compress slices, between two slide glasses, and place on the mechanical stage of a microscope. Observe the specimen under bright field at low magnification. To delineate metacercariae, adjust the contrast of the bright field to moderate/high because metacercariae are translucent like fish muscle. *C. sinensis* metacercariae can be differentiated from those of other species by cyst size and shape, the presence of oral and ventral suckers of equal size, and a dark triangular excretory bladder.

To more clearly view and identify metacercariae, fish muscle can be removed by artificial digestion. Briefly, fish muscle is ground in a mortar and pestle and mixed with approximately 10 times its volume of artificial gastric juice (6 g of pepsin (1:10 000, Sigma Co.), 10 ml of concentrated HCl, distilled water made up to 1 l). The mix is incubated at 37 °C for 1 h and stirred intermittently with a glass rod. The digest is filtered through a 212 μm mesh sieve and sediment in the filtrate is washed until clear with physiological saline. *Clonorchis sinensis* metacercariae can be collected from the particulate sediment under a dissecting microscope, mounted on a slide and observed in detail at higher magnification under a light microscope.

Nucleic Acid Based Methods

It is difficult to detect *C. sinensis* metacercaria in fish muscle by conventional light microscopy, and to differentiate them morphologically from those of other digenean trematodes. DNA detection methods, that is, polymerase chain reaction (PCR) and loop-mediated isothermal PCR (LAMP), can be used. Metacercarial genomic DNA can be extracted from freshwater fish after artificial digestion or can be extracted with fish DNA by treating a fish flesh with SDS/proteinase K and following this with spin column chromatography. A PCR method, targeting mitochondrial ITS2 and employing *C. sinensis*-specific primer pairs, detected one metacercaria in 3 g of flesh without cross-reaction with ITS2 of the genera *Opisthorchis* and *Heterophyes*. A LAMP method targeting the cathepsin B3 gene has also been reported to be able to detect 9 metacercariae per g of flesh. LAMP assay is cost-effective, rapid, and can be used to detect *C. sinensis* metacercariae accurately in the field in clonorchiasis endemic areas.

Deactivation Methods

When frozen in liquid nitrogen for 10 s, *C. sinensis* metacercariae in the flesh of *P. parva* remain infective, but all are killed by complete freezing for 30 s. It takes 4 min 50 s to freeze *Cyprinus carpio* (35 cm long) completely in liquid nitrogen and 2 min 4 s for *C. carassius* (15 cm long).

The *C. sinensis* metacercariae in *P. parva*, frozen at −12 °C for 10–18 days or at −20 °C for 3–7 days remain viable and infective to experimental animals. However, when stored at −12 °C for 20 days, metacercariae lose their infectivity. *C. sinensis* metacercaria in the flesh of *P. parva* kept at a heavy salt concentration (fish/salt = 10 g/3 g) for 5–7 days remain viable and infective. However, storage in this concentration for longer than 8 days reduced metacercariae survival in freshwater fish. Accordingly, freezing or storing infected freshwater fish in salt for long periods seems to inactivate *C. sinensis* metacercaria effectively.

The metacercariae in the decaying flesh of dead fish remain infective to experimental animals for 20 days and loose viability after 30 days. Furthermore, nitrogen compounds, mainly ammonia, produced endogenously in decaying fish can be lethal to *C. sinensis* metacercariae. In addition, *C. sinensis* metacercariae isolated from fish flesh can survive in water for longer than 1 week and can retain infectivity in PBS at 4 °C for 3 months. Thus, it seems that liberated metacercariae can contaminate food and utensils and be a source of contamination for family members.

Gamma-ray irradiation at high doses adversely affects the survival of all organisms. Isolated *C. sinensis* metacercariae irradiated with 50 Gy all failed to survive in rats (ID_{50}=16.5 Gy), and irradiation of metacercariae in the flesh of a small fish, *P. parva*, with 100 Gy killed 99% of metacercariae with an LD_{50} of 47.5 Gy.

Food Safety and Control Measures

In endemic areas, human infections are contracted by eating the raw or undercooked flesh of freshwater fish. The most practical measure for prevention, therefore, is not to eat raw or undercooked fish. However, food consumption governed by traditional customs and cultures, and thus, to change the food habits of a community, health education should be well organized and persistent. Health education should include topics, such as modes of infection, infectivity of *C. sinensis* metacercariae, freshwater fish harboring metacercariae, safe cooking procedures, hazards and illnesses associated with infection, diagnosis and treatment, and prevention measures. Control programs against clonorchiasis can be run in endemic areas with the cooperation of regional health staff.

The only source of human infection is freshwater fish infested with *C. sinensis* metacercariae. To prevent contamination of the snail host by eggs, sources of infection should be reduced or eliminated by chemotherapy of infected humans and reservoir hosts. In particular, aquaculture facilities and fishponds must be protected from contact with human and animal feces. Control measure includes sanitary treatment and disposal of feces, and regulation regarding the use of fertilizers.

HELMINTH-TREMATODE

Dicrocoelium dendriticum

G Cringoli and L Rinaldi, University of Naples Federico II, Naples, Italy

Glossary

Cercaria Term derived from the Old Greek word *kérkos*, which means tail, referring to a larval stage of Digenea, which is provided with a tail (cercariae are extruded from the snails in slime balls and ingested by the ants in the case of *Dicrocoelium dendriticum*).

Definitive host The host, usually a vertebrate, in which the parasite reaches maturity and reproduces sexually (mainly ruminants in the case of *D. dendriticum*).

Digenea Term derived from the Old Greek words *dis* (double) and *ghénos* (generation), referring to trematodes characterized by a life cycle with alternation of sexual and asexual reproductive phases.

Fluke Term derived from the Old English name for *flounder*, referring to the flattened shape of trematodes.

Intermediate host The host, usually an invertebrate, in which the parasite reproduces asexually through different larval stages (*D. dendriticum* has two intermediate hosts, i.e., land snails and ants).

Metacercaria Term derived from the Old Greek words *metá* (after) and *kérkos* (tail), which means the next stage of the cercaria, referring to the larval stage of trematodes that is encysted (within the ants in the case of *D. dendriticum*).

Miracidium Term derived from the Old Greek word *meirákion*, which means young, referring to the first larval stage of Digenea, pyriform, and ciliated (it is located in the egg ingested by the first intermediate host, land snails, in the case of *D. dendriticum*).

Prepatent period Time taken for development from infection (ingestion of ants with metacercariae in the case of *D. dendriticum*) until mature parasites reproduce sexually and produce parasitic elements (eggs in the case of *D. dendriticum*).

Sporocyst Term derived from the Old Greek words *sporá* (seed) and *kýstis* (cyst), which means a cyst containing a number of germinal cells, referring to a larval stage of Digenea that develops into the intermediate host (land snail in the case of *D. dendriticum*).

Spurious infection A case in which a parasite or parasitic elements (e.g., eggs) invade a host but do not infect it, for example merely passing through the digestive tract.

This article focuses on *Dicrocoelium dendriticum*, a small lanceolate trematode parasite (fluke) located in the biliary tract of animals (mainly ruminants) and humans. The life cycle is complex with two intermediate hosts, land snails and ants. Infection (foodborne zoonosis) occurs by passive ingestion of ants containing the infective stage metacercaria. Dicrocoeliosis, although very common and prevalent in ruminants, is considered rare in humans or sporadically reported. Misdiagnosis is frequent due to spurious infections as a consequence of eating raw or undercooked animal liver. The characteristics, clinical manifestation, epidemiology, diagnosis, and control of *D. dendriticum* are presented.

D. dendriticum (from the Old Greek words *dicròos*: double, *choilìa*: gut, and *dentrìticon*: branched) was firstly described in 1819 by the Swedish naturalist Karl Asmund Rudolphi, who is also considered the father of helminthology.

This parasite is located in the bile ducts and gall bladders of numerous species of mammals, mainly domestic and wild ruminants (e.g., sheep, goat, cattle, buffalo, deer), rabbits, and occasionally horses, pigs, dogs, and humans. Infection by *D. dendriticum* is a foodborne zoonosis of the biliary tract, considered to be very rare in humans or at least under-reported.

D. dendriticum (synonym *D. lanceolatum*) belongs to the phylum Platyhelminthes (flatworms commonly referred to as flukes), class Trematoda, subclass Digenea, order Plagiorchiida, and family Dicrocoelidae.

D. dendriticum is a small lanceolate fluke, 0.6–1.0 cm long and 1.5–2.5 mm wide, characterized by a dorsoventral, flattened, bilaterally symmetrical body. Like other Digenea, the body surface is covered by the tegument, i.e., a syncytial epithelium with sensory functions, implicated in nutrient absorption, synthesis, secretion, and osmoregulation; it also protects the parasite from the immune system of the host. The tegument of *D. dendriticum* is typically smooth without spines; therefore this fluke is typically semitransparent, with a black uterus and white testes visible to the naked eye (**Figure 1**). Adult *D. dendriticum* has two muscular suckers: the oral sucker (300–400 μm in diameter) at the anterior end surrounding the oral opening, and the ventral sucker (500–600 μm in diameter) also named *acetabulum*, located in pre-equatorial position, used by the fluke to attach to the wall of the small bile ducts of the definitive host (**Figure 2**). The digestive system is simple and contains the oral opening, pharynx, esophagus, and two branched intestinal ceca, which end

 doi:10.1016/B978-0-12-378612-8.00151-7

blindly. Excretory and nervous systems are simple; respiratory and circulatory systems are absent. As most trematoda, *D. dendriticum* is hermaphrodite with both the male and female reproductive systems. The male system is composed of two testes arranged in tandem, two vas deferens, a seminal vesicle, and a primitive penis called cirrus that terminates at the common genital pore; the female one is composed of a single ovary, oviduct, ootype, vitelline glands and ducts, uterus, and a common genital pore.

The egg of *D. dendriticum* (Figure 3) is small, 35–40 µm long and 25–30 µm wide, thick-walled, dark brown and operculate, oval, and slightly flattened on one side, and contains a miracidium (having 2 typical germ balls similar to two little eyes) when excreted with the feces of the host.

Variability of adult *D. dendriticum* specimens has been observed both upon morphoanatomic parameters and genetic – using random amplified polymorphic DNA. However, a lower intraspecific variation has been observed when using the second internal transcribed spacer (ITS-2) rDNA, a reliable genetic marker already used for molecular systematic studies

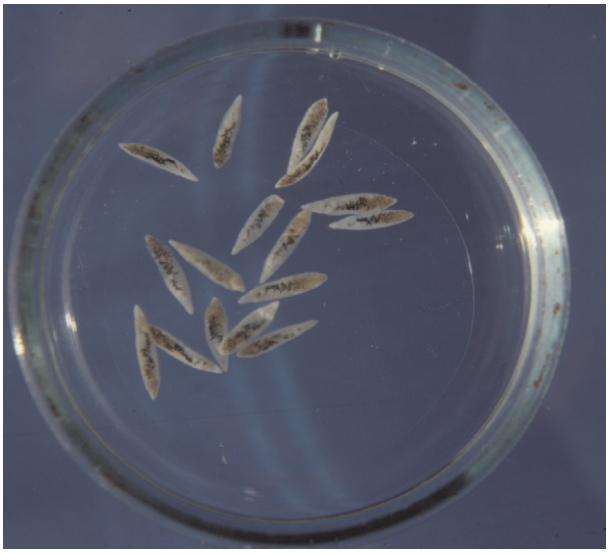

Figure 1 Adults of *D. dendriticum*.

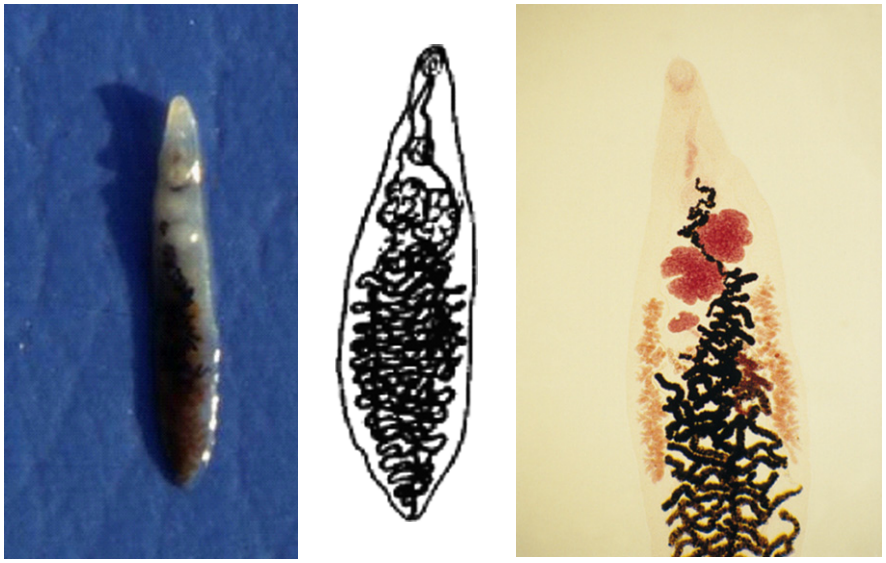
Figure 3 Egg of *D. dendriticum*.



(a) (b) (c)

Figure 2 Adults of *D. dendriticum* (a), scheme (b), and under the microscope (c).

of platyhelminthes. Nevertheless, genetic factors have not yet been associated to *D. dendriticum* virulence so far.

The entire life cycle of *D. dendriticum* (Figure 4) was elucidated between 1952–53 by the naturalists Krull and Mapes. It is indirect and very complex, with two intermediate hosts. The first intermediate hosts are land snails (Figure 5) of at least 30 genera (e.g., *Zebrina*, *Cionella*, *Helicella*, *Abida*); the second intermediate hosts are brown ants (Figure 6) of the genus *Formica* (e.g., *Formica fusca*, *Formica rufa*, *Formica rufibarbis*, *Formica pratensis*).

Like other Digenea there is alternation of sexual and asexual reproductive phases in the definitive hosts and the intermediate hosts, respectively, with four larval stages (miracidium, sporocysts, cercaria, and metacercaria).

In the bile ducts of the definitive host, adults *D. dendriticum* reproduce sexually by self- or cross-fertilization. Then they release eggs containing a miracidium into the environment through the host feces. After being ingested by a snail, these eggs hatch and release the miracidium, which migrates to the hepatopancreas of the snail. Then, two generations of sporocysts (elongated sacs containing a number of germinal cells) develop by asexual multiplication. From the germinal cells of the sporocyst (the redia stage is absent unlike other trematodes) arise the cercaria, a stage provided with a long tail. Numerous mature cercariae migrate to the respiratory chambers of the snail and are extruded from the snails in masses cemented together in mucilaginous slime balls. These slime balls are then ingested by ants, in which they develop to the encysted stage, called metacercaria, mainly in the body cavity and occasionally in the brain of the insect. The presence of a brain lesion in the ant, induced by one or few metacercariae, causes a cataleptic cramp (especially in early morning), which 'paralyzes' the ant on the tips of herbage and grass, thus increasing the chance of infection by the definitive host.

Infection of the definitive host is by passive ingestion of ants containing metacercariae. The metacercariae hatch in the small intestine and the young flukes (adolescariae) migrate to the small bile ducts, to the larger bile ducts and then to the gall bladder via the choledochus without any parenchimal migration into the liver.

The total life cycle (from egg to egg) of *D. dendriticum* requires *circa* 6 months. The prepatent period is 10–12 weeks. Adults flukes are long-lived in the bile ducts and gall bladder and can survive for several years.

Food accidentally contaminated with ants containing *D. dendriticum* metacercariae is the source of infection to humans. Metacercaria is a very resistant stage and has great potential for survival extending to months. Indeed, metacercariae in the ant live as long as the ant itself. Once ingested, the opening of the metacercaria occurs in the intestine of the host and depends on enzymatic factors as well as phenomena of oxidation–reduction and the presence of carbon dioxide.

The duration of clinical manifestation varies mainly according to the status of the patient.

