[a]Breastfeeding.
[b]Infant formula feeding.
[c]As a function of % bioavailability.
[d]Neonatal iron reservoirs are sufficient to meet the iron requirement for the first 6 months in full term infants.
[e]Bioavailability of dietary iron during this period varies greatly.
[f]Owing to the high variability in bodyweight at these ages, the recommended intake is expressed as μg per kg bodyweight per day.
[g]For preterm infants.
[h]Depending when the growth spurt starts.
[i]It is recommended that iron supplements in tablet form are given to all pregnant women because of the difficulties to correctly evaluate iron status during pregnancy. In the nonanemic pregnant woman, daily supplements of 100 mg of iron (e.g., as ferrous sulfate) provided during the second half of pregnancy are adequate. In anemic women, higher doses are usually required.
[j]It is maintained that the recommendation corresponds to the age group of the mother.
[k]Available data are insufficient to establish recommended intake for vitamin E. Thus, only 'acceptable intakes' are shown in the table.

The possible risks associated with micronutrients (minerals and vitamins) deficit and toxicity are described as follows.

Minerals

Minerals are chemical elements essential for normal metabolic functioning of the human body, so they are considered essential. They must be provided by the diet (food and drink) on regular and daily basis, ranging from grams per day for major minerals (macro) to milligrams or micrograms per day for trace elements and other microminerals, some of which can be probably considered as essential elements or contaminants.

All minerals have the ability to produce toxicity symptoms if they are consumed over its maximum tolerable intake level (tolerable upper intake level (UL)). On the contrary, the absence of one of them produces specific deficiency diseases, which are often adjusted with suitable dietary supplementation. The deficiency prevalence of only four minerals is actually known: those of iron and iodine are widespread among the population, whereas the lack of zinc and selenium occurs just in some population groups under very specific conditions. For all other minerals, deficiency takes place in exceptional situations.

Macrominerals

Calcium (Ca)

It is the most abundant mineral in the human body and 99% of body Ca is found in the bone system; the rest is present in the intracellular and extracellular fluids. It participates in important functional processes such as the formation and maintenance of bones and teeth, and it is also involved in the nerve impulse transmission, neuronal excitability, neurotransmitter formation, and blood coagulation.

Milk and dairy products are the major dietary sources of calcium. They are also important because they contain substances that promote calcium's absorption, such as vitamin D, lactose, and proteins. Other Ca dietary sources are fish, whole grains, nuts, and legumes.

Ca deficiency can be caused by inadequate dietary intake of this mineral, vitamin D deficiency, a very low dietary Ca/P ratio, and high Ca losses. The main consequence of this deficit is inadequate mineralization of the bone matrix or osteoporosis, which can cause rickets in children and youths. It is also associated with osteomalacia, growth arrest, hypertension, increased cancer risk (especially in colon), and seizures.

In normal situations, dietary toxicity of Ca is rare, but it can occur by supplement consumption. Doses more than 2 g day^{-1} can cause hypercalcemia, with more or less severe effects depending on its intensity. Besides interfering with the absorption of other divalent metals (such as iron, magnesium, manganese, and zinc), hypercalcemia can lead to constipation, nausea, polyuria, and kidney stones and, in extreme situations, loss of muscle tone, coma, and death.

Phosphorus (P)

Approximately 80% of the total body content of P is contained, together with Ca, in the bone structure and teeth; the rest of this mineral is mostly present in soft tissues, and a very low amount (1%) is dissolved in the extracellular fluid. Its main function is structural, as it is part of hydroxyapatite in calcified tissues, phospholipids in biological membranes, nucleotides, and nucleic acids. Other functions include acid–base balance in blood as phosphate buffer, temporary reserve and transfer of energy from metabolic substrates, and participation in phosphorylation processes.

Meat, fish, dairy products, nuts, legumes, and cereals are good dietary sources of phosphorus. Processed foods also contain considerable amounts of this mineral as it is present in various additives that are added therein.

Inadequate intake of P results in the development of hypophosphatemia, whose characteristic symptoms are muscle weakness, bone loss, decreased growth, poor dental development, rickets, and osteomalacia.

On the contrary, P excess or hyperphosphatemia is not common in healthy subjects, but it can be found in patients with renal diseases, which may lead to the production of calcium phosphate calculi in the body tissues and to muscular symptoms (such as tetany). Recently, a higher P intake has been detected, which has been associated with an increased intake of cola drinks and food with P-containing additives.

Magnesium (Mg)

Approximately 65–70% of this mineral is bound to Ca and P as bone constituents, whereas the rest is distributed in various organs and tissues, in fact, it is the second most abundant intracellular cation. This mineral participates mainly in the metabolism and maintenance of bone structure, in various enzyme, nervous, and cardiac functions, and in the regulation of blood pressure.

Foods with a high Mg content include whole grains, legumes, green leafy vegetables, tofu, meat, fruit, and dairy products.

Mg deficiency is observed only in two situations: as a secondary complication of a primary disease (like cardiovascular or neuromuscular diseases) and as a result of rare genetic disorders of homeostasis. This deficiency is usually associated to tachycardia, which can be accompanied by weakness, muscle spasms, disorientation, nausea, vomiting, and seizures.

Toxicity resulting from an excessive Mg intake ($>$350 mg day^{-1}) is rare in healthy people, but it can occur in patients with renal failure, which can cause diarrhea, nausea, and abdominal pain.

Sodium (Na)

It is the principal cation of the extracellular fluid, 30–40% being fixed in the skeleton. It is an essential regulator of extracellular fluid (cardiac output or blood pressure), and it also plays an important role in regulating the osmolality, the acid–base balance, cell membrane potential, and active transport across cell membranes.

Most ingested Na comes from sodium chloride (common table salt, of which 40% is sodium), which is added during food cooking or industrial processing. Food products prepared by salting and curing (such as hams, sausages, and salted fish) are characterized by a high Na content.

Na deficiency is rare, even with low-sodium diets. Under extreme conditions of intense and persistent sweating, trauma, chronic diarrhea, or kidney disease, it may be a necessary supplementation treatment with salt.

Na excessive consumption is associated with the development of hypertension and edema. However, acute toxicity related to dietary Na is not a concern as kidneys excrete Na excess.

Potassium (K)

It is the main cation of the intracellular liquid, 98% being present inside the cell. It is, therefore, essential for the acid–base balance of the body, water maintenance; transmission of nerve impulses, and contraction of smooth, skeletal, and cardiac muscles.

It is widely distributed in legumes, dried fruits, and nuts. Potatoes, spinach, bananas, and avocados are also good dietary sources.

There are several situations that can cause hypopotassemia, such as insulin excess, chronic kidney disease, diarrhea, vomiting, and excess of laxatives. This deficiency can affect nerve and muscle activities and can lead to renal, metabolic, and heart alterations.

Excessive consumption of potassium can cause gastrointestinal disturbs; this is not considered a real toxic effect unless kidneys do not function properly. In this case, it could lead to a cardiac arrest in an extreme situation. Thus, K supplements can play an important role in the chronic heart failure.

Chlorine (Cl)

It is the main anion present in the extracellular fluid. Along with sodium, sulfate, phosphate, and bicarbonate salts, it maintains the acid–base balance of body fluids, performing a passive role in this regulatory system. In addition, it is involved in the formation of digestive gastric juices.

Most of the ingested chlorine comes from sodium chloride or table salt (60% chloride), which is added to food in its various preparation stages. Food with a high Cl content includes seaweed, rye, tomatoes, lettuce, celery, and olives.

Within a balanced diet, it is difficult for chloride deficiency situations to appear. However, vomiting, chronic kidney disease, renal failure, and respiratory acidosis can lead to Cl deficiency. On the contrary, the only known dietary cause of hyperchloremia is dehydration due to water deficiency. Consumption of large amounts of chlorine (in salt form) has been associated with arterial hypertension in predisposed subjects.

Microminerals/Trace Elements

Iron (Fe)

Fe acts as a catalyst for a broad spectrum of metabolic functions. It is a component of hemoglobin and it is required for oxygen transportation, essential for cellular respiration. In myoglobin, it represents the muscle oxygen reservoir. It is also a component of enzymes, such as cytochrome (essential for energy production) and others required for immune system functioning.

There are two types of dietary Fe: (1) nonheme Fe (the most abundant one), present in both plants and animal tissues and (2) heme Fe (more bioavailable), from hemoglobin and myoglobin in food from animal origin. Nonheme Fe is found mainly in vegetables, whole grains, nuts, and oil seeds, whereas heme Fe is present in viscera, red meat, fish, and seafood.

The increase of iron and prebiotics in the plant edible parts is expected to improve human health in both industrialized and developing countries exposed to endemic infections. In collaboration with the HarvestPlus Challenge Program, the high-iron rice group is using biotechnology to generate new rice varieties to increase Fe concentrations in the grain.

Fe deficiency remains the most common nutritional deficiency in industrialized countries despite dietary improvements. This occurs when the ingested amount does not meet the body requirements, due to insufficient dietary intake, poor absorption, or excessive physiological losses. It is manifested by iron deficiency anemia, which usually causes pallor signs, splenomegaly, and a lying weight curve in infants.

Fe toxicity in healthy people is unusual as there is a quite effective homeostasis mechanism. However, toxicity problems can arise if the subject has a genetic disease (hemochromatosis) and/or if repeated blood infusions are carried out. Abuse of Fe supplements (>45 mg day^{-1}) may also pose a health risk due to free radical reactions resulting from this excess. Consequently, there may be an increased risk of bacterial infection, neoplasia, arthropathy, cardiomyopathy, and endocrine disruption.

Zinc (Zn)

It is the most abundant intracellular trace element, and it is involved in three main function groups in the human body: catalytic, structural, and regulatory. It is, therefore, fundamental for the regulation of gene expression, for the organism growth and development, and for the immune system function.

It is widely distributed in foods and the main Zn sources are viscera, meat, seafood, whole grains, nuts, and oil seeds. The most bioavailable Zn is provided by foods from animal origin.

The clinical manifestations are observed in communities or people who eat small amounts of animal protein. It can cause growth retardation, sexual and skeletal immaturity, neuropsychiatric disorders, dermatitis, alopecia, diarrhea, increased infection susceptibility, and loss of appetite.

Zinc deficiency caused by inadequate dietary intake is a global nutritional problem in human populations, especially in developing countries. Biofortification of wheat and other staple foods with Zn is, therefore, an important challenge and a high-priority research task. The results of many studies suggest that foliar Zn application in wheat represents an effective approach to provide more dietary Zn from wheat-derived products.

Regarding its toxicity, it has been reported that at doses higher than 40 mg day^{-1}, Zn can interfere with copper, thus leading to a decrease of some enzymatic activities. Doses more than 100 mg day^{-1} can cause diarrhea, cramps, nausea, vomiting, and depression of the immune system. These levels can be reached with the intake of certain vitamin and mineral preparations that already contain Zn.

Iodine (I)

It is an essential constituent of the thyroid hormones (thyroxine (T_4) and triiodothyronine (T_3)), which play an essential role in gene transcription so as to regulate the basal metabolic rate as well as body growth and development. The thyroid gland actively absorbs iodide from the blood stream to synthesize these hormones and release them back into the blood.

Seafood (fish, shellfish, and seaweed) concentrate iodine from seawater, and they are generally the richest source of such mineral. In some populations, milk has become the main iodine source due to the use of iodized salt and I-fortified feed

for cattle breading. Processed foods can also provide some extra iodine, as some additives already contain it.

Iodine deficiency is one of the most serious public health problems according to the World Health Organization, as it can cause mental and physical retardation of children (cretinism) if it occurs during fetal development. Other disorders related to hypothyroidism include goiter (hypertrophied thyroid gland), mental slowing, depression, weight gain, and low basal body temperatures.

The toxicity of this mineral may be associated with impaired immunity leading to excessive production of thyroid hormones. A high consumption of algae or dietary supplements used for weight loss can also lead to an excessive I intake. Symptoms of I toxicity include: increased basal metabolic rate, voracious appetite, thirst, weight loss, general weakness, heat intolerance, nervousness, and heart problems.