In humans, symptoms of true *D. dendriticum* infection can vary from null to mild, but may also include chronic diarrhea, constipation, right upper abdominal pain, vomiting,

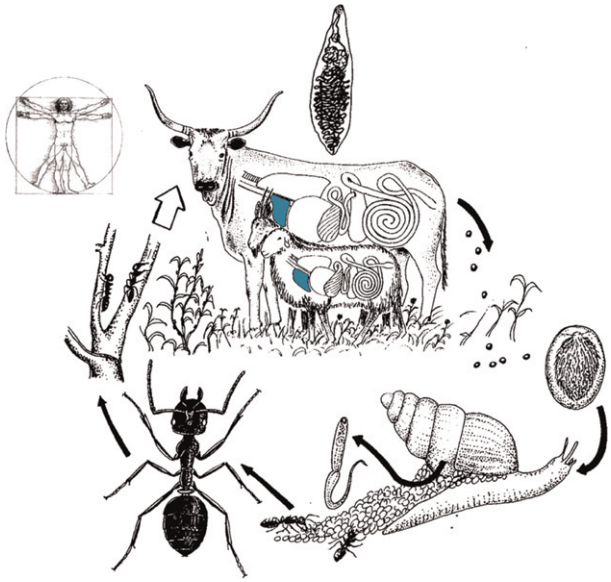


Figure 4 Life cycle of *D. dendriticum*.

Figure 5 Land snails, first intermediate hosts of *D. dendriticum*.

Figure 6 Ants, second intermediate hosts of *D. dendriticum*.

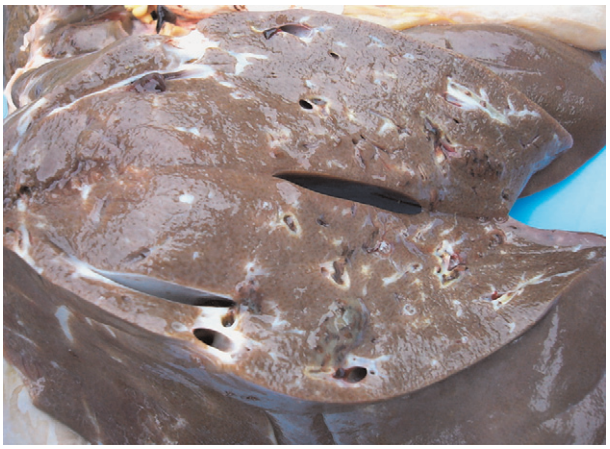

Figure 7 Sheep liver infected by *D. dendriticum*.

weight loss, and fatigue. Hepatomegaly, peripheral eosinophilia, biliary obstruction, and cholangitis may also occur. The pathogenesis is similar to other infections caused by liver trematodes such as *Fasciola*, *Opistorchis*, and *Clonorchis*. In ruminants, in the case of heavy infections, fibrosis of the small bile ducts and extensive cirrhosis can occur (Figure 7).

Pathological consequences of infection by *D. dendriticum* vary with host species, and are generally dose-dependent and attributed to complications arising from chronic inflammation of the mucosal epithelium. The infective dose is unknown. Infected ants may contain several metacercariae (up to 200) and a high percentage of ants may be infected. In infected humans, complications may be related to immunesuppression; indeed cases of patients infected with human immunodeficiency virus (HIV) and *D. dendriticum* have been reported. In addition, acute urticaria associated with *D. dendriticum* has also been reported as complication of the infection.

In animals, especially ruminants, dicrocoeliosis is an important parasitic infection from an economic and health point of view. This infection causes severe economic losses, in terms of milk and meat production in many countries, due to liver function impairment. The disease can be fatal on rare occasions. The economic significance of infection by *D. dendriticum* is due to the direct losses occasioned by the confiscation of altered livers and also to the indirect ones caused by the digestive disorders derived from the hepatobiliary alterations, such as decreased animal weight, growth delay, and reduced milk production, as well as by the cost of anthelminthic treatments.

Risks of misdiagnosis are very high in humans. Indeed, spurious infection (pseudoparasitism) by *D. dendriticum* is very frequent as a consequence of eating raw or undercooked animal liver; in such a case eggs pass unchanged through the digestive tract of an uninfected patient.

The only reliable methods to differentiate true from spurious infections are: (1) repeated coprological examinations (consecutively over 3 days) from patients with a diet from which liver is excluded and (2) examination of duodenal or biliary fluid to detect *D. dendriticum* eggs.

Palaeoparasitology studies show that the presence of *D. dendriticum* in Western Europe was attested from 550 000 years Before Present (BP) to the sixteenth century AD. Moreover, the parasite was identified in the New World and approximately the seventeenth century AD following the colonization of Canada by Europeans. Geographic distribution of *D. dendriticum* covers Europe, Asia (in particular China, Japan, Malaysia, Indonesia, and ex-USSR), North Africa, South America, and some focal points of North America.

Up to now, the importance of *D. dendriticum* as a food safety problem is quite low due to the rarity of human clinical cases of dicrocoeliosis. These few clinical cases, however, could represent only the tip of the iceberg.

Clinical cases of true human dicrocoeliosis have been reported sporadically in various parts of the world. Most reports of human infection by *D. dendriticum* originate in Europe and the Middle East; however the lanceolate liver fluke has been also reported in humans in Canada.

Nevertheless, statistical data on prevalence and/or incidence of dicrocoeliosis in humans are limited and scarce, contrary to what occurs with other foodborne trematodes (e.g., *Clonorchis*, *Opistorchis*, *Fasciola*, *Paragonimus*, *Fasciolopsis*, *Echinostoma*, and Heterophydae). For these latter trematodes, indeed, even if they are still neglected, at-risk population, number of infections, and global burden have been estimated in humans.

This situation in humans contrasts sharply with *D. dendriticum* infection in ruminants. Indeed, dicrocoeliosis is typically considered a 'disease of sheep and cattle' distributed worldwide in lowland or mountain pastures, which provide adequate conditions for the survival and development of terrestrial snails and ants. Prevalence values are usually higher in sheep and goats (up to 100% in many Mediterranean and Middle Eastern areas) than in cattle and buffaloes.

Therefore, the main reservoirs of *D. dendriticum* are ruminants, especially grazing sheep, which eliminate the eggs of the parasite that may overwinter and remain infective for up to 20 months on pastures. Eggs can be found in raw and treated wastewater.

The only vehicle of transmission to humans are field ants infected with metacercariae of *D. dendriticum*. The soil is the reservoir of these infected ants that can be found everywhere by chance, example, on grass, herbs, raw fruit, vegetables, cereals, foodstuffs, and drinking water. Therefore, swallowing infected ants, example, in unwashed fruits and greens or while playing in grass (children) is the main way of infection to human. Furthermore, other sources of ants potentially infected by *D. dendriticum* metacercariae are large warehouse supplies or even supplies outdoors without any barriers to prevent any invasions such as in refugee camps or food banks. Bottled water contaminated by infected ants has also been demonstrated as source of *D. dendriticum* infection. The possibility of transmission through ants in households invading kitchens has not been studied until know.

D. dendriticum is usually found where dry and calcareous or alkaline soils are present, because they represent a favorable biotope for its intermediate hosts, land snails, and ants. A study performed by multivariate spatial analysis of *D. dendriticum* infection in sheep in Italy showed that wood, rocks, and arable with sparse trees explained the spatial

distribution of the fluke. In another study, mountainous pastures with a mean slope of higher than 25%, situated over 600 m, where precipitation was high and temperature low, had involved the highest risk of infection by *D. dendriticum* in cattle in Spain.

However, impact of climatic change seems to be limited on the spatial and temporal distribution of *D. dendriticum* compared to other liver flukes such as *Fasciola hepatica*, whose rise in recent years has been attributed to climate change.

Dicrocoeliosis often remains clinically undetected or undiagnosed, most likely because of its subclinical nature. Its diagnosis in animals is mainly due to recovering adults in the liver at necropsy or detecting eggs at coprological examination. Flotation techniques using jodomercurate-based or zinc-sulfate-based solutions (specific gravity = 1.350–1.450) perform better than sedimentation techniques. As with other foodborne trematode infections, diagnosis is often unsatisfactory when using the current copromicroscopic techniques (e.g., Kato–Katz, ether sedimentation, McMaster technique). Recently, new multivalent techniques for qualitative and quantitative copromicroscopic diagnosis of parasites in animals and humans, the FLOTAC techniques, showed a higher sensitivity and efficiency for detecting *D. dendriticum* eggs in fecal samples from animals and humans.

Immunological and molecular techniques have been developed for the detection of dicrocoeliosis in animals.

As with other foodborne trematodes, there are only two drugs available for treatment and control of *D. dendriticum* in humans: praziquantel and triclabendazole. In the case of a spurious infection, treatment is not recommended. Prevention of contamination by *D. dendriticum* in the environment is difficult because of the longevity and resistance of the eggs in the environment, the number of reservoir hosts, and the wide distribution of intermediate hosts. Methods against the intermediate hosts (e.g., using calcium cyanamide molluscicide and chemical fertilizers) are not feasible because of their high costs and ecological unsustainability. Education measures becomes important especially for young children. Prevention of contamination in the environment depends almost entirely on regular anthelmintic treatments of ruminants.

As it happens for other parasites, *D. dendriticum* is often forgotten in the food safety and hygiene community. Therefore, regulatory measures are still unavailable, and only some practical commonsense preventive measures (e.g., keeping ants away from all food supplies) may be useful to reduce the risk of infection. However, regulatory and education measures should be strengthened because the high prevalence in animals and the high number of human spurious infection detected show that true infection is likely to occur in humans. Improved access to clean water, appropriate sewage disposal and treatments, enhanced food safety measures, and collaboration between public health and veterinary medicine are important integrated measures to reduce transmission to humans through food.

Regarding public health, the global burden of *D. dendriticum* infection is yet to be determined as it is for other foodborne trematode infections, considered an important group of neglected tropical diseases. However, since 2007, *D. dendriticum* has been included in the list of causative agents for which burden of disease estimates are to be derived according to Task Force 1 of the Foodborne Disease Burden Epidemiology Reference Group (FERG) of the World Health Organization.

Diphyllobothrium

J Dupouy-Camet, Université Paris Descartes, Paris, France
R Peduzzi, Istituto Cantonale di Microbiologia, Bellinzona, Switzerland

Glossary

Cestod A class of parasitic flatworms, commonly called tapeworms, of the phylum Platyhelminthes. Several species parasitize humans after being consumed in underprepared meat such as pork (*Taenia solium*), beef (*Taenia saginata*), and fish (*Diphyllobothrium* spp.).
Copepods Microscopic crustacean, part of the zoonotic plankton.
Coracidium Ciliated swimming larvae of the genus *Diphyllobothrium*, exiting the egg through the operculum, that need to be ingested by a copepod to develop in a procercoid.
Diphyllobothriosis A disease caused by the cestode species of the genus *Diphyllobothrium*.
Plerocercoid Larval stage of parasitic species of the genus *Diphyllobothrium* found in fish.
Procercoid Larval stage of parasitic species of the genus *Diphyllobothrium* found in the copepod.
Proglottids Part of the adult worm composed of different segments containing eggs and passed through the feces.

Background

Tapeworms of the genus *Diphyllobothrium* are widely distributed all around the world, with a dozen species that are known to be agents of human diphyllobothriosis, one of the most important fish-borne zoonoses caused by a cestode parasite. Intermediate hosts include both freshwater and marine fish, mainly the anadromous species. Piscivorous birds and mammals (including humans) are definitive hosts and contract these parasites by eating raw or poorly cooked fish containing plerocercoid larvae. *Diphyllobothrium* cestodes are commonly present in the wildlife including fish, mammals, and birds which are important reservoir hosts. This parasitosis is known since antiquity: in Europe, eggs of *Diphyllobothrium latum* were discovered by the archeologists in lake villages dating from the Neolithic era in France and Germany. The parasite was first described as *Taenia lata* in 1592 by Dunus, a physician established in Locarno (Switzerland). Nearly 300 years later, Parona working in the subalpine lake regions of the north of Italy, and Janicki and Rosen in Neuchâtel, definitively described the parasitic cycle, which proved to be one of the most complex known at the time.

Characteristics

The genus *Diphyllobothrium* belongs to the family Diphyllobothriidae, order Diphyllobothriidea (formerly Pseudophyllidea), class Cestoda, and phylum Platyhelminthes. To date, approximately 50 species have been described but only 12 have been reported as human pathogens (Table 1). The most frequent are *D. latum* (cosmopolitan), *Diphyllobothrium nihonkaiense* (Japan, South Korea, Eastern Russia, and probably North America), *Diphyllobothrium dendriticum* (northern part of the Northern Hemisphere), and *Diphyllobothrium pacificum* (Argentina, Chile, Peru). Infections with *Diplogonoporus balaenopterae* (syn. *Diphyllobothrium grandis*) have been reported in Japan and recent molecular studies revealed a close relationship with the cetacean tapeworm *Diphyllobothrium stemmacephalum*, which in turn is probably synonym of *Diphyllobothrium yonagoense*. Other species (*Diphyllobothrium alascense*, *Diphyllobothrium cameroni*, *Diphyllobothrium cordatum*, *Diphyllobothrium dalliae*, *Diphyllobothrium hians*, *Diphyllobothrium orcini*, *Diphyllobothrium ursi*, *Diphyllobothrium scoticum*, and *Diphyllobothrium lanceolatum*) have also been described in humans, but very few details are available in the scientific literature.

The life cycle of *D. latum*, probably the most frequent species in humans, is complex and involves several hosts (Figure 1). Released in freshwater, the eggs mature within 8–12 days at a water temperature of 16–20 °C, and yield coracidium larvae that are ingested by zooplanktonic crustaceans; 40 copepod species (Copepoda: Diaptomidae and Cyclopidae) are likely to serve as the first intermediate hosts. The coracidium develops into a procercoid larva within the general cavity of the copepod. When a carnivore fish ingests planktonic crustaceans, the procercoid develops into a plerocercoid larva (Figure 2), a few millimeters long. It migrates into the host musculature or to the viscera, where it can remain inactive in a cyst for several years, but can excyst and re-encyst repeatedly if an infected fish is ingested by other predatory fishes (paratenic hosts). In Europe, fish species recorded as susceptible *D. latum* plerocercoids are perch (*Perca fluviatilis*), pike (*Esox lucius*), Arctic charr (*Salvelinus alpinus*), and burbot (*Lota lota*). Coregonidae and probably Salmonidae

 doi:10.1016/B978-0-12-378612-8.00152-9

Table 1 Species of *Diphyllobothrium* reported from humans

Species	*Fish hosts*	*Other hosts*	*Distribution*
D. alascense (Rausch and Williamson, 1958)	Burbot, smelt	Dog	Alaska
D. cameroni[a] (Rausch, 1969)	Marine fish	Monk seal	Japan
D. cordatum (Cobbold, 1869)	Marine fish	Seals, walruses	North Atlantic
D. dalliae (Rausch, 1956)	Alaska blackfish, Dolly Varden	Gulls, dog	Alaska
D. dendriticum (Nitzsch, 1824)	Salmonids, coregonids	Fish-eating birds	Circumpolar
D. hians[a] (Diesing, 1850)	Marine fish	Arctic seals	North Atlantic
D. lanceolatum (Krabbe, 1865)	*Coregonus*	Fur seals	North Pacific
D. latum (L, 1758)	Pike, burbot, perch, Arctic char, other percids	Terrestrial mammals	Cosmopolitan
D. nihonkaiense[a] (Yamane, 1986)	Pacific salmons	Brown bear	Eastern Eurasia, Japan
D. pacificum (Nybelin, 1931)	Marine fish	Sea lions, eared seals	South America
D. ursi (Rausch, 1956)	Red salmon	Bears	Alaska, British Columbia
D. grandis[b] (Blanchard, 1889)	Anchovy, sardine	Cetaceans	Circumpolar, Japan

[a]*D. nihonkaiense* and *klebanovskii* (Muratov and Psokhov, 1988) are synonymous.
[b]This could be synonymous with *Diphyllobothrium stemmacephalum*.

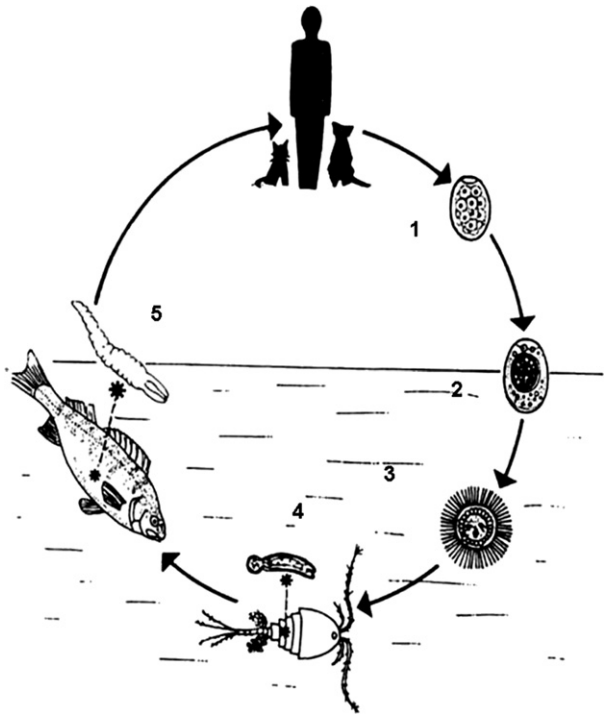

Figure 1 Life cycle of *Diphyllobothrium latum*: 1, egg; 2, embryonated egg; 3, coracidium; 4, procercoid larva in a copepod; 5, plerocercoid larva in a fish.

of the *Salmo* genus do not host *D. latum* larvae, but they can serve as a host for *D. dendriticum*. Pacific salmon of the genus *Oncorhynchus* are the usual hosts of *D. nihonkaiense*. Marine fish are the intermediate hosts for *D. pacificum* and *D. balaenopterae*. Humans and other ichthyophagous animals become infected by ingesting raw infected fish. The plerocercoid larva then develops rapidly into an adult (Figure 3) in the intestine that yields its first eggs 2–6 weeks after the infection.

Figure 3 Proglottids of *Diphyllobothrium latum* obtained from a patient contaminated after eating raw fish from Lake Geneva. Note the ventral opening of the genital pore (picture: J Dupouy-Camet).

Clinical Manifestation

Diphyllobothrium tapeworms are the longest human parasites known (2–15 m long) and can live for several years. The ingestion of a single plerocercoid larva can lead to infection. The larva will grow 1–2 cm per day and 3 weeks after ingestion will provoke the occurrence of symptoms. The symptoms of human diphyllobothriosis, although limited, are polymorphous and may include abdominal discomfort, abdominal pain, diarrhea, weight loss, asthenia, and vertigo. All these symptoms are vague and are quite common among the general population. A study performed 50 years ago during an extensive field investigation in Finnish Karelia compared 295 parasitized persons with 1127 controls. Statistical analysis showed that the worm carriers had a significantly higher frequency of fatigue, weakness, diarrhea, and numbness of extremities. A sensation of hunger and craving for salt was also associated with the worm infection. Some carriers experience very little discomfort and become alerted when proglottids are passed in the feces. The parasite can also be found accidentally when performing a colonoscopy. Megaloblastic anemia due to vitamin B_{12} deficiency has been described in cases of prolonged infection in a malnourished Finnish population after World-War II, but it is only rarely reported nowadays. Most of the time, the parasitosis is mistaken for functional colopathy. *Diphyllobothrium* parasites are sensitive to praziquantel (25 mg kg^{-1} day^{-1} in one dose is effective against most human pathogen species) or to niclosamide (2 g on an empty stomach in two doses an hour apart).

Epidemiology

In the early 1970s, the worldwide prevalence of human diphyllobothriosis was estimated to be 9 million cases. More recent data indicate that 20 million people are infected worldwide, but many more are at risk; estimations of global prevalence have not been adequately performed. The parasitosis is frequently reported from Japan, South Korea, the Baltic countries, Scandinavia, Western and Eastern Russia, and North America (Pacific Northwest). Only sporadic cases have been reported in South America.

Diphyllobothrium latum is present in America (Canada, Chile, Brazil), but recent surveys have indicated that this parasitosis was emerging or re-emerging in some countries, particularly in Italian and French-speaking subalpine regions. This species is especially encountered in Scandinavia, the Baltic States, around the Lake Leman, in France, and Switzerland and in the north of Italy around the Lakes Maggiore and of Como. In Switzerland, between 2002 and 2007, more than 250 cases of diphyllobothriosis were reported in the canton of Geneva (230 cases), in Tessin (11 cases), and in the cantons of Vaud (10 cases). In Geneva, a small epidemic was reported in June 2006 after a wedding banquet where 8 people out of 26 were infested by *D. latum* after consumption of marinated raw perch. Over the same period (2002–2007), 44 cases were reported in the department of Haute-Savoie (France) exclusively in towns located on the shores of Lake Leman. The average prevalence of the parasite (pleurocercoids) in perch filets from the lakes of the subalpine region ranges from 5% to 14%. *D. nihonkaiense* cases are often reported in Japan, in South Korea, and Russia, but this species was also reported in France and in Switzerland after the consumption of imported Pacific salmon (*Onchorhynchus* sp.). *D. pacificum* is frequently found on the Pacific coasts of Chile and Peru. Diphyllobothriosis is a zoonosis and infected piscivorous mammals (cat, dog, fox, etc.) can serve as reservoirs for the parasite and maintain the cycle in the lake ecosystems.

Analytical Methods

Conventional Techniques

All members of the genus *Diphyllobothrium* are morphologically very similar and are sometimes distinguished by hosts and geographical origin. Human infective species can be identified by skillful parasitologists using morpho-anatomical criteria, which, are relative, however, as they vary with the age and the degree of development, and are influenced by physiological modifications. Diagnosis is possible on the whole adult parasite (rarely obtained) showing a medium-sized to large tapeworm with strobila that is usually segmented. Genital apertures are on the ventral face and the scolex is unarmed with a pair of dorsal and longitudinal grooves, named bothria. Segments (proglottids) are wider than long with genital pores opening medioventrally (Figure 3). Each segment measures 2–7 mm × 10–12 mm. Eggs are oval and operculated. The eggs of *D. latum* are grayish brown with a 50–85 × 40–60 µm average size, whereas those of *D. nihonkaiense* are smaller (53–59 × 35–45 µm). However, sizes vary considerably among individual worms and could decrease with the intensity of infection. Eggs can be mistaken with those of *Paragonimus* spp. or *Fasciola hepatica*, but their sizes are larger.

Plerocercoid larvae can be searched for in the host tissues by the candling of thin fillets or by cutting fillets in thin slices and then direct observation with magnifying glasses. The compression method and digestion have not been evaluated but have a major drawback that such treatment could destroy the fish. The plerocercoid larvae, obtained from fish, range from a few millimeters to a few centimeters long and their identification has always been the job of an expert. They appear as white elongated masses in the skeletal muscle of certain fish families (Figure 2). They can be confounded by non-experts with acanthocephalans (easily distinguishable by the presence of an evertable proboscis armed with spines) or with cestodes of the genus *Proteocephalus*. Identification keys are based on the features of gross-morphology visible under a light or a scanning electron microscope, on body-length and site within the host, and features visible in the histological sections.

Molecular Techniques

Biochemical techniques (isoenzymatic assay or immuno-electrophoresis) have been used as alternatives to the traditional tools for species identification, but the development of molecular biology resulted in a better knowledge of the *Diphyllobothrium* genus. For example, Matsuura *et al*. utilized restriction fragment length polymorphisms (RFLPs) of ribosomal DNA (rDNA) to distinguish between *D. latum* and *D. nihonkaiense*, as

the profiles generated with restriction enzymes *Sma*I, *Hinf*1, and *Hha*I provided valuable species-specific markers. Since 1998, important systematic data on the *Diphyllobothrium* genus have been obtained by sequence analysis of the 18S ribosomal RNA (18S rRNA) and cytochrome *c* oxidase subunit 1 (cox1 or COI), NADH dehydrogenase subunit 3 (NADH3) genes, and of the partial internal transcribed spacer 2 (ITS2) region. Recently, 18S rRNA, internal transcribed spacer 1 (ITS1), cox1, and cob (cytochrome *b*) sequences were used to differentiate between *Diphyllobothrium* species isolates. Sequences from samples of plerocercoids, adults or eggs of *D. latum*, *D. nihonkaiense*, *D. ditremum*, *D. dendriticum*, *Diphyllobothrium stemmacephalum*, and *D. pacificum* have been examined. Cox1 and cob sequences analyses were clearly more discriminative than those of the ITS1 and 18S rRNA, therefore representing a useful tool for identifying specimens.

Control and Preventive Measures

Information campaigns directed at consumers must make them aware of the dangers of raw fish consumption. In some countries (e.g., France and Switzerland), legislation requires that any fish intended to be consumed raw must be frozen at a temperature lower than −20 °C, for at least 24 h. But these measures are not reliably performed by individual consumers. In practice, the freezing of fish in the standard home freezers for a week seems to be the simplest precautionary measure. Cooking to 55 °C for at least 10 min kills the parasite. These measures also have the advantage of protecting infection by other zoonotic parasites in fish, such as anisakids and the opistorchids. Salting, smoking, and pickling have not been demonstrated to be effective against the plerocercoids larvae.

Conclusions and Future Perspectives

The growing popularity of raw fish specialties has probably favored the increase of diphyllobothriosis in subalpine regions and elsewhere, and importation of Pacific salmons, or travels to endemic countries, have led to the occurrence of cases of allochtonous *D. nihonkaiense* and *D. dendriticum* in France, Switzerland, Finland, and New Zealand. In the light of these considerations, infections with allocthonous species of *Diphyllobothrium* are probably more widespread than has been recognized. In addition, these parasites sometimes show a high colonization potential, as was the case in South America for introduced *D. latum* and *D. dendriticum*. Although human-infecting species can be easily treated with the same anthelminthic (praziquantel), their correct diagnosis by laboratories and physicians is of great importance from an epidemiological perspective and must be improved. The genetic identification of broad tapeworms and the analysis of anamnestic data of the patients can contribute to clarify the distribution of such parasites and help in detecting the sources of the infections.

Echinostoma

R Toledo, Universidad de Valencia, Valencia, Spain
B Fried, Lafayette College, Easton, PA, USA

Glossary

Cercaria A free-swimming trematode larva that emerges from the first intermediate host (snail); it may penetrate the skin of a final host, encyst on vegetation, in or on fish, or penetrate and encyst in various amphibian hosts.
Echinostomatidae A family of flukes (Trematoda) characterized by a collar of spines at their anterior end. The body is elongated and is covered with spines, and the two suckers are usually close together.
Echinostomiasis Intestinal parasitic disease caused by trematode flukes from the family Echinostomatidae.
Food-borne trematodiasis Parasitic disease caused by members of the class Trematoda transmitted by food.
Metacercaria The encysted maturing stage of a trematode in the second intermediate host before transfer to the definitive host, usually representing the organism's infectious stage.
Miracidium A small free-living larval stage of parasitic flatworms in the class Trematoda. It is released from eggs which are usually shed in the feces of its vertebrate host and infects the first intermediate host.
Redia Intramolluscan larval stage of trematodes that produces more rediae or cercariae in the first intermediate host.
Sporocyst Intramolluscan larval stage of trematodes that produces more sporocysts or rediae in the first intermediate host.

Background

The term echinostomes includes the trematodes belonging to the family Echinostomatidae. These digeneans are characterized by the presence of a prominent cephalic collar of spines. Echinostomes are a rather heterogeneous group of cosmopolitan hermaphroditic digeneans that, as adults, inhabit the intestine of a great spectrum of vertebrate hosts such as birds, mammals and, occasionally, reptiles and fishes. They also are able to parasitize humans causing the food-borne infection called echinostomiasis. Humans become infected after ingestion of the second intermediate host harboring the encysted metacercariae. Infections are associated with common sociocultural practices of eating raw or insufficiently cooked mollusks, fish, crustaceans, and amphibians, promiscuous defecation, and the use of night soil (human excrement collected from latrines) for fertilization of fish ponds. Echinostomiasis is aggravated by socioeconomic factors such as poverty, malnutrition, a lack of supervised food inspection, poor or insufficient sanitation, and other helminthiases. In the present article, the authors review the main features of these trematodes with emphasis on their food-borne transmission and control.

Morphology and Classification

The morphology of several stages of echinostomes is shown in Figure 1. Adult worms of the family Echinostomatidae are morphologically characterized by the presence of a head collar with collar spines around the oral sucker (Figure 1(a)). The number and arrangement of collar spines is an important feature for taxonomic purposes. Considerable variation exists in size of echinostomes depending on species, fixation procedures, definitive host, and crowding effect. Echinostomes are referred to as small if up to 5 mm in length, medium if 5–10 mm, and large if longer than 10 mm. The spines of the cephalic collar may be arranged in one or two circles and the number of spines is constant within the species. The tegument contains scale-like spines on both dorsal and ventral surfaces, though the number and size of the spines is reduced in the posterior half of the body (Figure 1(b)). The oral and ventral suckers are close to each other. The two testes, usually in tandem, are posterior to the ovary. There is considerable confusion in relation to the systematics of the members of the family Echinostomatidae, particularly within the genus *Echinostoma*. This is attributable to a number of factors, including misidentified species or species that have been insufficiently described, the existence of substantial interspecific homogeneity of the morphological characteristics of the adult stages, as well as the broad range of final vertebrate hosts and the wide geographical distribution. The Echinostomatidae has been viewed as a monophyletic taxon, though the morphology and the diversity of the criteria adopted by different authors have led to its division into an impressive number of taxa (i.e., a total of 21 nominal subfamilies).

 doi:10.1016/B978-0-12-378612-8.00153-0

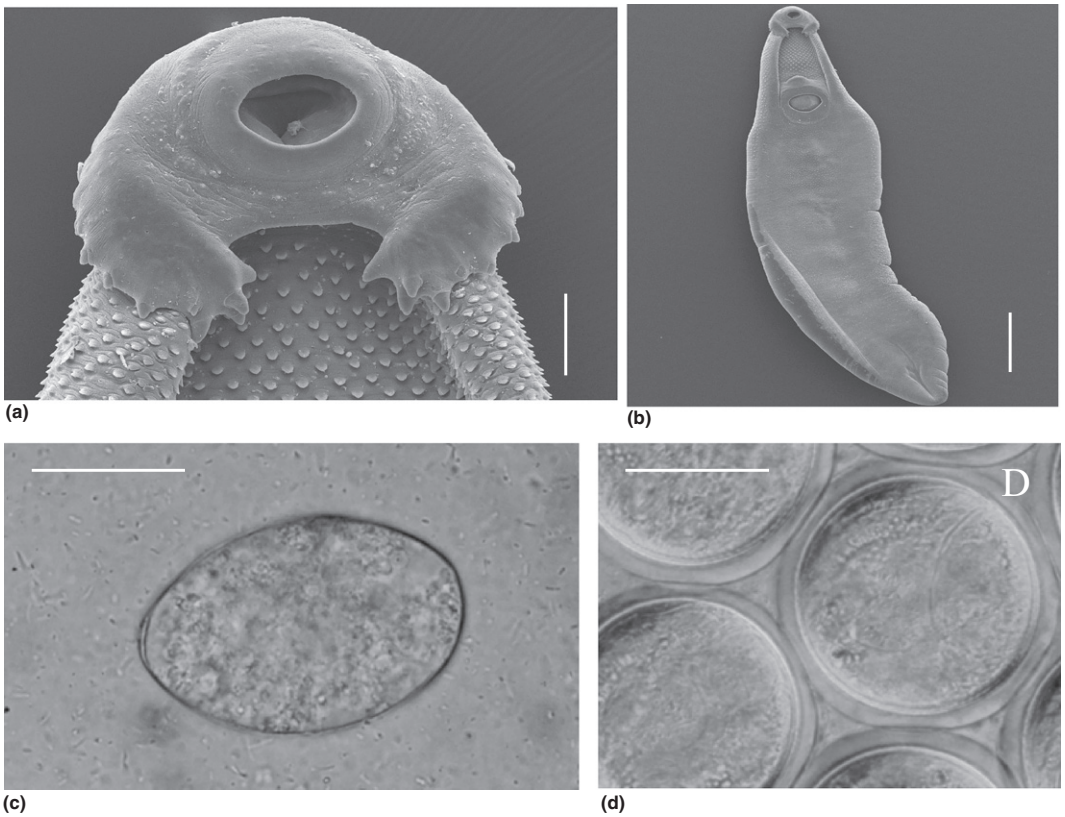

Figure 1 Microscopy of *Echinostoma*: (a) low-magnification scanning electron micrograph of the cephalic collar of spines of an adult worm of *E. caproni* (scale bar: 200 μm); (b) low-magnification scanning electron micrograph of an adult worm of E. caproni showing the spined collar (scale bar: 1 mm); (c) egg of E. sp. in human feces (scale bar: 50 μm); and (d) metacercariae of E. sp. collected from specimens of *Biomphalaria glabrata* (scale bar: 75 μm).