However, dietary iodine intake is generally lower than recommended daily levels because the amount and consumption frequency of iodine-rich foods are not enough to satisfy the requirements. Therefore, the introduction of iodized salt has been the basis of international iodine deficiency eradication efforts because it is an inexpensive source of stable iodine content, and salt is consumed in relatively similar quantities worldwide. Furthermore, agronomic biofortification has proven to be effective on iodine enrichment of fodder, rice, potatoes, carrots, tomatoes, and leaf vegetables.

Copper (Cu)

It is a component of several enzymes, cofactors, and proteins in human body; approximately 90% of Cu is located in muscles, bones, and liver. It contributes to the formation of red blood cells and the maintenance of blood vessels, nerves, bones, and immune system; it is also present in antioxidant enzymes such as superoxide dismutase.

Rich food sources of this mineral include viscera (especially liver), seafood, legumes, nuts, seeds, and drinking water.

Deficiency is rare, but children with poor Ca diets are more predisposed, especially if they also have diarrhea or malnutrition. There are also diseases that decrease Cu absorption, such as celiac disease, cystic fibrosis, or tracking of restrictive diets. It manifests with anemia, neutropenia, and severe bone demineralization.

Acute toxicity in humans is very rare and it usually occurs by contamination of drinking water and food due to Cu pipes and utensils. Symptoms include vomiting, diarrhea, hemolytic anemia, liver and kidney damages, and even death. It can also appear as a rare hereditary disease (Wilson's disease) with signs of liver damage.

Selenium (Se)

Selenium is an essential micronutrient as it is component of the amino acids selenocysteine and selenomethionine and it functions as cofactor for reduction of antioxidant enzymes such as glutathione peroxidase. It is also involved in the thyroid gland functioning and stimulates the immune system.

Fish, shellfish, and viscera are good sources of this mineral, followed by meat and eggs. Despite the low Se content of cereals and their derivatives, they are good sources of this mineral because of their high consumption. Cereal biofortification by means of Se-enriched fertilizer is an efficient way to increase their relatively low Se level, as it has been successfully used for potatoes and carrots.

Selenium deficiency is very rare, but it can occur in patients with severe intestinal dysfunctions or subjected to total parenteral nutrition; populations dependent on food grown in selenium-deficient soils are also at risk. Symptoms include pain, muscle wear, and cardiomyopathy.

A dietary excess ($>400\ \mu g\ day^{-1}$) can cause selenosis, which manifests by hair loss, halitosis, gastrointestinal disorders, fatigue, nail disorders, irritability, and neurological damage. Extreme cases of selenosis can result in liver cirrhosis, pulmonary edema, and death.

Fluorine (F)

This mineral is involved in Ca uptake, prevents tooth decay, and aorta calcification, is part of dental enamel, and reduces osteoporosis due to its beneficial effects on bone tissue.

The main dietary source is drinking water, especially fluoridated drinking water; among food, seafood, tea, and infant formulas (prepared with fluoridated water) also represent a good source of this mineral. Fluoride dental products can sometimes exceed the dietary intake, especially in young children with poor control of swallowing reflex.

Fluoride deficiency usually occurs in people living in areas where drinking water supplies less than $1\ mg\ ml^{-1}$ of fluoride, which manifests as dental caries.

The chronic toxicity due to its overconsumption is called fluorosis, which affects bone health, producing teeth yellowing, and bones and enamel weakness; this can lead to decalcification, osteoporosis, and tooth decay. It can also affect kidney, muscle, and nerve functions.

Chromium (Cr)

The trivalent chromium (Cr^{+3}) is an essential nutrient in the metabolism of carbohydrates (enhancer of insulin action), lipids, and proteins (involved in phosphorylation and dephosphorylation mechanisms of insulin receptor proteins). Brewer's yeast, black pepper, and grape must are good dietary sources of this mineral.

Cr deficiency can be observed in populations of developed countries that consume refined food, as well as in subjects undergoing long-term total parenteral nutrition with low Cr levels. Symptoms include glucose intolerance, hyperglycemia, hypoglycemia, glycosuria, insulin resistance, and hypercholesterolemia.

If orally administered, it is slightly toxic due to the low absorption of Cr^{+3} (predominant form in food); it can induce a chronic renal failure. On the contrary, the toxicity of the mineral in its hexavalent (Cr^{+6}) form is common in industrial environments and can cause dermatosis and lung cancer.

Molybdenum (Mo)

This mineral may exist in various oxidation states (+3, +4, +5, and +6) and, therefore, it functions as a facilitator of electron transfer reactions, being a cofactor of iron- and flavin-containing enzymes in the metabolism of pyrimidines, purines, pteridines, and sulfur-containing amino acids.

Milk, dairy products, legumes, liver, kidney, cereals, cereal products, and nuts are good sources of this mineral.

Mo deficiency is uncommon, but, in case it occurs, it produces acidosis, mouth and gums disorders, rapid heart rate, mental and metabolic alterations, and male sexual dysfunctions.

Regarding its toxicity, oral doses of 10–15 mg day^{-1} may lead to a gout-like syndrome. Higher Mo intakes can cause anemia, anorexia, diarrhea, joint abnormalities, osteoporosis, hair bleaching, and death.

Manganese (Mn)

This mineral is an important catalytic cofactor for some metalloenzymes such as superoxide dismutase (cellular antioxidant system), arginase (urea cycle), and pyruvate decarboxylase (gluconeogenesis).

It is mainly found in cereals, black bread, nuts, ginger, and tea. The latter contain tannins that bind to this mineral, forming insoluble complexes that decrease Mn absorption at intestinal level.

Mn deficiency data in humans are scarce, but it can cause weight loss, dermatitis, delayed growth of hair and nails, hair color change from black to red, and decreased blood lipids. It may be more common in infants due to the low concentration of this mineral in breast milk.

It is not toxic if orally administered, but it may lead to psychiatric disorders in persons overexposed to high Mn levels present in the atmosphere and smoke.

Other Elements

There are other microminerals (such as lithium, silicon, vanadium, nickel, and boron) that can also be considered essential, based on data obtained from animal models or biochemical reactions that suggest a beneficial biological role in humans. In addition, other minerals (such as lead, arsenic, cadmium, and mercury) have no beneficial effects in humans and these are considered as food contaminants that may derive from agricultural technology, industrial emissions, geological sources, and certain processing technologies.

Vitamins

Vitamins are essential micronutrients, which are necessary for every living cell function, growth, and development. Because human endogenous metabolism is not able to produce them or generates negligible amounts, they should be regularly introduced through the diet. Vitamins are involved in multiple functions of cell metabolism as catalysts and enzyme prosthetic groups. As biocatalysts, vitamins activate food oxidation and facilitate energy release and utilization, so that human body can take advantage of the plastic and energetic elements deriving from redox reactions.

Hydrosoluble

Vitamin B_1 (Thiamine)

This vitamin plays a fundamental role in the carbohydrate metabolism by means of the formation of its coenzyme derivative (thiamine pyrophosphate (TPP)).

It is mainly found in pork meat, pork meat products, viscera, dried beans, wheat germ, breakfast cereals, sunflower seeds, and oleaginous nuts.

Deficiency of this vitamin causes beriberi, which can manifest itself in two different ways (wet or dry) depending on whether it is edematous or neurological. In general, patients exhibit weakness, poor coordination, and functional impairment of the cardiovascular, muscular, nervous, and gastrointestinal systems.

When a mother has thiamine deficiency, the newborn may develop a serious, acute form of beriberi, which is one of the most important causes of perinatal mortality in Southeast Asia. In industrialized countries, thiamine deficiency can be developed under the following conditions: high consumption of refined food, anorexia, gastrointestinal disturbances, excess of carbohydrates in the diet (athletes), and total parenteral nutrition based on glucose.

In people with alcohol abuse problems, Wernicke–Korsakoff syndrome can occur, where thiamine absorption is decreased, whereas its elimination is increased. This causes vision changes (double vision, crossed eyes, and rapid eye movement), staggering gait, and impaired mental functions.

A dietary excess of thiamine generally does not produce harmful effects and, because it is easily eliminated, it is not possible to speak about B_1 hypervitaminosis. However, sensitization phenomena have been observed in some subjects after repeated intravenous administration of thiamin.

Vitamin B_2 (Riboflavin)

This micronutrient is easily absorbed, plays an important role in the energy utilization, and is required for the metabolism of fats, carbohydrates, and proteins. Once absorbed, especially in the small intestine, heart, liver, and kidney, it is converted into its two coenzyme forms (flavin mononucleotide and flavin adenine dinucleotide).

It is widely distributed in foods, but it is especially found in viscera, breakfast cereals, meat (beef and duck), blue fish, milk powder, cheese, fresh yeast, pate, foie gras, wheat germ, egg yolk, and almonds.

Isolated riboflavin deficiency is rare, given its abundance in natural food products. Reported cases usually correspond to generalized hypovitaminosis, being characteristic of the one produced by excessive alcohol consumption as it interferes with vitamin digestion and absorption. The observed signs and symptoms usually affect mucous membranes, leading to cracked and red lips, tongue inflammation (glossitis), cracking of mouth corners (cheilitis), mouth ulcers, and sore throat. The deficiency can also cause dry skin, fluid in mucous membranes, and anemia. At eye level, burning sensation and ocular pruritus are detected, as well as photosensitivity.

No toxicity has been established for an excessive dietary intake of riboflavin.

Vitamin B_3 (Niacin, Vitamin PP)

The generic name 'niacin' is used for nicotinic acid, its amide (nicotinamide), and all derivatives that can be transformed into biologically active compounds. This vitamin is the precursor of two coenzymes involved in almost all redox reactions (nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate), which can act as coenzymes or participate in anabolic and catabolic reactions of carbohydrates, proteins, and lipids.

Liver can synthesize niacin from tryptophan, but it is very inefficient as 60-mg tryptophan is required to synthesize 1 mg of niacin.

The best sources of niacin include blue fish, liver, meat (beef, rabbit, and chicken), breakfast cereals, mushrooms, seafood (squid and cuttlefish), meat products, peanuts, and peanut butter.

Niacin deficiency causes pellagra, a disease characterized by skin lesions (scaly skin sores), gastrointestinal disorders (diarrhea), and mental disorders (mental confusion and hallucinations).

A large niacin intake may lead to decreased levels of low-density lipoprotein-cholesterol and to an increased content of high-density lipoprotein-cholesterol. In fact, very high amounts of niacin (approximately 100 times higher than the actual recommendations for its dietary intake) have been used as drugs.

Vitamin B_5 (Pantothenic Acid)

This vitamin has two coenzyme derivatives of great biological importance. The acyl carrier protein is part of the enzymatic complex used for fatty acid synthesis and it is, therefore, essential for lipogenesis. The coenzyme A is required for metabolical activation of acyl groups, including fatty acids and acid metabolites arising from catabolism of carbohydrates and some amino acids. Thus, it is essential for an efficient utilization of all types of macronutrients, from an energy standpoint.

Pantothenic acid is practically found in all foods. Meat, cereals, and legumes are rich sources of this vitamin, whereas fruits and vegetables contain a lower amount.

Given its abundance, serious deficiency of this vitamin is very uncommon. Deficiencies occur only when there is a generalized malnutrition with lack of other vitamins. Signs and symptoms include general malaise, gastrointestinal disorders, and muscle and neurological disorders.

No toxicity cases have been reported for high doses of pantothenic acid.

Vitamin B_6 (Pyridoxal)

Vitamin B_6 is actually a group of three chemical compounds called pyridoxine (or pyridoxol), pyridoxal, and pyridoxamine. Their phosphorylated derivatives (pyridoxal phosphate and pyridoxamine phosphate) act as coenzymes. They are involved in many enzyme reactions of the amino acid metabolism and their main function is to transfer the amino group.

They are all abundant in foods, especially in the liver, legumes, nuts, and bananas. Pyridoxine and pyridoxamine are predominant in plants, whereas pyridoxal prevails in food from animal origin.