Life Cycle

Echinostome adults are hermaphroditic digeneans that live in the intestine and bile ducts of numerous vertebrate hosts, particularly aquatic or semi-aquatic birds and mammals, including humans. In the wild, the life cycle of an echinostome is maintained when a definitive host releases eggs (Figure 1(c)) into ponds, streams, and lakes. The fertilized eggs are undeveloped when laid and take approximately 2–3 weeks at 22 °C to reach the fully developed miracidial stage. Miracidia hatch from eggs and actively locate the first intermediate snail host in response to host signals and emitted products. Several species of planorbids, lymnaeids, and bulinids have been recorded as first intermediate hosts of echinostomes. Miracidia usually enter the head foot region of the snail and transform into sporocysts in the heart. In the snail first intermediate host, two generations (mother and daughter) of rediae occur. Cercariae develop within daughter rediae and begin to emerge from infected snails 4–6 weeks postinfection. In an aquatic environment, cercariae actively search for the second intermediate host. Echinostome cercariae show a low degree of host specificity, and several species of snails, frogs, tapdoles, and fish may serve as second intermediate hosts. Cercariae enter the second intermediate host via the cloacal opening of a tapdole or the excretory pore of a snail and encyst mainly in the tadpole kidney and kidney/pericardial cavity of the snail; cercariae may also penetrate into the musculature of fish and encyst there.

Definitive hosts become infected after ingestion of the second intermediate host-harboring encysted metacercariae (Figure 1(d)). Echinostomes do not undergo tissue migration in the definitive host. Following infection of the definitive host, the metacercariae excyst in the duodenum and the juvenile parasites migrate to the small intestine where they attach to the mucosa by the ventral sucker. Numerous vertebrates including waterfowl, rodents, and humans, among others, can serve as definitive hosts for echinostomes. The release of eggs from the definitive host usually begins 10–16 days postinfection. Although the release of eggs is continuous from the first day of patency, significant variations over the course of the infection in egg output have been documented. The duration of the infection varies from one to two weeks to more than one year depending on the echinostome species and the host species (Figure 2).

Clinical Manifestations and Pathology

Major clinical symptoms due to echinostome infection may include abdominal pain, diarrhea, easy fatigue, and loss of body weight. The severity of the symptoms depends on the parasite load. Heavy infections are associated with local

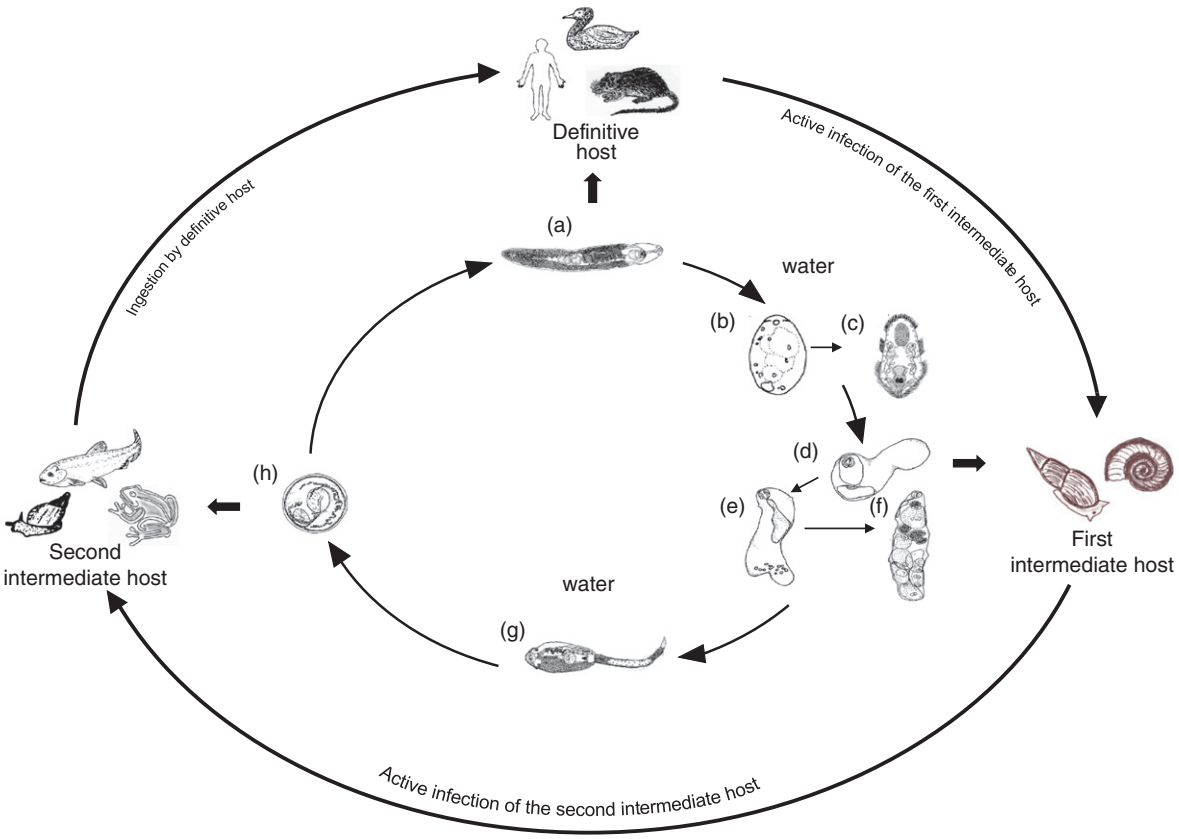

Figure 2 Generalized life cycle of *Echinostoma* spp.: (a) adult worms inhabit the small intestine of several vertebrate hosts, including humans; (b) eggs are voided with the host feces; (c) miracidia hatch in fresh water and actively infect snails; (d) sporocysts, (e) mother rediae, and (f) daughter rediae, are the intramolluscan stages; (g) cercariae are released and swim to locate the second intermediate host (snails, amphibians, bivalves, fishes) in which they encyst to become metacercariae; (h) metacercariae are ingested by the definitive host and excyst to become adults. Reproduced with permission, from Toledo and Fried (2005).

eosinophilia, abdominal pain, watery diarrhea, anemia, edema, and anorexia, and pathological features include catharral inflammation, erosion, and even ulceration. Peripheral blood eosinophilia is commonly observed. In *Echinostoma hortense* infections, the level of peripheral blood eosinophilia was dependent on the worm burden; 11–24% in patients with more than 100 worms; 4–21% among those with 51–100 worms; and 2–14% among those with less than 50 worms. Several studies on *E. hortense* have shown that patients suffered epigastric and abdominal pain, acid belching, weight loss discomfort, anorexia, headache, nausea, and vomiting. Patients infected with *Echinostoma ilocanum* suffered intestinal colic and diarrhea.

The intestinal histopathology in echinostome infections was studied using laboratory rodents. The pathology of echinostomes represents a complex set of reactions and the complexity is dependent on a wide variety of factors including characteristics of the echinostome species, the host species, and intensity of the infection. Pathological changes are often seen at worm attachment sites. Such areas may show marked dilation, erosion of the villi, and lymphocytic infiltration. Moreover, increases in goblet cells, mucosal neutrophils, mononuclear inflammatory cells in the mesentery, and crypt hyperplasia have been observed. Cellular infiltration of lymphocytes, eosinophils, and plasma cells was observed in the lamina propria and submucosa.

Epidemiology

Echinostomes are commonly found in birds (waterfowl) and mammals associated with freshwater habitats, and their distribution is ubiquitous. In general, their specificity toward the definitive host is low and a single echinostome species is able to infect several species of vertebrate hosts. The distribution of echinostomes is mainly dependent on the presence of snail first intermediate hosts because these parasites are more restrictive in their specificity toward this host.

Current incidence of human echinostomiasis is difficult to determine accurately because of the unavailability of epidemiological surveys and most of the available information is based on the occasional case reports. Table 1 summarizes the species of Echinostomatidae infecting humans, their geographical distribution, and the source of infection. Distribution of human echinostomiasis is strongly determined by dietary habits. Humans become infected when they eat raw or inadequately cooked food, especially fish, snakes, amphibians, clams, and snails containing encysted echinostome

Table 1 Geographical distribution and possible source of infection of species of Echinostomatidae infecting humans.

	Echinostome species	*Geographical distribution*	*Possible source of infection*

	Isthmiophora melis	All Europe	Tadpoles and loaches
Oceania	*Echinostoma revolutum*	Australia	Snails, tadpoles and clams

metacercariae. Infections are thus most prevalent in areas where traditional cultural practices encourage ingestion of raw or undercooked fish, frogs, snakes, or snails and bivalves. In the Philippines, human echinostome infections are due to eating raw fish dipped in a salt and vinegar mixture, known as *kinilaw*. Other methods of fish preparation are *tinola* (boiled), *ginataan* (stewed in coconut milk), and *sinugba* (charcoal-grilled). All echinostome-infected patients had a history of having eaten snails, *kuhol*, and *kiambu-ay*, prepared raw with coconut milk and lime juice (kinilaw), especially when found in greater abundance during the rainy season. This suggests that various types of marinades and food preparations may not affect the viability of echinostome metacercariae. Moreover, it has been suggested that drinking untreated water containing echinostome cercariae can be a source of human infection.

Human echinostome infections are limited to areas where both intermediate hosts live together in the same habitat and suitable climatic factors are present. Hence, distribution is highly focal. Most human infections are reported from foci in East and Southeast Asian countries such as China, India, Indonesia, Korea, Malaysia, Philippines, Russia, Taiwan, and Thailand. Moreover, occasional cases have also been reported in other countries (Table 1). Characteristic of several of the food-borne diseases, changing infection patterns have been observed in recent years. Population growth, pollution, poverty, and lack of improved sanitation have contributed to increased infection rates in several areas. In contrast, social and economic advances, combined with health education campaigns and mass drug administration, have reduced prevalence in other settings.

Analytical Methods

The diagnosis of human echinostomiasis is usually based on detection of eggs in fecal examinations. The most frequently used method of diagnosis is the Kato-Katz thick smear, though

other techniques such as the Stoll's dilution or the quantitative formalin acetate concentration can also be used. In the Kato-Katz technique, the fecal sample is processed in a staining procedure and the slide is examined by light microscopy. The eggs are oval in most cases, yellowish, with a thin and refractile shell and with a small inconspicuous operculum located at the anterior end. The operculum may be difficult to see using the Kato-Katz method. The size of echinostome eggs of zoonotic species is in the range of 0.066–0.149 mm in length and 0.043–0.090 mm in width. With careful microscopic observations including egg measurements, specific diagnosis may be possible in known endemic areas with a single or a mixed echinostome species infection. However, recovery and identification of the adult flukes, following anthelmintic treatment and purgation, is recommended if a definite diagnosis is preferred.

Occasionally, human echinostomiasis has been revealed by gastroduodenal endoscopy performed in relation to severe epigastric symptoms and ulcerative lesions in the stomach and duodenum. In Japan, four cases of *E. hortense* infections were reported based on worm recoveries by upper endoscopy.

From a food-safety standpoint, detection of the metacercariae in an intermediate host, especially fish, is vital. The metacercaria is morphologically distinct from other zoonotic and nonzoonotic trematode metacercariae, particularly by the possession of a cephalic collar of spines. The specific diagnosis may be performed on the basis of adult morphology, after metacercarial infection of a laboratory animal, or by polymerase chain reaction (PCR).

Examination for echinostome metacercariae in the second intermediate host, especially in fish, is commonly performed by two methods, i.e., muscle compression and pepsin–HCl artificial digestion. In the compression technique, a sample of flesh from different parts of the fish (e.g., head, gill, muscle, fin, scale, intestine, and other viscera) or other host is compressed between two glass slides and examined under the stereomicroscope with 20- to 100-fold magnification. The artificial digestion method is more complicated. Small pieces of flesh are minced and mixed in a breaker with artificial gastric juice (concentrated HCl 8 ml + pepsin 1:10 000 6 g + distilled water 1000 ml) and incubated at 37 °C for 2 h with occasional stirring. After removal of the larger particles by filtration (1 mm × 1 mm of mesh), 0.85% saline is added. The supernatant is discarded and the sediment retained. This procedure is repeated until the supernatant becomes clear. Finally, the sediment is examined under a steromicroscope for the presence of metacercriae.

Immunological methods have been developed but their application is presently limited to experimental infections in animals. The application of molecular methods for the diagnosis of echinostomes is still very limited. However, in recent years a number of species-specific PCR-based methods have been developed that are capable of detecting and differentiating trematode species from environmental and clinical samples obtained from definitive and intermediate hosts. These methods are rapid, provide increased discriminatory power, and have the ability to analyze small amounts of sample. Moreover, they negate the need for laborious morphological examination of the individual adult flukes following anthemintic purging (in humans) or morphological investigation of the intermediate host for the presence of metacercariae. For example, a tandem repeated DNA sequence has been recently described and used to detect metacercariae of *Echinostoma caproni* from snail tissues. This methodology could be used in other intermediate hosts such as fish.

Treatment and Control Measures

In human infections, praziquantel is the drug of choice for echinostomiasis. Mebendazole and albendazole have also been shown to have an effect against echinostomiasis.

Eating raw or improperly cooked freshwater fish and fresh or brackish water snails should be avoided to prevent echinostome metacercarial infections. There is evidence that various types of marinades and food preparations commonly used may not affect the viability of echinostome metacercariae. In a local market in Thailand, the fish (*Cyclocheilichthys armatus*) were infected with large numbers of *Echinostoma* metacercariae and were used to evaluate the effect of traditional food preparation on the viability of the metacercariae. The metacercariae *in situ* were evaluated using the following preparations: (1) left to dry at room temperature; (2) frozen; (3) refrigerated; (4) marinated in saline; and (5) marinated in 5% acetic acid solution. It was found that degeneration of the metacercariae was slowed by cooling: complete degeneration of metacercariae required approximately 10 h in the refrigerated or frozen fish, compared with only 4 h in fish left at room temperature or marinaded in saline or acetic acid solution.

Various physical and chemical factors have been studied to determine their effects on the viability of encysted metacercariae of *E. caproni*. Viability was determined by the ability of the metacercriae to excyst in an alkaline trypsin–bile salts medium. Of numerous marinades tested, vinegar was the most harmful to cysts. Concentrated solutions of NaCl and sucrose had no effect on the viability, suggesting that their use in food preparations would not be effective in killing echinostomatid cysts, especially those in freshwater snails.

The nature of echinostomiasis does not justify the establishment of a separate control program because it can be controlled along with other food-borne diseases for which there are World Health Organization control programs. The control of human echinostomiasis via blocking or interruption of the life cycle can be achieved through proper diagnosis, followed by pharmacologic treatment and prevention of reinfection. The control of echinostomiasis should be focused predominantly on a reduction or elimination of the transmission of the disease. In theory, the means of control in endemic regions can include: a reduction of the sources of infection, particularly humans, through effective treatment; the protection of fish ponds and aquaculture systems from contamination with feces from people and other definitive hosts; the treatment or sterilization of feces; the control of snail host populations; and the implementation of education campaigns. Because infection of the definitive host is only contracted through the ingestion of metaceracriae harbored by the second intermediate hosts, the most practical measure for preventing and controlling human infection is to eliminate the consumption of raw, undercooked, or freshly pickled fish and shrimp flesh and to instill the principle that only

adequate cooking will render such fish safe for human consumption. However, this strategy may be difficult to implement in some endemic regions because of the ancient tradition of eating raw fish. Nonetheless, together with education awareness programs focused particularly on teaching young children about the parasite, its life cycle, and the disease it causes, prevention and control could be successful.

Although a reduced number of cases in other trematode infections have been reported in endemic regions, the prevalence of echinostomiasis has not changed, probably in relation to the extensive zoonotic reservoir hosts of echinostomes. Reservoir hosts other than humans may play a major role in sustaining transmission of echinostomes. There are a wide range of potential definitive hosts in the life cycle of echinostomes, particularly wild and domestic animals and fish-eating birds. Recent studies have shown that domestic dogs, cats, pigs, ducks, and chickens may act as reservoir hosts of echinostomes and other food-borne trematode infections. The reservoir hosts can become contaminated with eggs in water bodies and infect snail intermediate hosts. Because of these conditions, the prevention of echinostome infections in domestic animals must be included in any public health strategy. This can be accomplished by measures such as educating farmers about the risks associated with feeding animals with snails or raw fish or placing the animal houses as far away as possible from water bodies. However, the most effective measure may be the inclusion of these potential reservoir hosts in drug-treatment programs aimed at their human owners. A praziquantel dose of 40 mg kg^{-1} has been shown to be effective for the treatment of dogs and cats. Information on the optimal doses to treat other reservoir hosts should be further evaluated, as only little information is available on this topic.

Fasciola hepatica and *Fasciola gigantica*

MB Rokni, Tehran University of Medical Sciences, Tehran, Iran

Glossary

Contamination The introduction or occurrence of a contaminant in the food or food environment.

Control measure Any action and activity that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level.

Food Any substance, whether processed, semi-processed, or raw, which is intended for human consumption, including drink, chewing gum, and any substance which has been used in the manufacture, preparation, or treatment of 'food'; it does not including cosmetics, tobacco, or substances used only as drugs. (In the context of this topic-level contribution, drinking water is food).

Foodborne disease Any disease of an infectious or toxin nature caused by or thought to be caused by consumption of food or water.

Food safety Assurance that food will not cause harm to the consumer when it is prepared or eaten according to its intended use.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to hazard(s) in food.

Background

Fascioliasis or fasciolosis is a disease caused by two trematode parasites of the genus *Fasciola*, *Fasciola hepatica* and *Fasciola gigantica*. The former is reported from throughout the world whereas the latter occurs mainly in tropical regions of Africa, South and East Asia, and the Middle East. Two different reports have estimated the rate of global human fasciolosis as 2.4–17 million, whereas the population at risk was estimated to be 180 million (World Health Organization (WHO), 1995). Human beings together with at least 46 other species of both domestic and wild mammals are reported to be suitable as final hosts, either naturally or experimentally, whereas the intermediate hosts are snails of the family Lymnaeidae.

The earliest mention of *Fasciola* goes back to 1379, when Jean de Brie in France reported the impact of sheep liver rot on sheep management and wool production. Later, in 1547, it was identified in the livers of sheep and goats. The first record of human fasciolosis is that of Pallas in 1760 in Berlin, in a female patient found to be infected on autopsy.

Fasciolosis as a foodborne disease has been included in the list provided by the Institute of Food Technologists' Expert Panel on Food Safety and Nutrition, and by the Parasitic Task Force of The Foodborne Disease Burden Epidemiological Expert Group (FERG) of the WHO. The FERG is an advisory group to the WHO initiative to estimate the global burden of foodborne diseases from enteric, parasitic, and chemical causes.

Characteristics

Classification

Fasciola hepatica and F. gigantica are parasitic flatworms of the phylum Platyhelminthes, class Trematoda, order Digenea, family Fascioloidae, and genus *Fasciola*.

Other members within the family include *Fasciola indica*, *Fasciolopsis buski*, and *Fascioloides magna*.

Morphology

The characteristic trait of the *F. hepatica* adult parasite is that approximately all its internal organs, i.e., reproductive systems besides the two-gut ceca, are branched, so that it is almost unfeasible to differentiate those organs through a microscope (Figure 1). The hermaphroditic adult is as large as 2–3 cm long, and encompasses the characteristics of an anterior cephalic cone, an oral sucker, a ventral sucker, and a covered tegument with tiny spines.

Eggs measuring 130–150 μm × 60–85 μm are all thin shelled, ellipsoid, and quinone colored (bile stained) with an inconspicuous operculum.

Differential Diagnosis Between *F. hepatica* and *F. gigantica*

Before setting up the new molecular diagnostic methods, the differentiation between the two species was mostly based on morphological characters. Normally, *F. gigantica* is longer (Figure 2). Some minor and major characteristics are

 doi:10.1016/B978-0-12-378612-8.00154-2

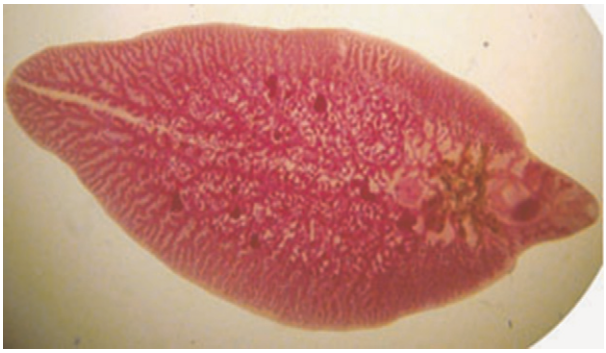

Figure 1 Adult of *Fasciola hepatica*.

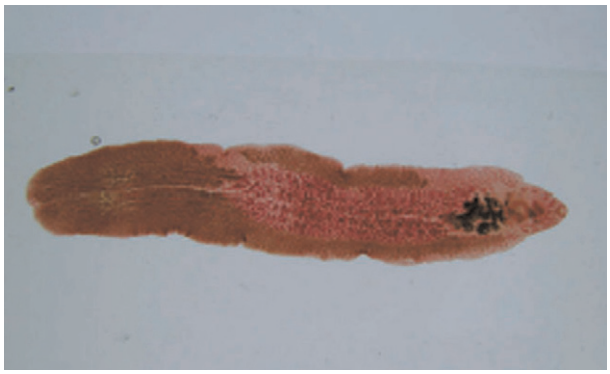

Figure 2 Adult of *Fasciola gigantica*.

Table 1 Comparative morphologic characteristics of *F. hepatica* and *F. gigantica*

Topic	*F. hepatica*	*F. gigantica*
Length	2–3 cm × 1.5 cm	2.5–7.5 cm × 1.2 cm
Cephalic cone	Pronounced	Shorter
Eggs	130–150 μm × 60–85 μm	Larger (160–190 × 70–90 μm)
Testes	–	More anterior
Ventral sucker	–	Larger

elucidated in Table 1. However, frequent variations in these morphological features often cause difficulties for accurate differentiation. In addition, abnormal diploidy, triploidy, and mixploid parthenogenesis as well as hybridization between different genotypes of *Fasciola* give rise to different forms of this genus. In some countries such as Japan, it is often impossible to morphologically differentiate between the two species; in many endemic countries, apparent intermediate forms have been reported.

To overcome these hybridization effects, molecular DNA-based approaches such as PCR-restriction fragment length polymorphism (RFLP) and Randomly amplified polymorphic DNA (RAPD)-derived sequences have been investigated to distinguish between these species. ITS1 and ITS2 sequences from rDNA provide reliable genetic markers for identification. Eventually, the new molecular methods described as reliable, fast, and straightforward devices for differentiating between *F. hepatica* and *F. gigantica*, seem to be acceptable for differential diagnosis. These methods are especially apposite for screening a large number of *Fasciola* isolates.

Life Cycle

Fasciola hepatica is a hermaphrodite and auto-fertilization is achievable, although cross-fertilization between two adult flukes is the most common form of sexual reproduction. *Fasciola hepatica* has two stages of growing in its life cycle: the sexual stage in its adult form and the asexual in the larval or intermediate stages (Figure 3). The normal habitat of the parasite is biliary ducts and gall bladder of the definite host. In these locations, the mature parasite releases its eggs, which escape the host's body via the feces. The undifferentiated ovum in the egg, after spending 9–15 days in the water, develops into miracidium which hatches out of the egg and searches for a snail intermediate host from the family of Lymnaeidae, including species of the *Galba*/*Fossaria* group for *F. hepatica* and species of *Radix* for *F. gigantica*. The life expectancy of miracidium is approximately 8 h, during which time it must find a suitable snail. It then goes through several development stages in the snail (i.e., sporocyst followed by redia), which include considerable asexual multiplication. In the final stage, tailed cercariae, measuring 200–300 μm, emerge from the snail and swim through the water until they locate suitable vegetation on which they encyst, becoming metacercariae.

A single miracidium can produce from 10 to 700 metacercariae. The metacercariae are ingested by the definite host through eating (or sometimes drinking water with floating metacercariae). In the duodenum, the metacercariae unencyst, releasing the juvenile stage, which burrow through the gut mucosa and migrate to the liver parenchyma. After 3–4 months, the juvenile flukes reach the deep-seated bile ducts where they mature sexually and initiate egg production. The adults lay, on average, between 8000 and 25 000 eggs per day.

Survival

Fasciola may live from 9 to 12 months in cattle, 11 years in sheep, and from 9 to 13 years in humans. *F. hepatica* eggs and metacercariae may remain alive for long periods under low temperatures, but they are susceptible to heat and drought. The longevity of metacercariae in the environment varies from 122 days in running water to 95 days in stagnant water. Under optimal conditions, metacercariae may remain viable for as long as 1 year on pasture and can even live for a few months on dry hay.

Diagnosis

Routine methods of stool examination normally are not capable to detect the parasite's eggs and methods such as the Kato-Katz technique, although efficient, are not normally conducted as a routine test particularly in developing countries. It is a specific but not sensitive diagnostic test, and has

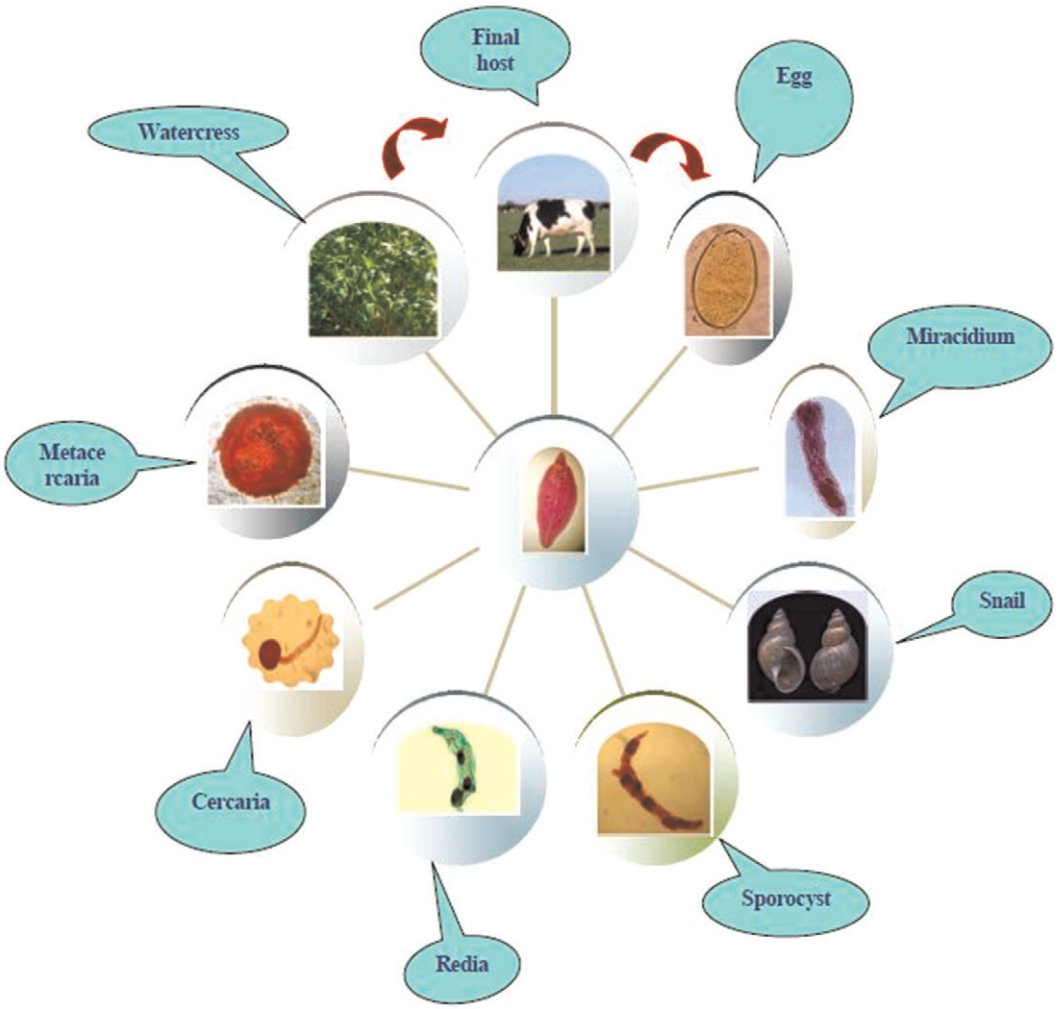

Figure 3 Life cycle of *Fasciola* spp.

been shown to underestimate by 30% the prevalence obtained by Fas2-enzyme-linked immunosorbent assay (Fas2-ELISA). Now, the method of choice is ELISA using excretory–secretory antigens.

Clinical Manifestation

Fasciolosis embraces two important phases in final host: immigrating and residing, or acute and chronic phases. The first phase, which lasts 1–3 months after ingestion of metacercariae, has symptoms including epigastric pain, fatigue, fever, right quadrant abdominal pain, indigestion, weight loss, and malaise. Extrahepatic abnormalities, such as pulmonary infiltrates, pleuropericarditis, meningitis, and lymphadenopathy, are also possible.

After establishment, a variety of signs and symptoms depending on the burden of the disease may be seen comprising hepatomegaly, obstructive jaundice due to biliary obstruction, cholecystitis, cholelithiasis, fibrosis, cirrhosis, liver abscesses, hyperplasia of the ductal epithelium, and subcapsular hemorrhages. Anemia, of normocytic normochromic nature, is likely. The presence of small multiple intrahepatic stones along with cholangitis and cholelithiasis constitute the features of the human chronic phase.

Although the routine habitat of *Fasciola* is the biliary ducts, at times the parasite lodges in abnormal spots of the body, due to deviation of the normal route for unknown reasons. The phenomenon is called ectopic fasciolosis. Almost all parts of the body have been reported as having ectopic fasciolosis, including gastrointestinal tract, subcutaneous tissue, heart, blood vessels, the lung and pleural cavity, brain, orbit, abdominal wall, appendix, pancreas, spleen, inguinal nodes, cervical nodes, skeletal muscle, and epididymis. The usual pathological effects of ectopic lesions are due to the migratory tracks causing tissue damage with inflammation and fibrosis. The prevalence of fasciolosis in Lima, Peru, where the disease is endemic, in these patients with established cirrhosis, was reported as 9.1%. This shows the necessity for more attention in patients with cirrhosis, due to the greater possibility of fasciolosis in these patients with cirrhosis in endemic countries. In endemic areas, due to gradual resistance of the body, half of the chronically infected patients might be asymptomatic or have few complications.

Considering mortality, appraisal literature shows very little documentation. These scanty reports were based on autopsy observations. Thus, nobody could be sure of fasciolosis as the sole cause of the death.

Epidemiology

Geographic Distribution

A typical hyperendemic area of fasciolosis is the Altiplano region of Northern Bolivia. Infection is highest in children and females, and prevalence can exceed 40% in certain communities. In Africa, the Nile Delta region between Cairo and Alexandria has also been reported as another hyperendemic area. In Europe, human fluke infections occur more sporadically. However, significant and recurrent outbreaks of fasciolosis occur in France, Portugal, and Spain. In Iran there have been two important outbreaks, each of which reported up to 10 000 infections in northern parts of the country. In the USA, sporadic cases have been reported but mostly of imported nature through immigrants and tourists.

Although most of the cases of fasciolosis have been ascribed to *F. hepatica*, the exact differentiation between the two species has only been recorded recently; therefore, in time the relative importance of the two species may change. However, there is evidence of a rise in the number of human cases of fasciolosis of *gigantica* origin in Vietnam. The possibility of more cases in some Southeast Asian countries has also arisen. In some countries of Africa and in Hawaii, where only *F. gigantica* occurs, fasciolosis cases can be attributed to this parasite. Apparently, humans are less sensitive to *F. gigantica*, and ectopic cases due to *F. gigantica* are more prevalent compared with *F. hepatica*. Cases of overlap between two species have been demonstrated in some endemic countries such as Egypt and Iran, and hybrids exist in eastern Asia and perhaps elsewhere.

Demographic Factors

Review of literature shows that Bolivia, Peru, France, Russia, Turkey, and Vietnam encompass a similar pattern of showing no significant difference in terms of the patients' sex, whereas in Chile, Spain, Egypt, and Iran, females are infected more than males. A wide age range among patients with fasciolosis is seen in Chile, France, Russia, Turkey, Egypt, and Vietnam; in contrast, in Bolivia, most patients are less than 20 years of age, and in Iran mostly adults are infected.