Pyridoxine deficiencies are rare in industrialized countries due to food abundance. In addition, a nonnegligible stored amount of vitamin is also available in human body besides the contribution of intestinal biota. The vitamin deficiencies give rise to neurological problems, growth retardation, hypochromic anemia, seborrheic dermatitis, glossitis, depression, and seizures. Some pyridoxine deficiencies often lead to a secondary deficiency of niacin, as its endogenous synthesis from tryptophan does not work properly.

It is one of the vitamins with greater therapeutic use, given its metabolic implications, particularly in the synthesis of biogenic amines. Excessive use of pyridoxine (2–4 g day^{-1}) may produce toxic effects, particularly peripheral neuropathy.

Vitamin B_8 (Biotin)

It is an essential vitamin for various animal species and humans, is found in different food products, and is synthesized by bacteria from the lower gastrointestinal tract and some fungi. Liver, egg yolk, soy flour, cereals, and yeast are rich sources of biotin.

It is the only vitamin that acts as coenzyme without structural modifications and, when covalently bonded to the enzymatic proteins, it is involved in carboxylation reactions that affect the Krebs cycle, lithogenesis, and the degradation of some amino acids.

Biotin deficiencies are uncommon, given its broad occurrence in most foods and additional endogenous contribution of intestinal microbiota. However, deficiency can arise when abundant raw eggs are ingested due to the presence of avidin (a thermolabile glycoprotein), which specifically binds biotin and prevents its intestinal absorption. The clinical consequences of this deficiency are primarily metabolic acidosis, digestive disorders, hypotonia, alopecia, skin and mucous membranes lesions, and general tiredness.

No toxicity cases have been reported for high doses of this vitamin.

Vitamin B_9 (Folic Acid)

Folate or folates are used as a generic name for this vitamin and refers to the different forms that naturally occur in foods. It is known that intestinal bacteria are able to synthesize folate, which is probably lost in the feces. The term folic acid refers to vitamin form found in supplements and enriched food.

The best dietary sources from both quantitative and bioavailability standpoints are liver, foie gras, legumes, green leafy vegetables, breakfast cereals, fresh yeast, wheat germ, soybean flour, peanut, chestnut, and hen eggs.

Vitamin deficiencies can occur due to insufficient ingestion, alcoholism (interferes with enterohepatic absorption), or increased requirements during certain life stage (such as pregnancy). The major disease associated with folate deficiency is megaloblastic anemia, with a consequent decrease of immunological functions. If the deficiency occurs during pregnancy, it can result in neural tube defects in the fetus (spina bifida and anencephaly (the absence of brain)). Moreover, the involvement of folate in the metabolism of homocysteine (a nonproteinogenic, cytotoxic amino acid produced during methionine catabolism) leads to a vitamin deficiency that may represent an independent risk factor for cardiovascular diseases and stroke. A low-folate nutritional status is a risk factor in cancer development, particularly colorectal one.

No vitamin toxicity has been recorded even when large amounts are ingested, as the excess amount is easily eliminated due to its hydrosoluble nature.

Vitamin B_{12} (Cyanocobalamin)

This vitamin is also known as cyanocobalamin, antipernicious, and extrinsic factor. It consists of a class of chemically related compounds (such as its two coenzyme forms, methylcobalamin and 5-deoxyadenosylcobalamin) that display vitamin activity. This vitamin can be synthesized by bacteria, fungi, and algae; some ruminants (cattle and sheep) can obtain it from endogenous bacterial activity.

Viscera (such as the liver and kidneys), meats, eggs, dairy products, and fish are good sources of this vitamin. It naturally

occurs in the animal kingdom only, and its presence is negligible in plants and vegetables; for this reason, vegans usually have vitamin deficiency and therefore they need to increase their dietary intake with vitamin supplements. At present, there are some enriched-plant products available, such as fortified cereals.

The lack of cobalamin or its derivatives leads to a shortfall in the transport of methyl groups, which adversely affects purine synthesis (deoxyribonucleic acid component) and therefore causes a deficiency in the cell multiplication process. This deficiency mainly affects the bone marrow where erythropoiesis (formation of blood cells) occurs, so it may result in a serious medical condition called pernicious anemia.

Another important alteration is a neuropathy that can be fatal due to a discontinuous, diffuse, and progressive demyelination. This produces sensory disturbances in the legs (tingling and numbness), loss of concentration or memory, disorientation, and dementia. Unlike other water soluble vitamins, vitamin B_{12} is stored in the liver and therefore its deficiency may arise months after a low or very low dietary intake.

As to their toxicity, it is advised to avoid it under myeloproliferative conditions, especially leukemia. Nevertheless, no toxicity cases have been reported for high doses of this vitamin.

Vitamin C (Ascorbic Acid)

The word vitamin C is used for L-ascorbic acid (or anti-scorbutic vitamin), other molecules having vitamin activity (such as ascorbic acid and its salts), and some of their oxidized forms (such as dehydroascorbic acid).

All the fruits and vegetables provide vitamin C, even though there are some of them that are richer sources, such as red and green peppers, Brussels sprouts, broccoli, fruit, and raw vegetables. Many food products are fortified with vitamin C, but several technological precautions must be taken as it is highly thermolabile and prone to oxidation.

Lack of this vitamin causes scurvy (<0.2 mg dl^{-1}), a disease that begins with symptoms of fatigue, pinpoint hemorrhages in the back part of arms, legs, joints, and gums, due to alterations of collagen synthesis. Several studies have linked vitamin C deficiency with increased risk of cardiovascular disease and preeclampsia; it also favors the development of lung infections.

In terms of toxicity, the main adverse effects are gastrointestinal disturbances, nausea, cramps, and diarrhea; the formation of kidney stones has also been reported.

Liposoluble

Vitamin A

Vitamin A is also known as the antixerophthalmic vitamin. It can be found as retinoids (retinol, retinal, and retinoic acid) and provitamin A carotenoids (mainly β-carotenoid); other natural carotenoids do not exhibit vitamin activity in humans.

The main dietary sources of total vitamin A are liver, cod liver oil, carrots, spinach, sweet potatoes, pate, foie gras, margarine, butter, egg yolk, mango, and cheese. In the case of carotenoids, they can be found in vegetables, milk caps, and fruits.

Deficiency of this vitamin is one of the key public health problems in developing countries. The most important disease deriving from this dietary deficiency is night blindness, which can end up in permanent blindness. It may also produce xerophthalmia (keratinization of ophthalmic tissue), and this is related to macular degeneration associated with age, xerosis, and diverse skin and immunocompetence problems.

The toxicity of this vitamin is called hypervitaminosis A and can be of three types: acute (due to very excessive intake), chronic (long-term high consumption), and teratogenic. During pregnancy, this can cause spontaneous abortion or birth defects. Toxic status only occurs when retinoids are used, whereas carotenoids cannot generate such symptoms. In severe cases, it manifests with muscle and bone pain, appetite loss, skin disorders, headache, dry skin, hair loss, liver damage, double vision, bleeding, vomiting, hip fracture, and even coma. Acute toxicity can cause gastrointestinal disturbs, headache, blurred vision, and muscle incoordination.

Vitamin D (Cholecalciferol)

It is also known as antirachitic vitamin, as its deficiency causes rickets. In the presence of sunlight, the epithelial cells are able to synthesize it from 7-dehydrocholesterol (produced in the liver and transferred to the skin). Both animals and humans are, therefore, able to synthesize vitamin D_3, and an adequate exposure to sunlight or ultraviolet radiation can avoid its deficiency.

The main food sources of vitamin D are cod liver oil, blue fish, caviar, milk caps, mushrooms, eggs, margarine, and breakfast cereals. There are also several fortified food products available in the market (such as milk, ready-to-eat breakfast cereals, and orange juice), which in some countries represent the main dietary source of vitamin D.

When the sunlight exposure is not enough to produce the required amount of this vitamin, dietary intake is essential. If the latter also fails, children rickets can thus occur, producing abnormal growth of head, thorax, and joints with curved pelvis and legs. Adults can present osteomalacia (weak bones) and even osteoporosis. Vitamin D deficiency has been epidemiologically linked with an increased risk of various types of cancer, hypertension, autoimmune, and infectious diseases.

Vitamin D is a very toxic substance, so an excessive intake of vitamin D can cause hypercalcemia, thirst, anorexia, risk of soft tissue calcification, and stone formation in the urinary tract.

Vitamin E

This vitamin is a family of eight natural compounds (four tocopherols (α, β, γ, and δ-) and four tocotrienols (α, β, γ, and δ-)) with different biological activity and antioxidant capacity. The most active form of this vitamin is α-tocopherol, which is widely distributed in nature and it is often used in vitamin supplements.

The main food sources are vegetable oils, nuts, oil seeds, wheat germ, and food products prepared with any of these ingredients (such as margarine).

The deficiency of this vitamin is rare, but it may occur in smokers (tobacco easily destroys it), people with a low dietary intake of lipids, or with a poor lipid absorption; it is also present when there is a genetic abnormality in lipoprotein synthesis. In animals, it has been demonstrated that the effects of this deficiency are associated with the lack of antioxidant protection provided by this vitamin; however, such effects have not been thoroughly proved in humans, even though they seem to be related to the development of anemia.

Vitamin E is practically classified as a nontoxic substance. Hypervitaminosis is not observed even after a high dose administration over a long time period.

Vitamin K

This vitamin prevents bleeding as it helps maintaining the blood clotting system. The natural forms of this vitamin are K_1 (phylloquinone or phytomenadione) and K_2 (menaquinone), which are of vegetable and microbial origin, respectively. Vitamin K_3 (menadione and menadiol) is a synthetic molecule, which displays an activity that is twice as much as those of the natural forms.

Different levels of vitamin K are found in milk, dairy products, meat, eggs, liver, whole grains, fruits, green vegetables, and vegetable oils.

Vitamin K deficiencies are rare because of the vitamin abundance in food and the endogenous synthesis by intestinal microbiota. However, when they occur, they result in a poor blood clotting that causes spontaneous bleeding or extended bleeding time. The deficiency may arise in the following situations: total parenteral nutrition without vitamin supplementation, presence of absorption problems (intestinal resection, biliary obstruction, etc.), medication intake of vitamin K antagonists, antibiotic treatment that destroys intestinal microbiota, laxatives, and vitamin A or E overdose (which inhibits the absorption of vitamin K).

Its deficiency is more likely to occur in newborns, especially premature ones, those who only breastfed (because breast milk contains a lower amount of vitamin K as compared with infant formula), or those whose mothers took anticonvulsant medication. In addition, the newborn intestines have not been yet colonized with bacteria that synthesize menaquinones, and vitamin K cycle may not work correctly in premature babies. Vitamin K deficiency in infants can cause a condition called hemorrhagic disease of the newborn, which occurs within the first days after birth (2–5 days) and manifests with bleeding in the baby's stool, urine, and also around the umbilical cord. Sometimes intracranial bleeding may also occur, which happens suddenly, thus causing serious injuries or even infant's death.

Despite being a fat soluble vitamin, no toxicity cases have been reported for high doses of the natural forms of this vitamin. Menadione, however, can be more dangerous, especially in neonates, as it can produce hemolytic anemia and hyperbilirubinemia.

Macronutrients: Essential Fatty Acids

BA Wilson, RD Pollard, and DS Ferguson, Wake Forest University School of Medicine, Winston Salem, NC, USA

Glossary

Elongase (ELOVL) Any enzyme that catalyzes the elongation of an aliphatic chain, preferentially fatty acyl chains.

Fatty acid desaturase (FADS) An enzyme that removes two hydrogen atoms from a fatty acid, creating a carbon–carbon double bond.

Lipid Organic substance that is relatively insoluble in water and soluble in organic solvents.

Monounsaturated fatty acid (MUFA) A fatty acid that contains one carbon–carbon double bond in its carbon chain length structure.

Omega-3 (ω3) fatty acid A fatty acid in which the first double bond is located between the third and fourth carbons from the methyl or omega (ω) end.

Omega-6 (ω6) fatty acid A fatty acid in which the first double bond is located between the sixth and the seventh carbons from the methyl or omega (ω) end.

Polyunsaturated fatty acid (PUFA) It is a fatty acid that contains more than one carbon–carbon double bond in its carbon chain length structure.

Prostaglandins A group of physiologically active substances derived from essential fatty acids. They are present in many tissues to perform functions such as the constriction or dilation of blood vessels and stimulation of smooth muscles and the uterus.

Saturated fatty acid (SFA) A fatty acid that contains only carbon–carbon single bonds in its carbon chain length structure.

Thromboxanes Biologically active substances produced in platelets that increase platelet aggregation (and therefore promote blood clotting), constrict blood vessels, and elevate hypertension.

Introduction

Essential fatty acids (EFAs) are needed for normal bodily function and development, but cannot be synthesized in sufficient quantities to meet human needs. Thus, humans must obtain EFAs through dietary consumption. Owing to this innate inability to synthesize EFAs *de novo*, these fatty acids have been termed 'essential' as this refers to their requirement in maintaining biological processes. Besides acting as fuel sources for the body, EFAs play a role in many physiological systems in metabolism, inflammation, and energy homeostasis. Only two EFAs are known for humans: alpha-linolenic acid (ALA, 18:3ω3), an omega-3 (ω3) fatty acid; and linoleic acid (LA, 18:2ω6), an omega-6 (ω6) fatty acid. These two EFAs were discovered in 1923 and were designated as 'vitamin F' due to their necessary role in the diet of rats for the sake of standard health. However, subsequent studies during the 1930s by Burr as well as Burr and Miller have determined that ALA and LA are suitable for being classified as fats rather than as vitamins.

LA and ALA serve as the building blocks to make other ω3 and ω6 families of long chain polyunsaturated fatty acids (LC-PUFAs). These EFA LC-PUFA derivatives are coined as only being 'conditionally essential,' because EFA precursors are needed for their production. LA is the parent of the ω6 fatty acid family. One of the main derivatives of LA is the LC-PUFA arachidonic acid (AA, 20:4ω6), which is known to play a role in many physiological functions concerning cell signaling and the inflammatory response progression. In addition, AA has been implicated in serving its role as a structural constituent of the central nervous system. In westernized diets, most vegetable oils, human milk, and meat products contain high amounts of LA, which tend to be excessively higher than that required for normal biological activity. As a result, this surplus of fatty acids is often stored by the body as excess fat.

ALA is the parent of the ω3 fatty acid family. ALA can be found in a variety of dark green vegetation, vegetable oils, and flaxseed. Main derivatives of ALA include the LC-PUFAs docosahexaenoic acid (DHA, 22:6ω3) and eicosapentanoic acid (EPA, 20:5ω3). The human body produces relatively low levels of EPA and DHA, because the conversion rate of these fatty acids from ALA is rather slow. However, EPA and DHA can enter the body directly through dietary consumption of foods rich in ω3 fatty acids, such as cold-water fish, shellfish, human milk, or supplements like fish oil. EPA and DHA have been implicated to play a pivotal role in the resolution of inflammation by displaying antiinflammatory properties that promote health benefits. If fish high in ω3 fatty acids (salmon, tuna, herring) is consumed in two or more servings weekly, it has been shown to protect against abnormal heartbeat,

hypertension, atherosclerotic plaque formation in arteries, stroke, and even sudden death. Particularly, DHA is concentrated within organs and systems that are vital for human life, such as the central nervous system (including the brain and retina) and the male reproductive organs.

Derivatives of ω3 and ω6 family LC-PUFAs include prostaglandins (PGs), leukotrienes (LTs), and thromboxanes (TXs). These highly biologically active derivatives, which are not themselves fatty acids, serve as potent signaling molecules in a variety of physiological systems. Moreover, these molecules tend to have somewhat combating effects. The ω6 derivatives often lead to inflammatory processes and vasoconstriction, whereas ω3 derivatives stimulate a less inflammatory response, vasodilation, and have also been implicated in preventing the formation of blood clots. Regardless of the antagonizing events already mentioned, both families of LC-PUFA derivatives have profound hormone-like effects that aid in the regulation of the immune system and inflammatory response. Collectively, the derivatives of ω6 and ω3 fatty acids are important for health and the overall energy balance of the human body.

The body's shift in ω6/ω3 fatty acid ratio can be influenced solely by the diet alone. The ratio of ω6/ω3 fatty acid intake is important because the actions and dietary influx of one family of fatty acids may adversely modify the concentration of the other in a disproportionate manner. Despite this fact, it has been generally accepted that the ideal ω6/ω3 ratio for optimal human health is the consumption of no more than 4 times as much ω6 fatty acids as ω3 fatty acids. In a westernized diet, although vegetable oils are consumed regularly by people, fish or fish products are also eaten but infrequently. Subsequently, the ω6/ω3 fatty acid intake ratio exceeds the ideal limit, indicating that it is necessary for individuals to consume more ω3 fatty acids.

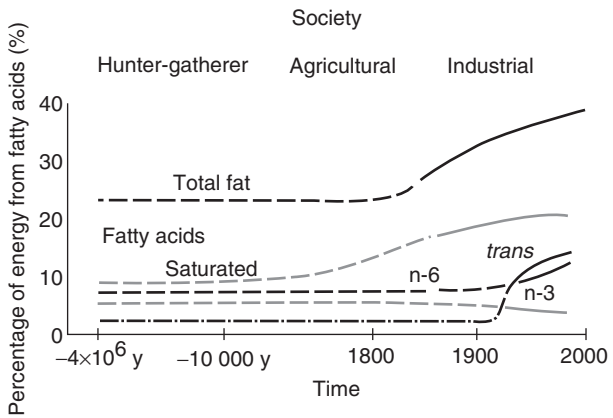

Figure 1 Hypothetical scheme of the relative percentages of fat and different fatty acid families in human nutrition as extrapolated from cross-sectional analyses of contemporary hunter-gatherer populations and from longitudinal observations and their putative changes during the preceding 100 years. Adapted from Simopoulos AP (1995) Evolutionary aspects of diet: Fatty acids, insulin resistance and obesity. In: VanItallie TB and Simopoulos AP (eds.) *Obesity: New Directions in Assessment and Management*, pp. 241–261. Philadelphia: Charles Press.

Dietary Evolution of PUFAs

Humans have undergone intense evolutionary selective pressures in order to optimize their capacity to obtain/store energy and utilize fatty acids – particularly PUFAs, for the purpose of growth, development, and survival. Conversely, dramatic dietary changes in LC-PUFA consumption over the past 100 years have probably created mal-adaptations for our ancient genome as humans have drastically changed the composition of their intake of fatty acids (Figure 1). These dramatic dietary changes are probably driving the onset of human diseases that relate almost exclusively to our current dietary consumption through interactions with human genomic adaptations over many generations when such adaptations have undergone development.

Moreover, the prevalence of disease within westernized countries has disproportionately affected individuals of different populational groups. For example, in the United States, remarkable differences are seen in the disease status between individuals of African and European descent. As a result, health disparities run rapid as populations of African ancestry are disproportionately impacted by inflammatory diseases when exposed to a westernized diet. Both genetic and metabolic changes are perhaps driven by the existing dietary patterns. Recent studies have revealed that the adaptive genetic changes are probably found within genes coding for enzymes by which LC-PUFA biosynthesis are regulated and increased risk for certain populational groups has thus been conferred. Identifying these specific gene-diet mismatches in different human populations will probably lead to both a better understanding of health disparities and effective strategies for preventing and treating human disease.

The topic of recent investigations have upheld the analysis of gene networks that code for enzymes and transporters necessary for the synthesis and incorporation of LC-PUFAs into human blood and tissue (LC-PUFA PATHWAY), Besides diet, active LC-PUFA content may be influenced by genetic fluctuation. LC-PUFAs and their downstream derivatives have been implicated in a variety of health outcomes including brain development, cardiovascular disease (CVD), and pyschological disorders. LC-PUFAs are highly enriched in the brain, being critical for its development and function. It is hypothesized that improvements in the efficiency of LC-PUFA synthesis enabled humans to convert short chain (SC) PUFAs for the synthesis of LC-PUFAs more efficiently. These implications have facilitated the use of the LC-PUFA DHA for its critical role in brain expansion and function. Moreover, one of the most striking dietary changes of the 20th century has been the massive increase in plant-based SC ω6 PUFA consumption that is coupled with lower ω3 PUFA ingestion, creating a dramatic shift in the ω3/ω6 PUFA ratio. This paradigm shift in dietary PUFA consumption has probably the potential to impact different populations at varying levels. In addition, recent studies are beginning to demonstrate the effects of secondary factors, such as genetics and racial ethnicity, on the predisposal of certain populational groups with higher/lower frequency of genetic-derived efficiencies in the LC-PUFA pathway. Thus, certain individuals within a population may be at a high/low risk of acquiring devastating mismatches between their genes and current dietary PUFA profile. This is

especially important because LC-PUFAs like DHA play a critical role during fetal and early infant development. Also, the development of chronic inflammatory diseases such as type-2 diabetes and metabolic syndrome are related almost exclusively to diet alone in adults and is associated with a shift in $\omega6/\omega3$ LC-PUFA content.

Dietary Sources and Recommended Intake of PUFAs

Consumption of 20–35% of total calories from fat has been currently recommended. However, much recent evidence has revealed that the 'type' of fat consumed may be more important to overall health rather than the total fat intake. Fats that elevate low-density lipoprotein (LDL) cholesterol levels (increased risk of heart disease) are attributed as being 'unhealthful,' whereas those that can raise levels of high-density lipoprotein cholesterol (displays opposite actions of LDL and helps eliminate excess cholesterol in the blood) are considered 'healthful'. Unhealthy fats include trans fats, saturated fats, and cholesterol. Healthy fats include monounsaturated fatty acids (MUFAs) and PUFAs, particularly ALA, DHA, and EPA. In an effort to combat the potential harmful effects of adding saturated fatty acids in processed food production, companies in the 1960s started utilizing unsaturated fatty acid oils such as soybean oil. The historical event that preceded the increase in soybean oil consumption in the United States was the 1961 American Heart Association (AHA) Central Committee Advisory Statement by which Americans were replace their saturated fat intake with polyunsaturated fats (Figure 2). Consequently, vegetable oils, shortening, and margarine were recommended as substitutes for animal fats such as butter, cream, and cheese. Unlike the increase in $\omega6$ consumption, dietary intake of $\omega3$ LC-PUFAs has declined, with a $\omega6/\omega3$ ratio now being as high as 15:1.