Epidemiological Classification Concepts

A new epidemiological classification for human fascioliasis has been proposed as follows: imported cases; autochthonous; endemic; and epidemic (Table 2).

Human Risk Factors

Some observations show that it is not necessary to presume a direct relation between the high rates of fasciolosis in humans and similar situation in animals in a given area. For example, in Kermanshah Province, western Iran, there is a high prevalence of fasciolosis in animals, whereas normally there are no reports of human cases, with the exception of a small outbreak (13 cases). It would seem that the factor of culture plays an important role in this regard.

Foodborne Transmission

Plants

The main source of infection is ingestion of metacercariae encysted on water plants such as watercress (*Nasturtium officinale*). Raw watercress in many countries is eaten as salad or in other dishes such as appetizers. However, other cultivated, freshwater plants are also reported as sources. Metacercariae were found in 1% of lettuce sold at a local market in the

Table 2 Proposed new epidemiological classification for human fascioliasis

Class		*Definition*
Imported cases		Human cases diagnosed in a zone lacking *Fasciola* spp.
Autochthonous		Humans who have acquired the infection in the area where they live and where animal fascioliasis is also present
Endemic (three types based on the prevalence)	Hypoendemic	Prevalence less than 1%; arithmetic mean intensity less than 50 epg
	Mesoendemic	Prevalence 1 ± 10%; 5- to 15-year-olds may present higher prevalences; arithmetic mean intensity in human communities usually 50 ± 300 epg
	Hyperendemic	Prevalence more than 10%; 5- to 15-year-old children usually present higher prevalences; arithmetic mean intensity in human communities usually more than 300 epg
Epidemic		A. Epidemics in areas where fascioliasis is endemic in animals but not humans B. Epidemics in human endemic areas: outbreaks in zones where the disease is endemic in humans

Source: Mas-Coma S, Esteban JG, and Bargues MD (1999) Epidemiology of human fascioliasis: A review and proposed new classification. *Bulletin of the World Health Organization* 77: 340–346.

Mantero valley, Peru. In Cuba, all cases of fasciolosis have been associated with consumption of watercress and lettuce. In France, *Taraxacum dens leonis* (dandelion leaves), *Valerianella olitora* (lamb's lettuce), and *Mentha viridis* (spearmint) are implicated. In Iran, *Nasturtium* spp. and *Mentha* spp. are important sources. In the Bolivian Altiplano, *Juncus andicola* (Juncaceae), *Juncus ebracteatus* (Juncaceae), *Mimulus glabratus* (Scrophulariaceae), and *Nostoc* sp. (Cianofitas) have all been reported as sources.

In Limousin, France, snails infected with *F. hepatica* were found in 14 watercress beds. Five percent of examined vegetables in Iran were contaminated with *Fasciola* eggs. *F. hepatica* eggs were isolated from irrigation water sources 2–5 egg l^{-1} in Ghana. Moreover, vegetables irrigated with water had 2–4 eggs 100 g^{-1} wet weight contamination.

Two of the most important sources of fasciolosis in endemic regions of Iran, i.e., the northern parts, are green salt (local name: *dalar*) and elaborated olive (local name: *zeitoon parvardeh*) (**Figure 4(a)** and **(b)**). Green salt is made from a mixture of ground aquatic plants such as *Mentha pulegium* (local name: khlivash) as well as *Mentha piperita* (bineh) and 30–40% salt. The final pH is 5. It is usually eaten with cucumber, prunes, yogurt, etc. *Zeitoone parvardeh*, an appetizer, is a mixture of stone-free olive, ground aquatic plants, mostly *Eryngium coucasicum* (local name: *choochagh*), walnuts, various spices, garlic, and sour-pomegranate juice. Regarding *zeitoon parvardeh* and *dalar*, 66.6% and 57.8% of the metacercariae, respectively, can be alive for 2 weeks after the preparation of the food.

Water

Normally *Fasciola* spp. use water plants as a matrix on to which they affix their metacercariae, but sometimes they release the metacercariae into water, hence contaminated water can be another source of infection. In some endemic areas, drinking contaminated water has been reported as the main source of infection. For example, in the Americas and Peruvian Altiplano, watercress is not normally consumed as in other nations. However, in the Bolivian Altiplano, 13% of the metacercariae of *Fasciola* isolates were floating on the water.

Beverages

In some parts of the world, people drink beverages made of local plants, for example, stalks of cane in Pakistan, roots of carrot in Iran, and alfalfa and watercress in Peru, and elsewhere. These plants have a high possibility of contamination with metacercaria due to the irrigation by contaminated water.

In Peru, people infected with fasciolosis mentioned a history of consuming watercress (45.6%), lettuce (31.6%), alfalfa (10.5%), spinach (5.3%), and drinking water from *puquiales* (10.5%) or emolientes (the warm beverages made from various plants, chiefly alfalfa and watercress) (5.3%).

(a) (b)

Figure 4 Two traditional dishes made from local aqua plants in endemic parts of fasciolosis in Iran: (a) elaborated olive (local name: *zeitoon parvardeh*); (b) green salt (local name: *dalar*).

Kitchen Utensils

Another source is kitchen utensils, which may be washed by contaminated water and used for preparing food.

Raw Liver

Raw liver as a potential source of infection of has recently come to light. It is generally considered that eating liver contaminated with *Fasciola* results only in transitory infection, whereby a lot of *Fasciola* eggs are released in the stool but the consumer is not infected and only acts as an egg passer. However, some researchers believe that eating raw fresh liver contaminated with *Fasciola* may establish the real infection. In fact, animal-based studies have demonstrated that consuming fresh raw liver infected with immature forms of *Fasciola* might cause fasciolosis. Definitely, this subject needs more clarification.

Analytical Methods

Verification of Metacercarial Viability and Infectivity

Metacercarial viability can be assessed by checking the refractile appearance of secretory granules through microscopy and the movements of juveniles within cysts. Metacercariae are inserted on a glass slide covered by a coverslip and examined under a light microscope. It can be verified by *in vitro* excystation capability of metacercariae as well.

Infectivity of metacercariae is measurable through animal infection assays. However, the mouse is not a suitable host for *F. gigantica*; instead, hamster and rabbit are considered appropriate.

Control and Preventive Measures

The life cycle of *Fasciola* contains three important key elements including the final host, the intermediate host, and the water plants. A successful preventive strategic planning must embrace all these factors.

Public Health Education

As other parasitoses, public health education should be placed in the front. People should learn how to wash vegetables so that the metacercariae can be separated from the surface of the plants. In many fasciolosis endemic areas, domestic animals, especially cows, roam freely and launch the start point of parasite life cycle, i.e., releasing parasite's eggs. In endemic parts of Iran, cows leave their owner's house for 3–4 months and return after spreading many parasite's eggs. Making people familiar with the hazard of watercress, the different ways

metacercariae are transferred, and modifying the processes of making certain domestic dishes, instead of halting the consumption, are some other possible strategies.

Control of Environmental Factors

Horizontal and downflow roughing filters could remove *Fasciola* eggs from drinking water and are advised for water and secondary effluent treatment. Another scheme, as a forecast model to strategic control of fasciolosis, is geographic information system (GIS). In Ethiopia, this model was created and managed based on moisture and thermal regime and the results were labeled as promising. It was shown that thermal and soil moisture regimes were particularly important in determining the patterns of seasonal infection in a region due to its adverse effects on intra-molluscan larval development, extra-lymneaid phases, and activity of the snail vectors. Regarding mapping and prediction devises, a model called the normalized difference vegetation index (NDVI) has been used in northern Bolivian Altiplano and has been branded as an advantageous data component in monitoring the fasciolosis control and management.

Control of the Intermediate Host

The snail, which is the intermediate host, is amphibious; hence using molluscicides is futile. Besides, the distribution of the snail is such that it is worthless to use this method. The snail is widespread throughout the affected regions, even in small holes filled with water, so there is the risk of hampering the ecology of these areas. Nevetheless, this method has been used mostly to target more than one parasite simultaneously.

Chemotherapy

Although many trials have not been able to establish a successful vaccine against fasciolosis, chemotherapy has remained the mainstay of treatment and a plan for the control of the disease. Chemotherapy of animal populations has been used effectively in many countries so far.

Vaccination

To date, there are no successful or commercial vaccines against fasciolosis. There are some reports of immunization of mice, rats, sheep, and some other animals against fasciolosis, but not in humans. Some antigens of *Fasciola* including leucine aminopeptidase, fatty acid-binding protein, glutathione S-transferase, and cysteine protease have been challenged with protection rates of 65–89.6%. Further, an Australian group has used a multivalent vaccine derived from E/S antigens to generate immune responses in the rat fascioliasis model.

Economic Damage

The economic losses due to fasciolosis are estimated at US $2000–3000 million annually, and to the livestock industry at more than US $3 billion per annum.

The most important economic effect of fasciolosis in terms of nutritional cycle is the daily demolition of infected livers as well as lost productivity, such as reduction of milk and meat yield.

HELMINTH-TREMATODE

Fasciolopsis buski

S Mas-Coma, Universidad de Valencia, Valencia, Spain

Glossary

Cercaria Fourth larval stage of a digenean trematode, which, owing to its tail, swims out from the snail in search for a support (e.g., a freshwater plant) or a second intermediate host to produce a metacercaria.
Cirrus pouch Thick-walled bursa present in the terminal part of the male genital apparatus of a fluke, which contains an internal seminal vesicle, pars prostatica, and prostate glands, and a usually evaginable male copulative organ called a cirrus.
Daugther redia Second generation of the third larval stage of a digenean trematode, which develops inside the intermediate snail host and produces cercariae.
Gymnocephalous cercaria Morphological type of digenean cercaria characterized by a body presenting two suckers and a long, simple, swimming tail.
Metacercaria Usually encysted fifth larval stage of a digenean trematode which attaches to a support (e.g., a freshwater plant) or inside a second intermediate host, to await the occasion to infect the definitive host by ingestion.
Miracidium First larval stage of a digenean trematode, which develops inside the egg, escapes by opening the operculum of the egg, and swims to infect the first intermediate snail host or vector host.
Mother redia First generation of the third larval stage of a digenean trematode, which develops inside the intermediate snail host and produces daugther rediae.
Planorbid Snail belonging to the family Planorbidae, a group of freshwater, mostly discoidal, snails within the molluscan class Gastropoda, which is of great medical and veterinary importance due to the parasitic diseases of humans and animals they transmit.
Sporocyst Second larval stage of a digenean trematode, which develops inside the intermediate snail host and produces rediae.
Vitelline glands Glandular follicles distributed into two bilateral fields in fluke adults and which secrete egg precursors.

Etiology: The Parasite

Fasciolopsis buski is the only species included in the genus *Fasciolopsis*. It is a trematode parasite commonly known as the giant Asian intestinal fluke, due to its large size, its geographical distribution restricted to Asia, and its location within the host's body confined to the intestine. Together with *Fasciola gigantica*, it is the largest of the digeneans to infect humans.

Fasciolopsis buski is usually elongated, oval in shape, without a cephalic cone. Its size varies depending on the host species, and is between 2 and 10 cm in length and 0.8 and 3 cm in width. The oral sucker is subterminal, small and approximately one-fourth the size of the ventral sucker, which is situated not far behind the former. An oval pharynx is present and the short esophagus leads to the caeca which are unbranched and terminate near the posterior end of the body. The two testes are highly branched, tandem, and situated in the posterior half of the body. The branched ovary is pretesticular situated in the middle of the body slightly to the right of the midline. A large cirrus pouch is present and opens at a genital pore immediately anterior to the acetabulum. The vitelline glands are numerous and small-sized, and extend from the level of the ventral sucker along the two lateral fields up to the posterior end of the body, where bilateral glands join together (Figure 1).

The eggs are ellipsoidal, rounded at both ends, yellow and unembryonated, and have a clear thin shell with a delicate operculum at one end (mean diameter of operculum 27 μm). The eggs measure 120–140/70–90 μm (mean 138/82 μm) (Figure 2).

Parasite Biology and Life Cycle

The giant Asian intestinal fluke is a parasite which, in humans, inhabits the duodenum and jejunum in light infections, either attached by their suckers to the mucosal epithelium or buried in the mucous secretions, and can also be found in much of the intestinal tract, including the stomach, in moderate and heavy infections.

In most endemic areas, pigs appear to be the only animal reservoir of any significance. Interestingly, pigs generally harbor fewer adult worms and egg production per worm is lower than in human beings. The pig has also proved to be a good experimental model.

 doi:10.1016/B978-0-12-378612-8.00155-4

Figure 1 Adult stage of *Fasciolopsis buski*, in ventral view. Note the unbranched bilaterally descending caeca, two pronouncedly branched testes in longitudinal tandem, slightly dextral branched ovary, and numerous brown eggs between ovary and large ventral sucker or acetabulum.

This parasite shows susceptibility differences in experimental tests when using different animal species: worms remain immature in dogs; both immature and mature worms were recovered from rabbits; immature flukes were recovered from young buffalo; mice, rats, monkeys, and dogs were completely refractory; and guinea-pigs were only partially susceptible. However, young rabbits (6–8 weeks old) were found to be susceptible and can be used as an animal model for experimental work. The parasite may establish temporarily in rabbits or the squirrel monkey *Saimiri sciureus petrinus*. It has been very rarely reported in the rhesus monkey of the species *Macaca mulatta*, but there is no report incriminating monkeys in endemic areas. It is worth mentioning that field studies showed no infection in cows, buffaloes, dogs, and horses where pigs were harboring the parasite.

The development of this trematode species follows a two-host life cycle, including a freshwater gastropod snail as intermediate or vector host and humans or pigs as definitive host (Figure 3). The adult stage of *F. buski* produces a large number of eggs in humans, counts showing between 13 000 and 26 000 (mean 16 000) per worm per day. Eggs are undeveloped when they leave the host with the feces and must reach freshwater to continue the cycle. The miracidium development period is 16–77 days, with a mean of 22 days, the optimum conditions being a water temperature of 27–30 °C and 6.5–7.2 as the pH range.

Intermediate hosts are limited to small planorbid snails (Figure 4) of the species *Segmentina hemisphaerula* (syn. *S. coenosus*, *S. nitidella*, *S. calathus*, *S. largillierti*), *Hippeutis cantori* (syn. *H. smackeri*), *H. umbilicalis*, and *Gyraulus convexiusculus* in China, Vietnam, and Thailand. In India (Assam), the snail host includes *S. trochoideus*, *S. hemisphaerula*, and probably also *H. umbilicalis*. In Thailand, the species *S. hemisphaerula*, *S. trochoideus*, and *G. chinensis* appear to be involved in transmission, whereas in Thailand it is *S. hemisphaerula*, in Laos *H. umbilicalis*, and in Bangladesh *S. trochoideus* and *H. umbilicalis*. The species *Indoplanorbis exustus* has also been recently involved in India.

Segmentina hemisphaerula and *H. cantori* live in similar habitats. The first one is extremely sensitive to dessication, the survival limit of snails kept out of water at 25 °C and 50% humidity being 25 h. Exposure of 2 h to real drying usually kills them, but they are able to live for some time in slightly moist mud.

The prevalence of infection in snails is usually very low (less than 2%), although local monthly prevalences of up to 20% have been found. Snail prevalence appears related to the distance of the snail habitat from a *F. buski* source: when the distance was 25 m, 26% of snails were infected, at 100 m it was 8%, and at 300 m only 6%.

The larval stages of sporocyst, mother and daughter rediae and cercariae develop in the intermediate snail host. Sporocysts are elliptical, and of 131–169/34–83 mm in size. Mother rediae develop rapidly inside the sporocyst, already emerging in days 9–10 after miracidium penetration into the snail. Mother rediae migrate to the ovotestis and are 701/159 μm in size. Daughter rediae may be up to 2.8 mm when mature and harbor up to 45 cercariae at one time. Gymnocephalous cercariae include a body of 195/145 μm and a tail of 498/57 μm, for a total length of the cercaria of 693 μm. Cercariae leave the rediae after 25–30 days but emerge from the snail after an average of 49 days, because they require a maturation period in the snail tissues. Other incubation periods recorded are 46–59 days at 22–24 °C, and 85–100 days at 18–22 °C, and beginning at 31 days after exposure to the miracidia. A very short prepatent period of only 21 days has been found in *S. trochoideus* and *H. umbilicalis*, in which *F. buski* causes mortality in 100% of the snails because of mechanical damage to the ovotestis.