LA is found in high concentrations in nuts, seeds, and certain vegetable oils made from soybean, safflower, or corn. LA is also abundant in some oils such as those made from canola or flaxseed, even though these oils have an abundance of ALA. Since foods containing oils are very common in the westernized diet, getting sufficient amounts of LA can be easily achieved. Conversely, $\omega3$ PUFAs such as EPA and DHA are

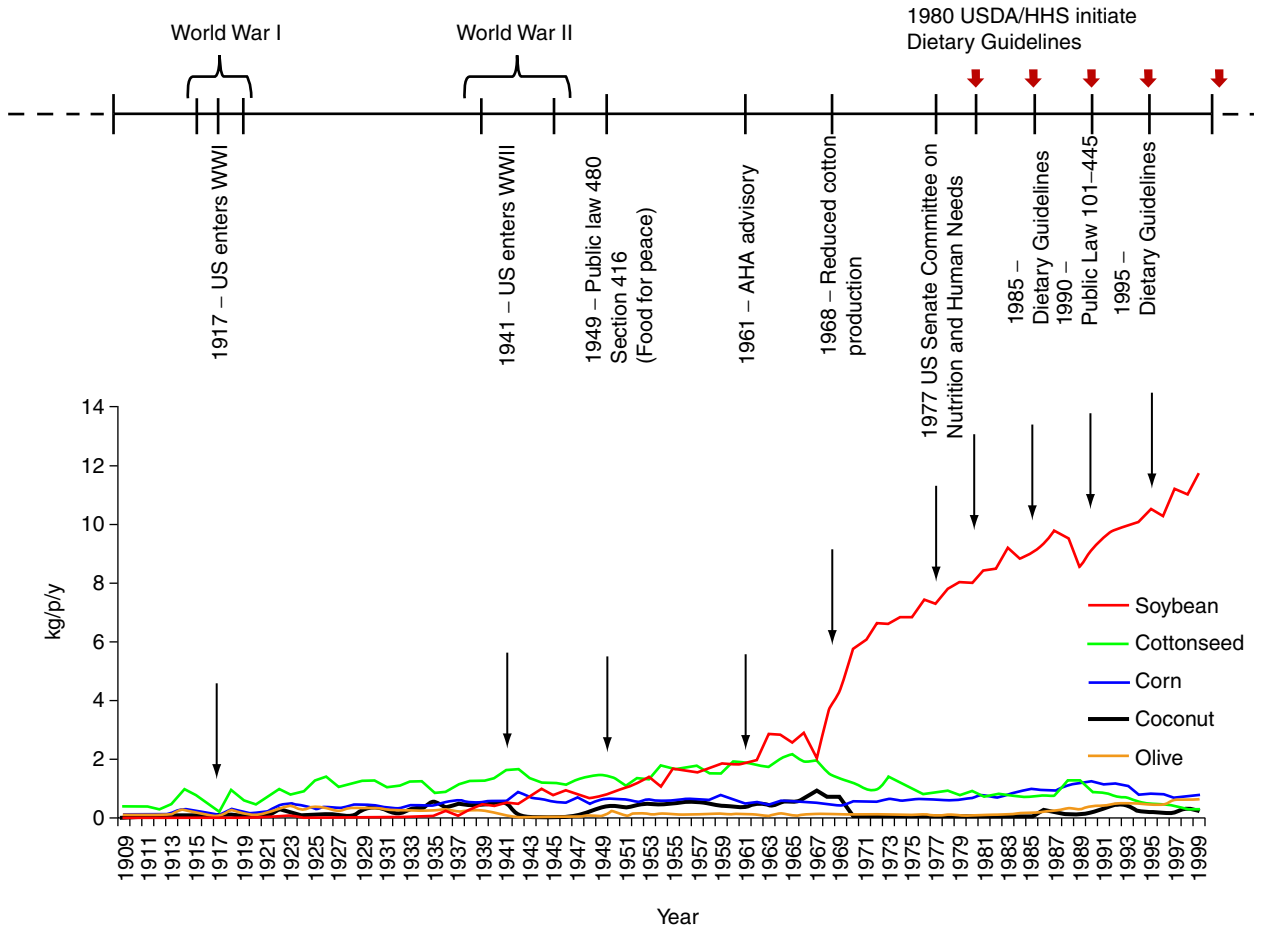

Figure 2 The historical event immediately preceding the largest increase in apparent consumption of soy oil in the United States was the 1961 AHA Central Committee Advisory Statement that advised Americans to replace their saturated fat intake with polyunsaturated fats. Vegetable oils and, to a lesser extent, shortening, and margarine were recommended as replacements for animal fats such as butter, cream, and cheese. Adapted from Blasbalg TL, Hibbeln JR, Ramsden CE, *et al.* (2011) Changes in consumption of omega-3 and omega-6 fatty acids in the United States during the 20th century. *American Journal of Clinical Nutrition* 93(5): 950–962.

found in smaller amounts of the westernized diet because fish and seafood consumption is very minimal when compared to unsaturated oil consumption. However, small amounts of the LC ω3 fatty acid DHA can be found in some meat and egg products.

Dietary Reference Intakes, or DRIs, for both ω3 and ω6 essential fatty acids may also be impacted by the age factor. Adequate intake levels (AIs) for LA are 17 and 12 g day^{-1} for adult males and females, respectively. For ALA, the AIs are 1.6 and 1.1 g day^{-1} for adult males and females, respectively. The Acceptable Macronutrient Distribution Ranges for LA and ALA are 5–10% and 0.6–1.2% of calories, respectively. Furthermore, one need to consume weekly at least two servings of fatty fish high in ω-3 fatty acids in addition to oils rich in ALA such as canola or flaxseed according to the recommendation of health agencies like the AHA and the US Department of Agriculture (USDA). Supplemental recommendations are also encouraged for patients with CVD, as a meta-analysis on the doses of EPA and DHA in fish oil necessary for optimal cardioprotection has demonstrated that a daily intake of 250 mg is an absolute minimum requirement to reduce the risk of some coronary heart diseases. The meta-analysis had revealed that when the intake of EPA and DHA exceeded 250 mg, the risk of sudden cardiac death in a healthy population was reduced by 35% as well as that of nonfatal coronary events by 16%. Further supplementation of EPA and DHA in amounts as much as 1000 mg in fish oil daily has been currently recommended by the AHA for those who already have heart issues.

Metabolism of PUFAs

Fats (lipids) are grouped into two basic subtypes: saturated and unsaturated. To determine whether a fat is saturated or not, there must be one or more double bonds between carbon atoms within the fatty acid carbon chain length. If only one double bond is present, then the fat is called a MUFA. However, if the fat molecule contains two or more double bonds in its carbon chain length, these fats are PUFAs. Saturated fatty acids (SFAs) are fats that do not contain any double bonds within their carbon chain length and are typically solid at room temperature. Many animal products such as butter, certain meats, cheese, and plant oils (coconut and palm) are rich in SFAs. In a westernized diet, most foods contain both SFAs and PUFAs; however, animal products probably contain more SFAs than PUFAs when compared to the products from plant oils.

LC-PUFA precursors are 'essential,' meaning that mammals lack the desaturase enzymes (delta-(Δ)12 and delta-(Δ)15), which add the carbon–carbon double bond to generate LA (ω6) and ALA (ω3). Thus, mammals must obtain the parent fatty acids LA and ALA through the diet, primarily from plant/botanical sources. The enzymes responsible for the subsequent desaturation (fatty acid desaturase (FADS)) and elongation (elongases; ELOVL) steps utilize ω9, ω6, and ω3 substrates (Figure 3). The omega number refers to the position of the carbon at the latest site of desaturation from the terminal methyl carbon atom (omega) of the fatty acid carbon chain. For example, in ω3 PUFAs, the last double bond is located three carbon atoms from the terminal methyl carbon of the molecule.

PUFAs are classified according to their degree of unsaturation and length of the hydrocarbon chain, and can be further subdivided into SC and LC classes. PUFAs that contain 20 or more carbon atoms are classified as LC-PUFAs. There are three PUFA subtypes: the ω9, ω6, and ω3 series. Once obtained through the diet, these parent unsaturated fatty acids can be further converted into fatty acids that are longer in chain length and higher in unsaturation by a series of elongation and desaturation steps, respectively. Through the unsaturated fatty acid pathway, ω9, ω6, and ω3 fatty acids may share similar enzymes for desaturation and elongation.

Oleic acid, the ω9 parent fatty acid, can be obtained through the diet in addition to being synthesized *de-novo* by the body. Palmitic acid (16:0,ω9) is elongated to form stearic acid (18:0,ω9), which is then further desaturated to produce oleic acid (18:1,ω9). The final major product of the ω9 series is mead acid (20:3,ω9), which is synthesized from oleic acid by Δ6 desaturation (FADS2). LA and ALA serve as substrates for other critical LC-PUFAs as well. Depending on which PUFA precursor is consumed, the metabolic fate leads to the production of either ω6 or ω3 LC-PUFAs. Because both fatty acids share comparable enzymes within their reaction pathways, competition may exist between both the ω3 and ω6 fatty acid subsets for metabolic conversion. LA and ALA can both be converted by the Δ6 FADS enzyme (FADS2) to gamma(γ)-linolenic acid (GLA, 18:3ω6) and stearidonic acid (SDA, 18:4ω3), respectively. This metabolic step is rate limiting and is subsequently followed by the elongation of GLA to dihomo-γ-linolenic acid (DGLA, 20:3ω6) as well as of SDA to eicosatetraenoic acid (ETA, 20:4ω3). Another key rate-limiting step is the desaturation of DGLA and ETA by the Δ5 desaturase (FADS1), which leads to the production of arachidonic acid (AA) and EPA, respectively. However, both AA and EPA can be further elongated on the ω3 branch of the PUFA pathway, and the very important LC-PUFA, DHA, is produced by the occurrence of several subsequent elongation and desaturation steps of EPA, followed by beta (β)-oxidation. This β-oxidation step is known as the Sprecher's Shunt and is essential for the retroconversion of EPA into DHA. The desaturation and elongation of fatty acids takes place in the endoplasmic reticulum, but the translocation of PUFAs into peroxisomes is necessitated by the β-oxidation step. Recent studies have revealed that besides peroxisome, mitochondrial β-oxidation may also serve as a secondary pathway for the production of DHA.

The Role of PUFAs in Chronic Disease and Inflammation

Chronic diseases such as CVD, diabetes, obesity, allergy, asthma, and arthritis have a strong underlying inflammatory component. With its normal operation to respond appropriately (pro-inflammatory events) to offending pathogens, the immune system encompasses and destroys these pathogens. After a pathogen is cleared, the immune system reverts back to the preexisting state by breaking the immune response and promoting tissue repair events (anti-inflammatory and

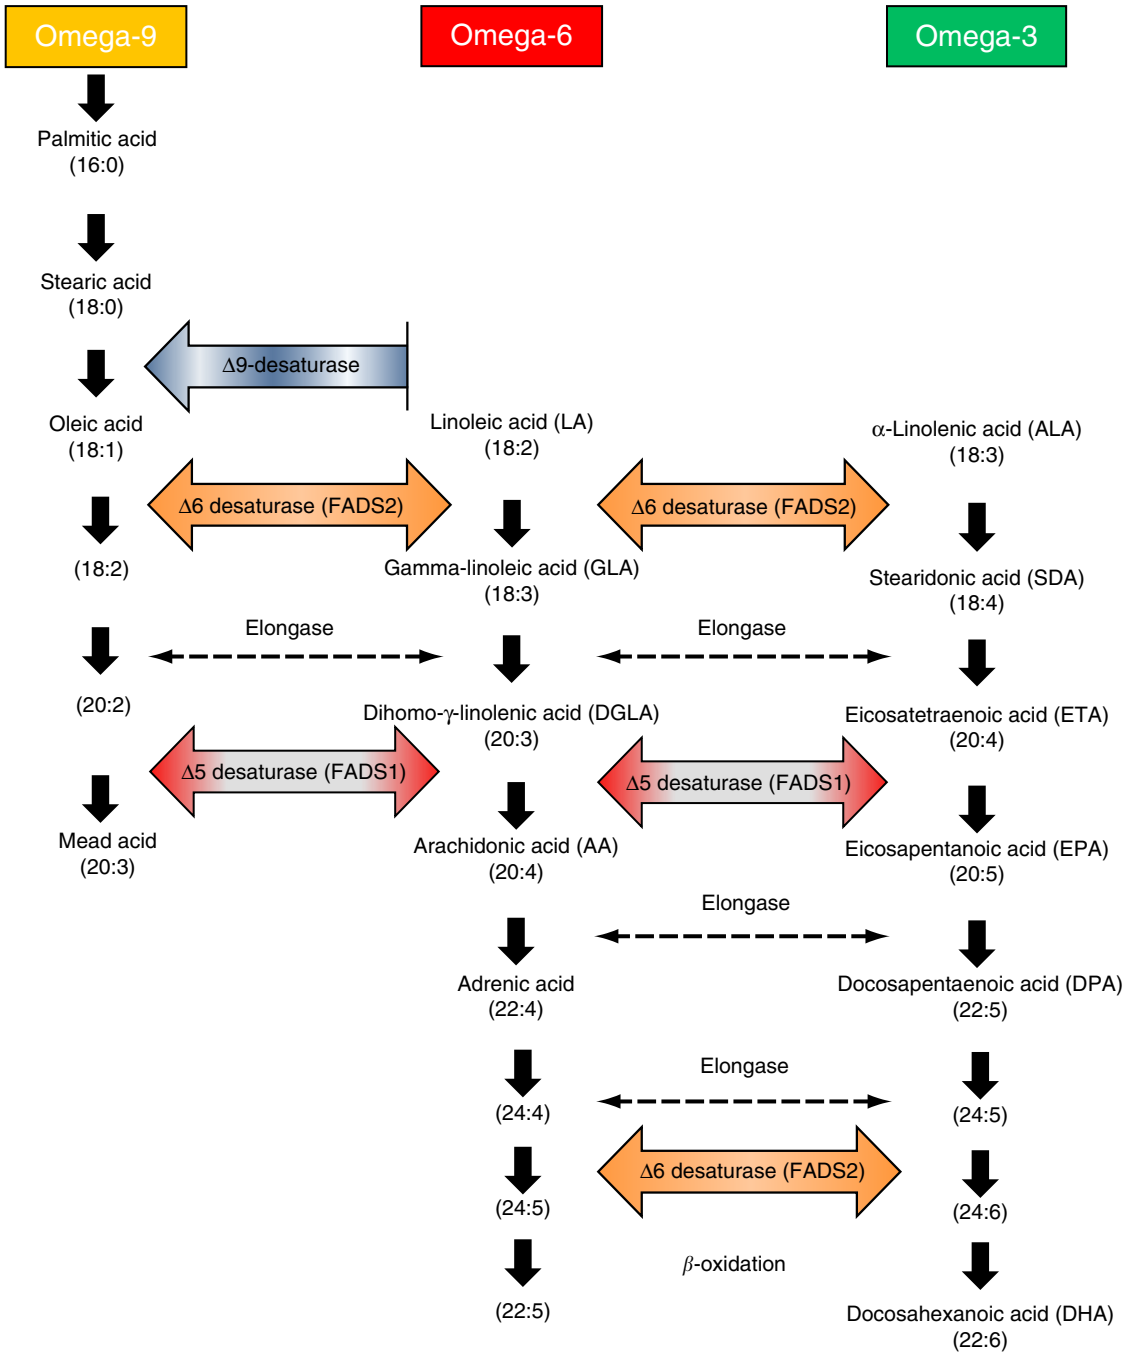

Figure 3 The ω9, ω6 and ω3 fatty acid metabolism pathways.

resolution). The immune system's homeostatic cycle is vital for health and is uniquely integrated with metabolic processesas immune responses are quite metabolically demanding. Metabolic dysregulation can therefore communicate inappropriately with the immune system, which leads to a state of unresolved chronic inflammation. Owing to decreased inflammatory resolution, the onset of chronic diseases can thrive. Despite the erstwhile notion of tissues being strictly in the metabolic realm (adipose, liver, and muscle), they are now recognized to generate a battery of mediators to which immune cells can respond.

Numerous inflammatory mediators are derived from LC-PUFAs. LA and ALA along with their derivatives (AA, EPA, and DHA) may serve as precursors to pro- and anti-inflammatory mediators. With their participation in numerous physiological systems, the ω3 and ω6 series LC-PUFAs have generally been shown to exert opposite actions in these systems (Figure 4). AA gives rise to a variety of lipid mediators (PGs, TXs, and LTs) that are potent stimuli of immune cells, platelets, and the vasculature. In general, pro-inflammatory actions are exhibited by AA-derived mediators. In contrast, anti-inflammatory properties are exhibited by both

the series-3 lipid mediators, which are derived from EPA, and the series-1 lipid mediators, which are derived from the AA precursor DGLA. The resolvin and protectin derivatives of DHA promote tissue repair as an immune response subsides. Thus, an imbalance between the intake and synthesis of the $\omega 3$ and $\omega 6$ LC-PUFAs has the potential to perturb immune system responses as well as the homeostatic processes associating with the system.

LC-PUFAs, especially AA and DHA, are critical for the proper development of the immune system during the neonatal period and neuronal development, respectively, and this role of LC-PUFAs is in addition to their role in immune responses, homeostasis, and energy storage. Fat constitutes almost 60% of the human brain mass and DHA comprises the PUFAs for the rest of the brain mass. Given the prominent roles of PUFA metabolism in both immune and nervous system development and maintenance, dramatic changes in dietary PUFA availability and/or metabolic capability can be predicted to have important health effects.

LC-PUFAs, Populational Differences, and Nutrigenomics

The major regulating enzymes of LC-PUFA biosynthesis are FADS1 and FADS2 (Figure 3). These desaturases are located in the plasma membrane of cellular surface bilayers. Both are located in a variety of tissues throughout the body, with the liver displaying the greatest level of enzymatic activity. Other major tissues displaying FADS1 and FADS2 activity include adipose, brain, heart, and lung. Three members of the FADS gene family have been identified in mammals. Located on chromosome 11, FADS1, 2 and 3 are speculated to have arisen through the mechanism of gene duplication as evidenced by their high degree of sequence identity (62–70%) and almost identical intron/exon organization (Figure 5).

There is strong evidence that FADS1 and FADS2 support the association of PUFA metabolism with circulating and cellular levels of PUFAs but only little evidence exists for loci outside of chromosome 11 being significant. Associations between genetic variants in the FADS gene cluster exist with CVD, cardiovascular mortality, insulin resistance, metabolic syndrome, breast milk fatty acid profile, and childhood IQ. Among FADS gene variants, many investigators have identified single nucleotide polymorphisms (SNPs). These SNPs are mapped to the FADS gene family on chromosome 11, and on observation the SNPs have strong genome-wide association signals that are associated with PUFA levels. Although these genetic findings are valuable, most have been conducted only in populations of individuals with European descent and there is limited data available for other ethnic populations. In contrast, when examining comparative studies involving American subjects of European and African descent, striking populational-based differences have been observed between circulating AA levels and estimated FADS1 activity. On average, African American subjects have exhibited significantly higher fasting AA levels than European Americans. Earlier comparisons of circulating fatty acids by population had revealed that AA levels in subjects of Zimbabwe Africa were almost twice that of Europeans.

Importantly, it was observed that such AA levels were strongly correlated with the genetic variations near the FADS gene cluster. When comparing the circulating AA levels between European and African Americans in the case of diabetes, metabolic syndrome, or healthy subjects, significantly higher levels of AA are found among African Americans. An inverse relationship was seen for DGLA, the immediate precursor of AA, suggesting that genotypic and populational differences in the enzymatic efficiency of FADS1 exist, as estimated from the AA/DGLA product–precursor ratio. Importantly, genetic

variants in the FADS gene cluster associated with high FADS1 activity were found to be nearly twice as prevalent in African Americans (~81%) than in European Americans (46%). In contrast, genetic variants associated with low FADS1 activity were observed as being rare within the sample of African American study participants. Collectively, these findings suggest that African Americans are genetically predisposed for more efficient conversion of dietary precursors to LC-PUFAs. Mapping these different genetic variants near the FADS gene cluster suggests that the fixation of PUFA metabolic variants has evolved throughout the African continent. In contrast, populations beyond Africa show increased frequency of genetic variants due to a lower rate of PUFA metabolism, and future studies are being focused on them.

Safety Considerations of PUFAs

Although optimal daily intake of PUFAs still remains unknown, additional questions regarding other dietary constituents need to be addressed. High dietary consumption of PUFAs and PUFA supplements may entail a potential risk of adverse effects and it is important to examine the experimental and clinical data regarding the safety of PUFA intake. When PUFAs are exposed to oxidative stress, they may be attacked by free radicals (reactive oxygen species) and are oxidized into lipid peroxides. The downstream derivatives of lipid peroxide metabolism include molecules such as ketones, aldehydes, and cyclic peroxides, which may potentially modify other lipids and proteins within the cell membrane that contain PUFAs. Lipid peroxidation is involved in the progression and pathogenesis of inflammation, various cancers, and atherosclerotic plaque formation.

Food products containing PUFAs that have been oxidized into lipid peroxides can be toxic; however, this is easily detectable. When PUFAs within food products are oxidized, such food products become rancid and develop an unpalatable taste. This often prevents the intake of large amounts of products containing lipid peroxide derivatives. Nonetheless, lipid peroxidation still remains a potential health hazard within industrial food settings because many products are manufactured and processed under conditions that allow oxidation. In a westernized diet, where the intake of processed foods using PUFA oils is high, it may be reasonable to consider supplementing the diet with antioxidants. Although dietary recommendations of antioxidants for diets rich in PUFAs have not yet been defined, their habitual incorporation may remedy the potential effects of lipid peroxide derivatives.

Derivates of ω3 PUFAs, which have been implicated in preventing the formation of blood clots, may also have undesirable effects when consumed in excess. The incidence of increased bleeding (from the nose, urinary tract, and/or obstetric bleedings) was associated with the unique diet of Greenland Eskimos. These individuals have ω3 PUFA intakes that are 7–10 g day^{-1}. This high ω3 consumption has been implicated in the inhibition of platelet blood clotting processes, causing a shift in eicosanoid metabolism when AA is replaced by EPA in platelet membranes. The increasing shift in PUFA intake leads to the generation of thromboxanes and prostacyclins that in totality leads to a more vasodilatory and antiaggregatory state. Additionally, very high ω3 intakes have been implicated in decreasing platelet counts.

Commercial PUFA supplements have recently become too popular. Drug stores, wellness clinics, and physicians are all working to determine the clinical efficacy of PUFA supplements or that of foods fortified with PUFAs. It should be noted that PUFA intake should be at the expense of saturated fat intake because SFAs are generally accepted as being less healthy than PUFAs. However, a habitual diet with high amounts of PUFAs can result in weight gain and possibly potentiate the progression of metabolic disorders. In regards to PUFA products, it is of critical importance that consumers are informed properly of potentially toxic substances such as those found in heavy metals, pesticides, fat soluble vitamins, and lipid peroxides.

The shift in consuming PUFAs instead of SFAs has been associated in promoting health benefits, especially in CVD. However, the current recommendation that at least 10% of daily energy intake must come from ω6 fatty acids may not be as practical for a variety of populational groups because studies to derive these current values have been performed predominantly on populations of European decent. Thus, further research is required to demonstrate populational differences in the capacity of separate ethnic groups to metabolize PUFAs. Defining differences in PUFA metabolism among ethnic groups allows for the potential to elucidate novel alternatives toward understanding undefined functions of lipid metabolism while deriving more sound recommendations for these nutrients.

Conclusions

Dietary fat consumption has undergone dramatic changes over the past five decades. The evolutionary discordance proposes a new set of interactions of how the human genome responds to its environment with respect to diet. Diets maintained by our ancestors, all the way to modern man, have been fairly constant, with minor changes occurring over long periods of time. The hunter-gatherer phenotype, seen by our ancestors, allowed for the stabilization of genomic alterations, which allowed for man to adapt to a changing environment and diet. However, due to the dramatic change in diets of westernized populations today, many diseases have emerged that are attributable to diet alone. In many westernized countries, such as the United States, sixty-five percent of adults over the age of twenty are either overweight or obese. In addition, recent studies have started revealing that there may be distinct ethnic differences in the efficiency of certain populational groups to synthesize LC-PUFAs. Previous studies have demonstrated increased levels of AA within the fasting serum of diabetic/metabolic syndrome patients of African descent when compared to those of European descent. Recent investigations have also explored genetic variations in FADS genes, using genetic tools like the International HAPMAP database (hapmap.ncbi.nlm.nih.gov/), and have identified many genetic polymorphisms that associate with PUFA metabolism.

The study of the genetic and physiological response to diet is known as nutrigenomics, which is a relatively new field of science, yet more commonly, it is personalized nutrition. The rapidly emerging field of personalized medicine will be important for identifying those at risk, for a given human disease. Nonetheless, the impact of personalized medicine is likely to be dwarfed by the significance of understanding the basis of chronic inflammatory diseases being observed epidemically, especially by certain racial/ethnic groups in developed countries. For these previously mentioned reasons, it is critical to study additional ethnic populations, which rather tend to be highly under-studied and neglected in the context of human genetics.