Cercarial emergence from the snails is remarkably dependent on light. The large sized cercariae appear to be strongly phototactic, and a great variation was noticed in the daily emergence patterns of cercariae. Cercariae swim in water until metacercarial encystment on a substrate, mainly aquatic plants and debris but also on the water surface. The survival time of metacercariae in water varies from 64 to 72 days.

Food-Borne Transmission

Infection of the definitive host takes place by ingestion of plants carrying metacercariae. There is little selective

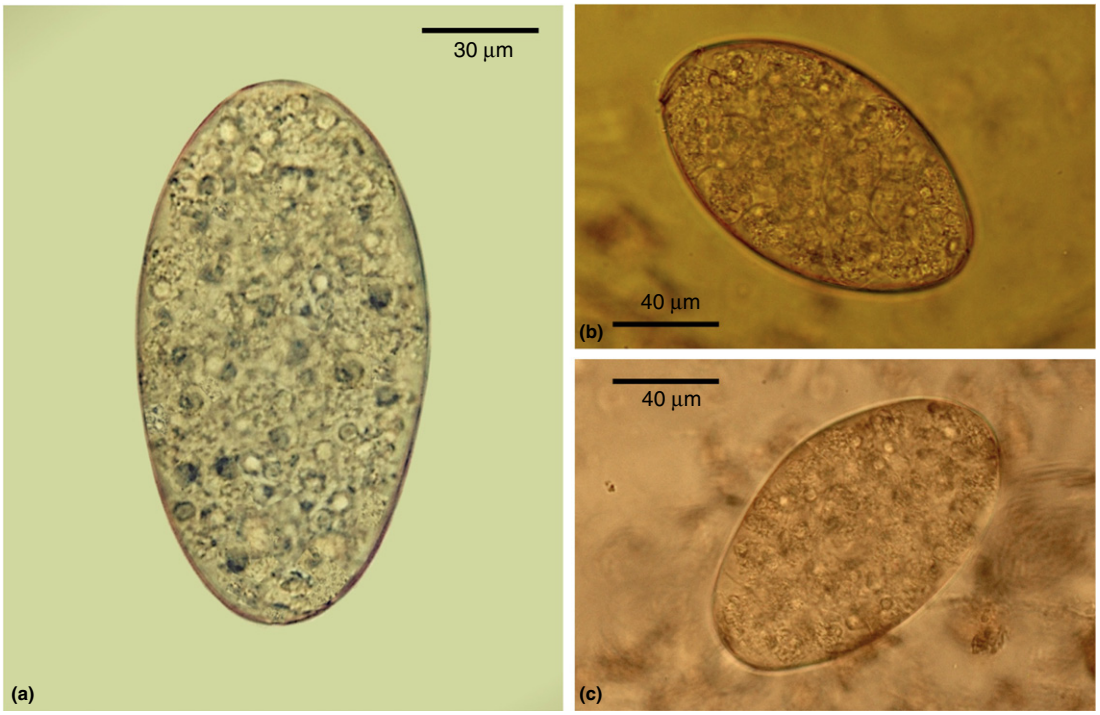

Figure 2 Eggs of *Fasciolopsis buski*: (a) egg isolated from the last part of the uterus showing typical aspect, thin shell, hardly visible operculum on top, refrangible brown-greenish granules equally distributed inside, and without irregular protuberance at abopercular end; (b) and (c) two eggs found in stool sample of Chinese patient (note small operculum microscopically focused in (b)).

specificity, metacercarial cysts attaching to all sorts of aquatic vegetation in stagnant ponds.

Of interest from the food point of view, there are various consumable water plants, among which are water caltrop (*Trapa natans* in China, *T. bispinosa* in Taiwan, and *T. bicornis* in Bangladesh and Thailand), water chestnut (*Eliocharis tuberosa*), water hyacinth (*Eichhornia* sp.), water bamboo (*Zizania* sp.), water lotus (*Nymphaea lotus*), water lily (*Nymphaea* sp.), watercress, gankola (*Otelia* sp.), and water morning glory or water spinach (*Ipomoea aquatica*) (**Figures 5** and **6**).

Encysted metacercariae exist not only on aquatic plants, but also on the surface of the water. This opens the probability of human and pig infection by drinking natural water. The proportion of the encysted metacercariae floating on the water surface is approximately 3.6% of that of the total encysted metacercariae. By inquiring into case histories, it has been found that 10.3–12.8% of patients and 35.1–40% of infested pigs are possibly infected by drinking water contaminated with encysted metacercariae.

Once ingested together with plants or drinking water, the metacercariae excyst in the duodenum and attach to the intestine wall to grow into sexually mature flukes in approximately 3 months.

Geographical Distribution

Human infection by *F. buski* has been reported in central and south China, Hong Kong, Taiwan, Bangladesh, India, Vietnam, Laos, Cambodia, Thailand, Kampuchea, Singapore, Burma, Malaysia, the Philippines, and Indonesia (**Figure 7**).

A summarized overview of the characteristics of fasciolopsiasis in China, Taiwan, Bangladesh, India, Vietnam, Laos, Cambodia, Indonesia, and Thailand is given in **Table 1**. In Vietnam, a curious case of a two and a half-year-old boy who vomited eight live *F. buski* adults has very recently been described from Vinh City, Nghe An Province.

Reports on Korean and Japanese subjects do not seem to be confined to their respective countries. Reports in the USA, Venezuela, Australia, Guatemala, Israel, and Cuba may be due to immigrants from the Far East or to misidentification of the eggs in feces.

Epidemiology

An estimated 10 million people infected by *F. buski* at the beginning of the twenty-first century is the figure now being quoted. Field studies suggest that the disease is underreported in the endemic areas, and is most prevalent in remote rural places and semiurban areas. Prevalences found in the endemic areas of different countries in both humans and pigs in studies and surveys performed during different periods are noted in **Table 1**.

Infection by *F. buski* is most prevalent in school-age children, where the number of worms per child can exceed 800. The highest infection rates were found in children in the age group 10–14 in Taiwan Hsien, southern Taiwan, some time ago. Within foci of parasite transmission, the prevalence of infection in children ranged from 57% in mainland China to 25% in Taiwan, and from 60% in India and 50% in Bangladesh to 10% in Thailand.

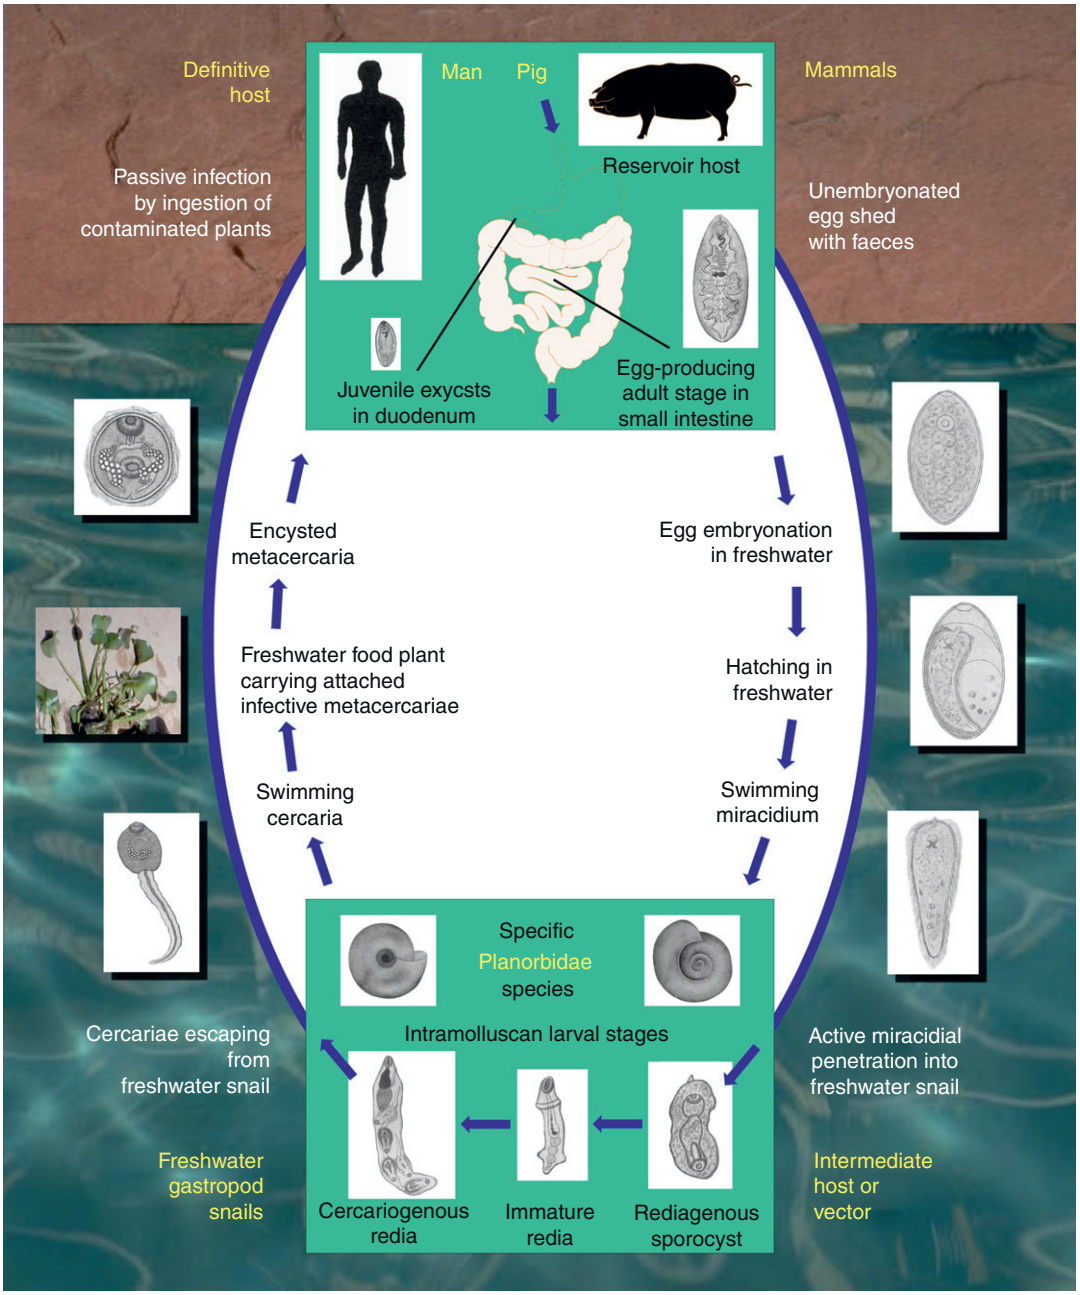

Figure 3 Two-host life cycle and transmission of *Fasciolopsis buski*. Note complete larval development and transmission by snail vector occurring completely in freshwater; only the adult stage develops in a terrestrial mammal (humans and pigs).

A higher prevalence among females (122 or 16%) than males (86 or 11%) was detected in a coprological survey of 1563 people (784 males and 779 females) in the endemic area of Thailand. The prevalence varied from 8% among adults (15 years and over) to 15% in children between 5–14 years old, with an average for all the age groups of 13%. Both in males and females, the severity of infection peaked between 10–14 years of age and decreased in older groups. The difference in prevalence and intensity is related to the activity of the various age groups. The school-age group, i.e., 5–14-year-olds, usually pick up and eat water caltrop on their way to and from school. In the older group, i.e., 15 years and over, the individuals usually do not pick up water caltrop as it would be considered stealing, but they contract the infection when they are engaged in the cultivation, harvesting, and selling of water caltrop.

Another survey in Thailand also found significantly more females than males were infected, the highest prevalence being among the 10- to 20-year age groups. A higher prevalence in females than in males after the age of 7 was also found in Bangladesh.

In endemic areas, the disease occurs focally, is wide-spread, and is linked to freshwater habitats with stagnant or slow-moving waters, is associated both with common social and agricultural practices, and with promiscuous defecation.

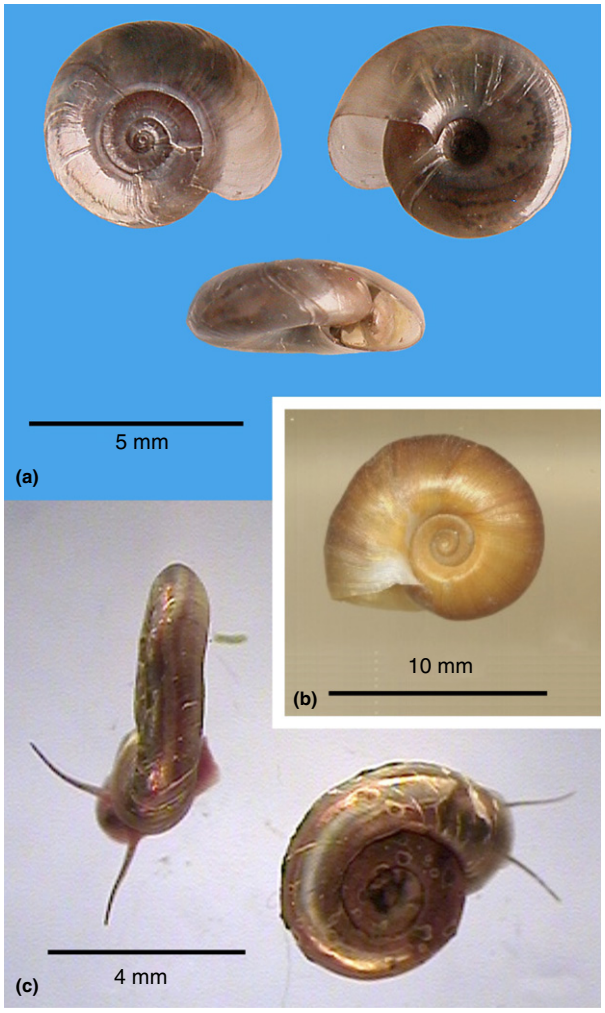

Figure 4 Small freshwater planorbid snail, vector species of *Fasciolopsis buski*: (a) shells of *Segmentina hemisphaerula* (furnished by H. Madsen); (b) shell of *Indoplanorbis exustus* (by M. Kohl); (c) living specimens of *Gyraulus chinensis*.

According to studies in pigs, it appears to follow a seasonal pattern. There is a peak between June and September and cases decline thereafter to a low level during winter and early spring (November–March), being absent during January and February, at least in a humid subtropic hilly city of north-east India where rearing of pigs is a common household practice.

Unnoticed ingestion of metacercarial cysts is the way by which humans and pigs contract the infection. This occurs through the eating of raw or undercooked aquatic plants, drinking or using raw water, and handling or processing water-derived plants, i.e., peeling plants using one's teeth. Infection takes place when peeling off the hull or skin of infected plants between the teeth because cysts are thus freed and are swallowed. Water caltrop is found in the wild, but, together with other plants, it is cultivated for its nuts in basins of stagnant water or in irrigation channels, which also harbor aquatic snails, among them the susceptible intermediate hosts. Cultivation of aquatic, metacercariae-carrying plants for consumption on a large scale and the pollution of the areas in which they are grown with human and animal (mainly pig) excreta are important epidemiological factors in the spread of the disease. The feces of infected pigs and the "night soil" (human excrement collected from latrines) used to fertilize fish ponds and to feed fish enhance the transmission of this parasite.

In Thailand, in the area of the Bang Kun Sri, the prevalence of *F. buski* infection among people living in the immediate vicinity of water caltrop plantations was much higher than in the villages a few hundred yards from plantations. Patterns were detected in children in Taiwan. Given that *F. buski* metacercariae do not withstand drying, plants have to be consumed shortly after they are harvested to cause infection. However, the common habit of dipping water caltrops in water from time to time to retain their freshness could help in the spread of the infection from areas near to where the plants are cultivated to areas where these plants are not grown.

In several countries where *F. buski* is endemic, pollution of the water apparently occurs through the use of human excreta as fertilizer. In Thailand, however, contamination of the fields in which water caltrop and water morning glory are cultivated takes place in areas where there is little or no dry ground and where the people defecate directly into the standing water beneath the houses. During the rainy season (June–October), water plants grow in abundance along the edges of rice fields and waterways throughout the central portion of the country. However, most of the edible plants are cultivated near the houses, that is, where pollution takes place.