Genetic analyses may show a trend toward FADS gene variants effecting FADS1 activity and ω6 PUFA metabolism. However, direct evidence is not yet available for demonstrating a correlation between genetic changes at the FADS gene locus impacting LC-PUFA metabolism and FADS1 activity. More importantly, these deoxyribonucleic acid (DNA) variations could confer different phenotypic outcomes among individuals from different populational groups. Besides direct changes in genomic composition, DNA variations may have the ability to impact disease onset or susceptibility by altering other components such as messenger ribonucleic acid transcription, protein expression, protein stability, and levels of metabolites. Although numerous genetic markers and metabolic changes are probably contributing to health disparities, certain genetic polymorphisms could confer increased risk for particular populations with western-type diet when the enzymes regulating PUFA biosynthesis (FADS) contain such genetic polymorphisms. Consequently, the examination of genetic differences, and whether they translate into functional differences in fatty acid metabolism may be critical toward understanding the potential role of populational-specific phenotypes/genotypes in health disparities. By identifying DNA variations in those populations that are associated with the pandemic of chronic inflammatory diseases, which are exacerbated by consumption of a western-type diet, it will be possible to detect and prevent disease progression by diet alterations in at-risk groups. Preventing chronic disease development will significantly decrease the burden on our healthcare system, and most importantly, the quality of life for patients and their families will improve.

Food Allergies and Intolerances

SM Gendel, Food and Drug Administration, College Park, MD, USA

Glossary

Basophils Basophils are circulating immune-system cells that bind IgE through a surface receptor and release effector molecules by degranulation after activation.

Eosinophilic esophagitis A condition characterized by infiltration of esophageal tissue by eosinophils. This can result in difficulty in swallowing, heart burn, and food impaction.

Eosinophilic gastroenteritis A condition characterized by infiltration of gastrointestinal tissues by eosinophils. This can result in a range of symptoms, including nausea, vomiting, diarrhea, and malabsorption.

Major histocompatibility complex The major histocompatibility complex (MHC) is a gene complex that produces a number of cell surface proteins that have a place in a number of roles in the immune system.

Mast cells Mast cells are noncirculating immune-system cells that bind IgE and release effector molecules by degranulation after activation.

Oral tolerance Also known as immune tolerance, oral tolerance is a state in which the immune system does not respond to a particular external antigen.

Introduction

Consumers experience adverse reactions to foods for a variety of reasons. Generally, these have been described as being immune-mediated (sometimes called hypersensitivities), nonimmune-mediated (also known as intolerances), or of unknown (or idiopathic) origin (Figure 1). Within each of these broad categories, there are multiple biological mechanisms that produce the final reaction.

Nonimmune-Mediated Adverse Reactions

The nonimmune-mediated intolerances can be broadly thought of as either being metabolic or toxicological in origin; that is, they derive primarily from causes that are either internal or external to the consumer. The most common forms of metabolic intolerance are associated with enzyme deficiencies. These include problems such as lactose intolerance, aldehyde dehydrogenase deficiency, and favism. Lactose intolerance is a common metabolic deficiency caused by a lack of the lactase enzyme, which cleaves the lactose in dairy products into glucose and galactose. This enzyme is needed during infancy and early childhood, when milk is the major (or only) form of nutrition. However, lactase production declines or stops as part of the normal maturation process after infancy in most of the population. It has been estimated that up to 70% of adults worldwide have reduced lactase activity. When lactase-negative individuals eat lactose-containing products, generally dairy foods, the sugar passes into the large intestine, where it is fermented by the gut microbiota. This can lead to abdominal pain or discomfort, flatulence, and diarrhea. A deficiency of mitochondrial aldehyde dehydrogenase results in reduced ability to oxidize acetaldehyde produced during the metabolism of alcohol. This leads to symptoms of alcohol-flush syndrome, erythema, or flushing, when alcoholic beverages are consumed. This deficiency is found primarily in Asian populations. Favism is the result of a deficiency in glucose-6-phosphate dehydrogenase (G6PDH), although not everyone with low G6PDH manifests favism. Favism is a hemolytic response (an abnormal breakdown and loss of red blood cells) that occurs after consumption of fava beans (broad beans) by individuals with low G6PDH. Although the mechanism of the response has not been fully described, it appears to involve oxidative damage linked to exposure to the glycosides vicine and covicine in fava beans.

The second form of nonimmune-mediated intolerance is caused by toxicological or pharmacological reactions to

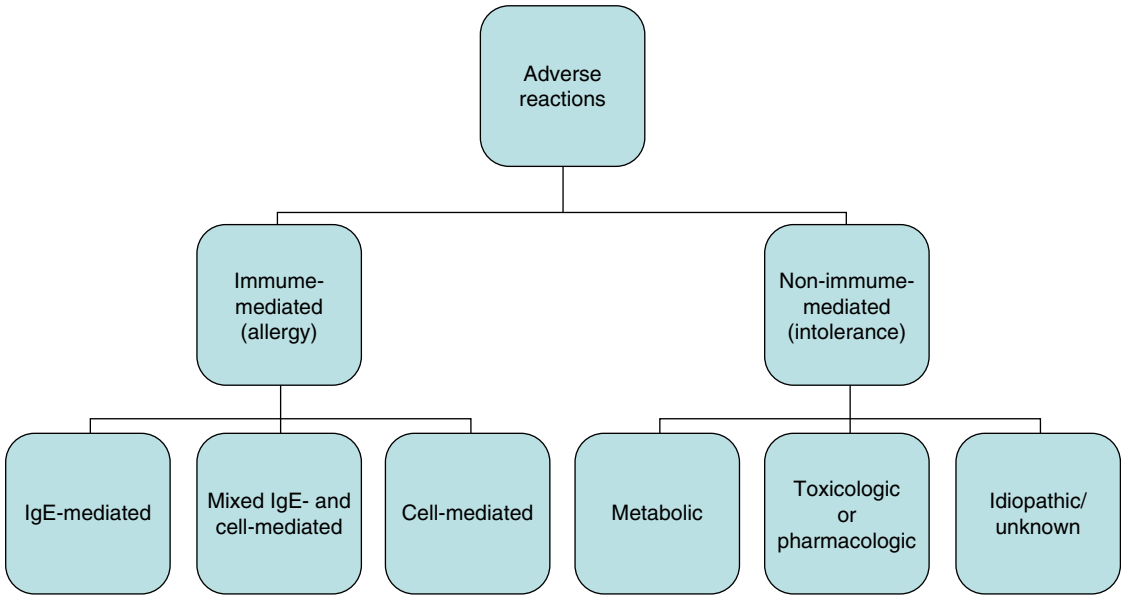

Figure 1 Types of adverse reactions to foods.

foodborne chemicals. These chemicals may include normal components of foods such as caffeine, chemicals added to foods such as monosodium glutamate or sulfites, chemicals formed by biological processes such as histamine, or chemical contaminants such as melamine. In many cases, the underlying metabolic process that leads to an adverse reaction is unknown. In other cases (e.g., caffeine) the pharmacology of the substance is well known although it may not be clear why certain individuals are more sensitive than others. These reactions generally occur after consumption of a relatively large amount of these chemicals in the food. Caffeine is the most widely consumed example of the methylxanthines. These compounds can affect a number of organ systems, including the nervous, respiratory, and cardiovascular systems. The most commonly observed adverse reactions are generally similar to panic or anxiety disorders. Histamine is a vasoactive amine produced by decarboxylation of a naturally occurring amino acid (histidine), generally by microbial action. Related compounds also produced in foods include tyramine, dopamine, and serotonin. Normally these compounds are rapidly converted to inactive derivatives. However, ingestion of large amounts can exceed the capacity of the metabolic system and can lead to clinical effects. For example, ingestion of large amounts of histamine (scombroid poisoning) leads to an adverse reaction that resembles anaphylaxis.

Immune-Mediated Adverse Reactions

Immune-mediated adverse reactions can occur through IgE-mediated, mixed IgE- and cell-mediated, or cell-mediated mechanisms. The IgE-mediated reactions represent the classic type of food allergy and are differentiated from the other forms of immune-mediated reactions in that they generally have a rapid onset and may be severe.

Food Allergy

The manifestation of an IgE-mediated food allergy is a two-stage process involving sensitization and elicitation (Figure 2). Sensitization triggers the production of IgE antibodies that recognize epitopes on food proteins. These antibodies bind to effectors cells, either mast cells or basophils. Re-exposure to the target food protein leads to crosslinking of IgE molecules on the surfaces of the effector cells, triggering release of effector molecules such as histamine and tryptase. These effector molecules interact with other cellular receptors to trigger the physiological processes that manifest as an allergic reaction.

Little is known about the overall mechanism of allergic sensitization in humans, although the general outline of the process can be inferred from detailed studies *in vitro* and from animal model systems. One important point that emerges from these studies is that sensitization can be viewed as the inverse of oral tolerance. Sensitization involves uptake of food proteins, intracellular processing of these proteins, and presentation of peptide fragments by major histocompatibility complex (MHC) proteins on the surface of antigen-presenting cells (APCs). The APCs then interact with CD^{4+} T-lymphocytes. Depending on a number of factors that are not yet fully understood, this interaction stimulates differentiation of the T-lymphocytes into Th2 type cells. The Th2 cells interact with B-cells to stimulate production of IgE antibodies to the proteins. These antibodies bind to the surfaces of mast cells and basophils through an IgE-specific receptor.

In some cases, sensitization to food proteins may occur through nonoral routes of exposure. For example, in oral allergy syndrome (OAS) sensitization occurs through inhalant exposure to pollen proteins. Immunologic crossreactivity between some pollen proteins and similar food proteins can result in a reaction involving pruritis and angiodema of the lips, tongue, palate, and throat in a sensitized individual. It

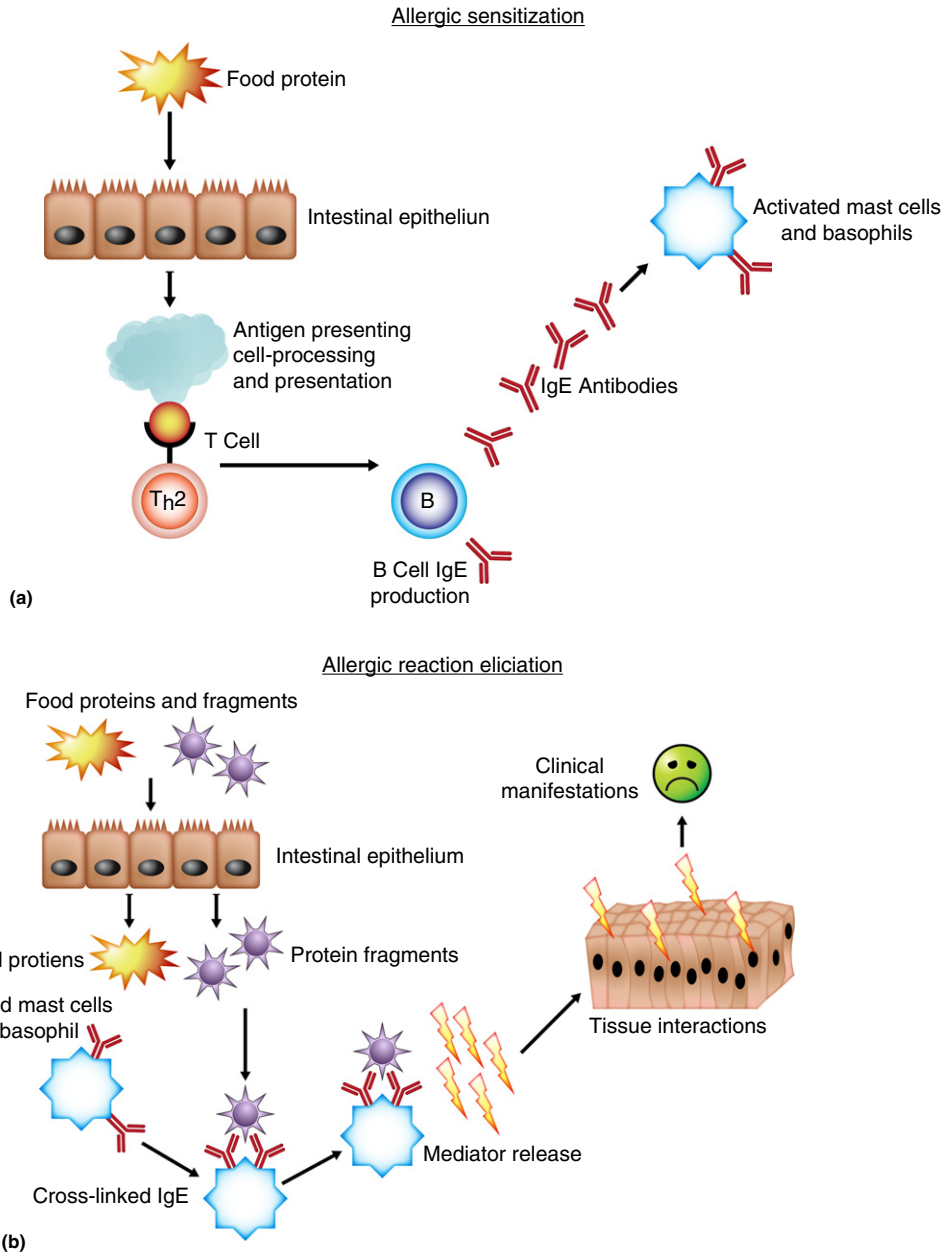

Figure 2 Mechanisms of an allergic reaction: (a) allergic sensitization and (b) elicitation of an allergic reaction.

may also be possible for sensitizing exposure to occur through skin contact.