In many oriental countries, human *F. buski* infection is aggravated by social and economic factors, such as poverty, malnutrition, and an explosively growing free-food market associated with a lack of food inspection, poor sanitation, other helminthiasis, and declining economic conditions. The differences in incidence in the same area are due to several factors, including economic status, educational background, standard of health, and mode of living.

The only effective reservoir is the pig (**Figure 8**). Under natural conditions, only 3–12 flukes are usually found in the pig. Water plants may serve as the main source of food for this animal. Fresh aquatic green fodder and raw water used to raise pigs are the main sources of *F. buski* metacercarial cysts infecting farm animals. Different pig infection rates have been reported in different areas: 30% in Uttar Pradesh, India; 10% in Kwangtung, China; and 52% in Taiwan Hsien, Taiwan. Interestingly, however, the expected correlation between human and pig prevalences is not always found, so there is still and disagreement as to whether there is only one strain of *F. buski*, or whether more than one local strain exists, with one being better adapted to man and another to animals. This would help to explain how infections among humans and pigs can show completely different epidemiological patterns, in certain areas e.g., (1) there are places in which the parasite is common in humans but absent in pigs, such as around Bombay, (2) there are areas where infection rates among humans and pigs are almost equal, and (3) there are other places with relatively important prevalences in pigs but very rare or even no infection in humans, as in Tonkin area, Vietnam. In Tonkin, the situation may be explained by the fact that inhabitants always cook aquatic plants (mainly water caltrop and water chestnut) and their fruits (the source of infection with the metacercariae) before they are eaten, whereas these plants, often carrying

(a) (b)

Figure 5 Freshwater food plants carrying metacercariae of *Fasciolopsis buski* attached to stems and leaves and thus participating in human infection by ingestion: (a) water caltrop *Trapa natans*; (b) water morning glory or water spinach *Ipomoea aquatica*.

Figure 6 In search of small freshwater planorbid snail vector species of *Fasciolopsis buski* in the water lotus *Nymphae lotus* taken out of a water pond.

infective metacercariae, are used for feeding pigs and other animals, resulting in the infection of pigs. Thus, different factors related to traditions, diet, and customs may go some way to explaining these local differences. Nevertheless, the controversy is still there, and recent studies having again referred to morphological and microtopographical strain variations among *F. buski* originating from different geographical areas.

Present Emergence Risk

Climate and global changes appear to increasingly affect the snail-borne helminthiases, which are pronouncedly dependent on the environment. This has been linked to the emergence of many trematodiases in different regions detected in recent years.

Fasciolopsiasis is a trematodiasis which shares many transmission characteristics (two-host life cycle, similar larval development pattern, freshwater snail vector, zoonosis, plant-borne infection) with fascioliasis, the best example of an emerging–re-emerging parasitic disease in many countries as a consequence of many phenomena related to climate change. However, the reservoir restriction to only the pig, in contrast to the low specificity of *Fasciola*, which is able to develop inside many different livestock species, suggests that the climate change influences on *F. buski* transmission increases (or decreases) may be somewhat buffered and thus perhaps less pronounced (or need more time to become obvious) when compared to fascioliasis.

In fasciolopsiasis, the life-cycle phases which develop in water are extremely susceptible to climate. Temperature and water-related climate variables greatly influence the embryonation of eggs in freshwater. The small planorbid snail vectors involved are extremely sensitive to dessication. Moreover, the parasite larval development within the snail vector is markedly dependent on abiotic factors such as temperature. Additionally, cercarial emergence is dependent on light.

The disease occurs focally, is wide-spread and is linked to freshwater habitats with stagnant or slow moving waters. It is therefore susceptible to climatic changes in precipitation rates as well as rainfall and extreme events such as floods and drought which may modify freshwater bodies and water velocity.

The disease appears moreover to follow a seasonality. A local climate change implying a modification of the current seasonality, by enlarging the yearly transmission window, would pronouncedly affect the epidemiological characteristics

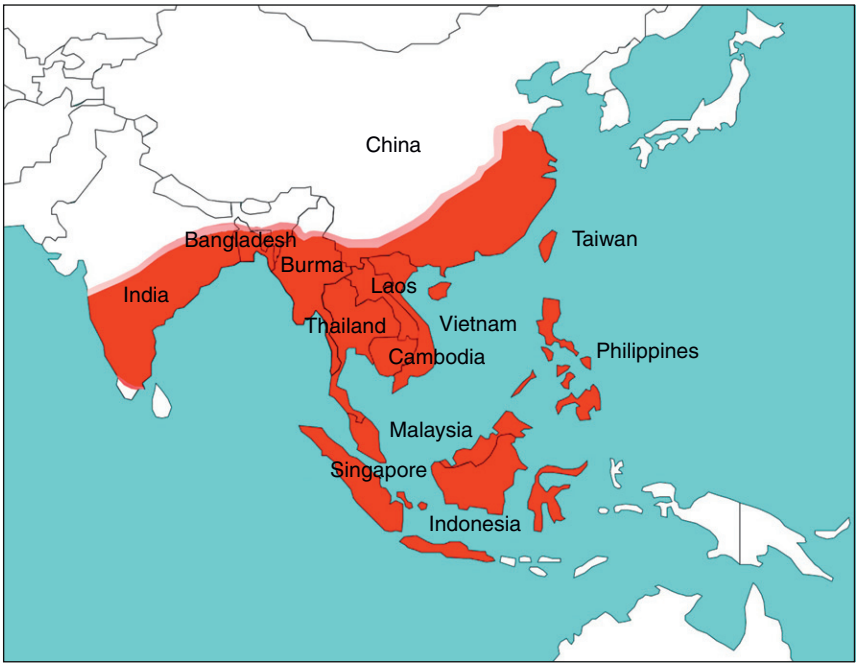

Figure 7 Geographical distribution of fasciolopsiasis in South East Asia, including countries in which human infection by *Fasciolopsis buski* has been reported.

of fasciolopsiasis in the area, with increase in prevalences, intensities, and geographical spread of infection both in humans and pigs.

Although there is still no data indicating a possible infection rate increase of fasciolopsiasis in humans or pigs related to climate change, (1) the absence of sufficient field surveys in the last two decades, (2) a few reports talking about a re-emerging infection in recent years, and (3) the present knowledge on climate-induced effects on fascioliasis, suggest that it would be prudent to undertake appropriate measures in fasciolopsiasis too. Field studies to assess such a potential phenomenon should be performed in endemic areas of Asia where climate change has shown to be more drastic in recent years.

Pathology and Symptomatology

The disease caused by intestinal *F. buski* infection is named fasciolopsiasis, which should not be confused with the similar term fascioliasis, which refers to another worldwide trematode disease caused by liver flukes of the genus *Fasciola*.

In humans, morbidity due to fasciolopsiasis in endemic areas appears to be high. Localized inflammation occurs at the site of worm attachment, which is usually followed by ulceration. When deep erosions take place, hemorrhage from the capillaries of the wall may result. Abscesses may also develop in the wall.

Intestinal obstruction may be caused by the large size of the worms. The worms feed actively not only on the host's intestinal contents but also on the superficial mucosa, causing extensive intestinal and duodenal erosions, ulceration, hemorrhage, abscesses, and catarrhal inflammation. Absorption of toxic and allergic worm metabolites cause ascites and both general and facial edema, for example, cheek and orbital edema. Pathological changes may be traumatic, obstructive, and toxic, especially in heavy infections. In such infections, the worms disturb the secretion of intestinal juices, cause excess mucus secretion, and obstruct the passage of food.

Feces are profuse, yellow-brown in color, and contain pieces of undigested food, due to malabsorption.

Clinical symptoms are related to parasite load (Table 2). Asymptomatic cases may be common, as found in Unnao district, Uttar Pradesh, India, where 61.2% proved asymptomatic among 181 persons shedding eggs in stools. The clinical disease appears to be only evident in cases with sufficient numbers of worms. The serious clinical picture caused by moderate and massive infections clearly demonstrates its public health importance.

Fasciolopsiasis is considered to be the main factor for persistent poor nutritional status of children in endemic areas of developing countries where it is present.

Advanced, heavy infections can be fatal. Mortality has been reported in children in with heavy infections owing to profound intoxication in India, China, and Thailand. In the autopsy of a fatal case, the mucosa of stomach and small and large intestine was hyperemic. Sections of the intestine showed hyperemia of both mucosa and submucosa, with hyperplasia of the lymphoid cells. Lungs revealed small scattered hemorrhagic spots. The liver was small, yellowish, and friable, with degeneration of the liver cells and fat vacuoles in the cytoplasm. Profound intoxication and sensitization are evidently produced by absorption of fluke metabolites into the system.

In pigs, intestinal lesions consist of minute foci of petechial hemorrhages scattered in the mucosal wall. Duodenum lesions show edema and congestion of the mucosa, with blood extravasation in both mucosa and submucosa. The mucosal

Table 1 Prevalences and other data characterizing fasciolopsiasis in the different countries

Country	*Endemic areas*	*Examples of prevalences*		*Other data*	*Year or period when studies were performed*
		In humans	*In pigs*		
China	Infections of humans and pigs reported from 10 provinces	• Up to 85% in certain areas of Chekiang and Kiangsi Provinces • A prevalence of 57% found in schoolchildren • In other areas it varies from less than 1% to 5%.		Recent nationwide surveys suggest a decrease in fasciolopsiasis	Different years
Taiwan	• In many parts of the island • Most highly endemic area appears to be Taiwan Hsieh in southern Taiwan	• 24%, 28%, 48%, and even 61% in Pa-Weng village • 25% were described in schoolchildren	Pigs appear to be also infected in many parts of the island	Intensity of 10 worms per person estimated in the Liuying area Recently also detected in immigrant aiwanese laborers	1960s and 1970s 1980s
Bangladesh		• 39.2% in one village near Dacca • 8.6% in another village • 50% found in schoolchildren in endemic focus		Endemic area in Bangladesh seems to be continuous with areas in India	1975
India	Assam	60%	Contrasting situation emphasized	1–57 worms per patient collected after treatment	First half of last century
	Calcutta	High infections reported	High infections		
	Bombay	29% in the city	Absence highlighted		
	Maharashtra	Human foci detected			
	Unnao district in Uttar Pradesh	22.4% out of 808 studied in six villages			1974
Vietnam		15% in Asians and 3% in Europeans			Old studies
		Positive cases	Positive cases		Up to the end of 1990s
Laos		Human infections reported			1990s
Cambodia	Area of Phnom-Penh	0.04%	5%		
Indonesia	Borneo and Sumatra	• 27.0% in Sei Papuyu village, Kalimantan • 20.3% in schoolchildren outside that area		Highest prevalence in the 5- to 14-year-old age group (56.8%) and decreasing with age	
Thailand	Main problems in central part of the country	• 13% out of 1500 people from three provinces • Estimated 100 000 persons infected among 500 000 persons	Closely parallel prevalence found in man		Mid-last century
	Areas as Pak Hai	Likely that 100% of the indigenous population is infected			
	Northern part	Lower than 10%		Immigrants from other parts of the country seem to be involved	

glands are cystic and in a catarrhal condition, and some mucus exudates may be present in the acini. There are patches of submucosal congestion where worms are attached and edema where worms are detached from the wall.

Figure 8 Free pigs constitute the main reservoirs and assure the transmission of the disease when entering in freshwater ponds inhabited by the planorbid snail vectors.

Diagnosis in Hosts

In endemic areas, the clinical picture becomes highly suggestive although usually not distinctive. Hence, diagnosis is routinely made by examining fecal specimens for the eggs, or occasionally by examination of expelled adult worms vomited or passed in feces.

When diagnosing coprologically, care should be taken with eggs, as they are not easily distinguishable from those of other trematode species usually infecting humans in the same endemic areas of Asia and which also produce unembryonated eggs. Thus, misclassification of eggs by nonspecialists may occur. A detailed comparative differentiation is noted in **Table 3**.

The differentiation with *Fasciola* species and hybrids becomes crucial due to the frequency of human fascioliasis infection worldwide. Therefore, the shape and nature of the granules in yolk cells might help. In *F. buski* eggs, the granules are larger in size, more refrangible showing a light shade of greenish-brown black in their appearance, and appear equally distributed all over the cytoplasm of yolk cells (**Figure 2**). In *Fasciola* eggs, the granules are smaller in size, less refrangible with a light shade of yellowish-brown in color and distributed densely near the yolk cell nuclei and hardly observed in the peripheral part of the cytoplasm.

The sequences corresponding to the 18S rRNA gene and the nuclear ribosomal DNA spacers ITS-1 and ITS-2 are

Table 2 Main characteristics of the clinical picture of fasciolopsiasis according to parasite burden and disease severity

Parasite burden	*Light infection*		*Moderate infection*	*Heavy infection*
	Asymptomatic	*Symptomatic*		
Symptoms	Usually asymptomatic, sometimes abdominal pain	Headache, dizziness, stomach ache, gastric pain	Headache, severe epigastric pain, abdominal pain, mild abdominal colic, acute ileus, anasarca	Common bitemporal headache, severe epigastric pain, common generalized abdominal pain, mild abdominal colic, acute ileus, anasarca, common ascites, giddiness
			Protuberant abdomen, abdominal distention, dysentery	Protuberant abdomen, abdominal distention, dysentery
			Nausea (especially in the morning and resolving after the first meal), vomiting	Nausea (especially in the morning and resolving after the first meal), vomiting
			Fever	Low-grade fever
				Asthenia, pallor
Toxic and allergic symptoms				Generalized toxic and allergic symptoms, usually in the form of edema, particularly of the face, abdominal wall and lower extremities
Liver and spleen				Nonpalpable
Feces	Sometimes diarrhea, alternating with periods of constipation	Loose stools	Diarrhea or bowel obstruction	Diarrhea or bowel obstruction
Blood		Anemia eosinophilia	Anemia marked eosinophilia leucocytosis	Anemia marked eosinophilia leucocytosis
Associations			Poor appetite, malnutrition	Poor appetite, malnutrition, malabsorption, lowering in serum vitamin B_{12} content in children

Table 3 Coprological diagnosis of fasciolopsiasis by morphological differentiation of the eggs of *Fasciolopsis buski*[a] by comparison with similar nonembryonated eggs laid by other human-infecting trematode species present in the same endemic countries of Asia and rest of the world

Characteristics	*Fasciolopsis buski*	*Fasciola hepatica*	*Fasciola gigantica*	*Fasciola hybrids*	*Gastrodiscoides hominis*	*Paragonimus* spp. *of Asia*
Egg length	120–140 μm	100.6–162.2 μm[a]	129.6–204.5 μm	Fh-like 106.5–171.5 μm[a] Fg-like150.9–182.2 μm[a]	127–160 μm	80–120 μm
Egg width	70–90 μm	65.9–104.6 μm[a]	61.6–112.5 μm	Fh-like 63.9–95.4 μm[a] Fg-like15085.1–106.2 μm[a]	62–75 μm	45–70 μm
Shape	Broadly ovoid, although sometimes more ellipsoidal and less slender than in *Fasciola*	Broadly ovoid as in *Fasciolopsis*, but sometimes spindlelike or slightly asymmetrical, with somewhat pointed ends	Broadly ovoid as in *Fasciolopsis*, but sometimes spindlelike or slightly asymmetrical, with somewhat pointed ends	Broadly ovoid as in *Fasciolopsis*, but sometimes spindlelike or slightly asymmetrical, with somewhat pointed ends	Broader, tapering more toward the opercular end	With broad end, several more broadly oval than others
Shell	Thin	Less thin	Less thin	Less thin	Thin	Moderately thick
Operculum	Delicate and difficult to visualize even at high magnification	Relatively well visible	Relatively well visible	Relatively well visible	Relatively less small but not well visible	Prominent, with lateral ledge
Abopercular end	Not blemished	Irregular protuberance	Irregular protuberance	Irregular protuberance	Generally thickened and rarely provided with a spine like elongation	With distinctly thickened shell
Color	Yellow	Yellowish-brown	Yellowish-brown	Yellowish-brown	More pale	Golden-brown
Shedding	Feces	Feces	Feces	Feces	Feces	Feces and sputum

[a]Measurements correspond to eggs found only in humans.

already known for *F. buski*. This may be useful for molecular confirmation of individual diagnosis of patients, whether by sequencing of eggs found in stool specimens or from fluke adults when vomited, as was recently demonstrated in a Vietnamese child in whom only two nucleotide substitutions were found when comparing.

Treatment