Elicitation of an allergic reaction occurs on subsequent exposure to the same (or similar) proteins through crosslinking of IgE molecules on the surface of the effector cells. This crosslinking triggers a degranulation process that releases a suite of active molecules, including histamine and cell-type-specific cytokines and chemokines. It is the interaction of these signal molecules with tissue receptors that leads to manifestation of the signs and symptoms of an allergic reaction. The need to crosslink two IgE molecules to initiate the degranulation process suggests that relatively large peptide fragments must survive digestion and uptake in the gut in order to provoke a reaction. However, it is not known if this requires a single polypeptide or whether hybrid molecules produced by aggregation during food processing or consumption can trigger reactions.

IgE-mediated allergic reactions are usually rapid in onset, occurring within minutes of exposure. However, biphasic reactions are also seen in which the initial rapid manifestations subside or are controlled, followed by more severe signs several hours later. The signs and symptoms of an allergic reaction can range in severity from mild (that is, tingling of the lips) to life-threatening (anaphylactic shock; Table 1). Reactions can involve one or more organ systems and can be either localized or diffuse. The most severe reactions involve

Table 1 Signs and symptoms of allergic reactions

Organ system	*Signs and symptoms*
Cutaneous	
Skin	Itching Flushing Pilor erection ('goosebumps') Urticria (hives) Angioedema (swelling)
Oral cavity	Itching Numbness Dryness Edema
Eyes/conjunctiva	Itching Edema (periorbital) Redness of conjunctiva Tearing
Gastrointestinal	Nausea Abdominal pain Vomiting Diarrhea
Respiratory	
Nose	Itching Congestion or runniness Sneezing
Throat	Itching Dryness Tightness Hoarseness Wheeze Cough Swelling
Lungs	Respiratory distress Wheeze Cough
Cardiovascular	Chest pain Tightness Faintness/fainting Dizziness Hypotension Dysrhythmia Shock

multiple organ systems, particularly the respiratory and circulatory systems. Extrinsic factors such as exercise, alcohol consumption, and viral infection can affect both the likelihood and severity of reaction in some individuals. Severe reactions are also more likely to occur in individuals with uncontrolled asthma. There are no treatments to prevent a food allergic reaction. The medical response to a food allergic reaction focuses on preventing the progression of symptoms by administering epinephrine followed by antihistamines and other agents such as corticosteroids to minimize effector molecule responses and to maintain fluid balance.

There are few data related to why some individuals develop food allergies whereas most others do not. There appears to be a genetic component to susceptibility because the odds of developing an allergy are greater for individuals with close relatives who are allergic than for the general population. However, this increased susceptibility is not predictive of whether an individual will develop a food allergy. There is also no indication that susceptibility is related to either the type of food allergy that might develop or to the level of individual sensitivity.

Although individual foods may contain hundreds of unique proteins and peptides, only a small percent of these appear to provoke sensitization. It is widely believed that highly expressed proteins that are resistant to processing and digestion are more likely to be allergens. Binding studies using sera from allergic patients show that an individual might be sensitized to one or more proteins in a single food, and that the spectrum of specific proteins varies between individuals. However, these studies have also shown that certain proteins are more likely to be allergens than others. Those proteins that are recognized by IgE antibodies from more than half of the individuals who are sensitive to a specific food are called the 'major allergens.'

Although any food can be allergenic, a limited number of foods are responsible for the bulk of clinically significant allergies and allergic reactions. The most common allergenic foods worldwide include milk, eggs, peanuts, tree nuts, wheat, soy, fish, and shellfish. In addition, in some countries allergies to sesame, mustard, and buckwheat are considered common. It is not clear why these particular foods are the most common allergenic foods, although patterns of exposure probably play a role in determining relative risk. Many allergies develop in early childhood, but some (e.g., fish and shellfish allergies) often develop in adults.

There are limited data on the prevalence of food allergies, either in aggregate or to specific foods. It is difficult to measure the prevalence of food allergies through general health surveys because different surveys have used different methods and diagnostic criteria. Attempts to measure rates of allergic reactions through review of hospital records are similarly difficult because of inconsistent recording practices. Nevertheless, it is generally estimated that 2–3% of adults and up to 5–6% of children have true IgE-mediated food allergies. Although most allergic individuals react to a single food, some individuals react to multiple foods. Evidence exists that the prevalence of food allergy (and respiratory allergy) has increased significantly over the last two decades. Although many allergies are lifelong, a significant fraction of children will outgrow milk and egg allergies.

The diagnosis of food allergies involves the use of both a medical history and clinical tests. The history is used to establish a temporal association between consumption and reaction and to distinguish food allergies from intolerances or foodborne illness. The most useful clinical tests are skin prick tests, *in-vitro* assays that measure IgE titers, and tests that detect the presence of IgE specific for a particular food. Negative results in these clinical tests are considered to have a high predictive value for the absence of a food allergy. Positive results have a lower predictive value for the presence of clinically significant allergies because individuals may be sensitized (that is, they may have food-specific IgE) without showing clinical reactions. The 'gold standard' for allergy diagnosis and for understanding levels of sensitivity is the double blind placebo controlled food challenge (DBPCFC) using the first objective sign of a reaction as the endpoint.

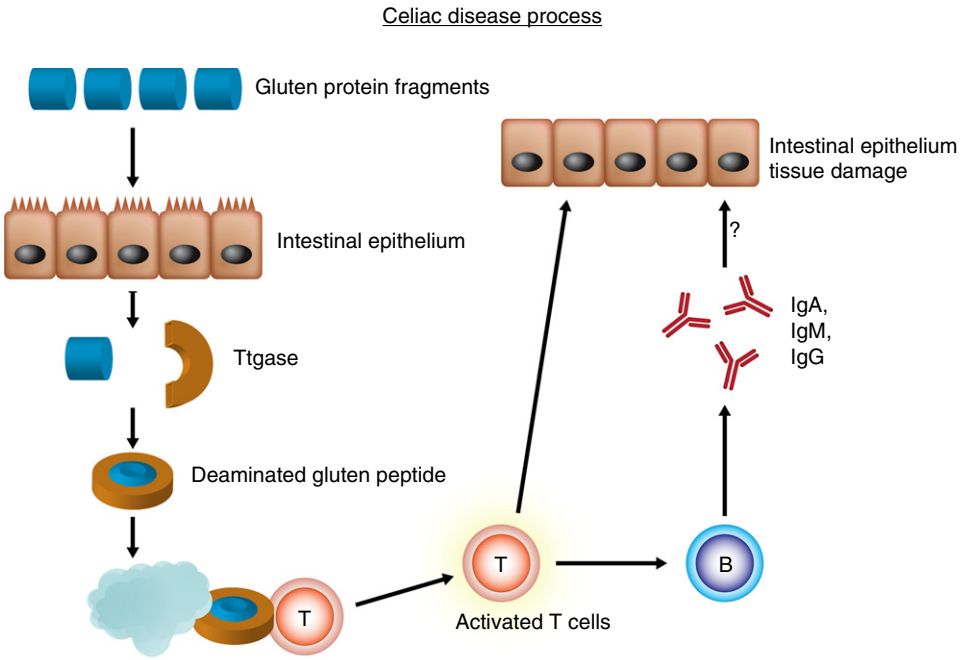

Figure 3 Mechanism of celiac disease.

The level of exposure required to elicit a reaction in a food allergic individual varies tremendously in the sensitive population. DBPCFC studies have found minimal eliciting doses for individuals over ranges as large as 6 orders of magnitude. The most sensitive individuals may react to less than 1 mg of protein. These studies also suggest that the specific food, the form of protein, the dose escalation pattern, and the nature of any masking agents used in a DBPCFC study may affect the observed minimal eliciting doses.

Because there is no cure for food allergy at this time, allergic patients must avoid eating those foods that provoke reactions. This includes avoiding both whole foods and any derivatives or ingredients that contain proteins from those foods. Practising avoidance is difficult when food labels use complex or technical terms to describe ingredients. In the last several years, a number of jurisdictions have implemented food allergen labeling laws or regulations that mandate the use of clear language to indicate the presence of ingredients derived from defined sets of food allergens. This improved clarity has not been extended to food service or retail environments.

Several approaches to eliminating or mitigating food allergies are currently undergoing preliminary clinical evaluation. These include desensitization, the use of anti-IgE antibodies, and herbal medications. Preliminary results indicate that some or all of these approaches may be effective for some sensitive individuals, although a number of questions must be resolved before these treatments can be applied more broadly.

IgE antibodies are also involved in 'mixed' reactions that involve both antibodies and cell-mediated processes. The two most common forms of these mixed reactions are eosinophilic esophagitis and eosinophilic gastroenteritis. Both of these syndromes involve eosinophilic infiltration of sections of the digestive tract. Food-specific IgE can be detected in individuals with these disorders and symptom resolution may occur after avoidance of these specific foods. However, reactions are typically localized to the intestinal tract and do not result in typical IgE-mediated symptoms.

Celiac Disease

Non-IgE-mediated reactions include protein-induced enteropathies, cell-mediated reactions, and celiac disease. Celiac disease is a hypersensitivity associated with consumption of gluten-containing grains (Figure 3). Celiac disease can have a wide range of clinical manifestations. The most distinctive effect is damage to the villi of the small intestine leading to gastrointestinal illness (including diarrhea, abdominal pain, nausea, and vomiting), and nutrient malabsorption. Celiac disease can also manifest through a wide range of symptoms that are less obviously linked to the digestive system such as anemia, fatigue, a skin disorder called dermatitis herpetiformis, or neurological problems. Individuals with celiac disease are also more likely to develop certain autoimmune diseases and malignancies than the general population. Definitive diagnosis of celiac disease requires histological examination of intestinal biopsy specimens. However, not all individuals with morphological changes have clinical symptoms, a condition that is sometimes called 'silent celiac disease.' It is not know what proportion of these individuals will eventually develop clinical manifestations.

Celiac disease occurs in genetically predisposed individuals who carry histocompatibility haplotyes HLA-DQ2 and HLA-DQ8. Although these haplotypes are necessary for development of celiac disease they are not sufficient. Other genetic and environmental factors determine which susceptible individuals will develop either 'silent' or frank celiac disease. These factors probably also determine the age at which symptoms

develop, the severity of those symptoms, and the progression of symptoms over time.

In susceptible individuals, a cascade of events occurs when the enzyme tissue transglutaminase (tTG) binds to gluten, which potentiates uptake and presentation by APC in the intestinal lamina propria. This triggers a T cell response leading to production of antibodies directed at gluten and to tTG as well as to direct T cell-mediated tissue damage that leads to disease manifestation.

As with food allergy, there is no treatment or cure for celiac disease. Individuals with celiac disease must avoid consumption of 'gluten,' which includes wheat, rye, and barley, and ingredients containing proteins from these grains. A fraction of individuals with celiac disease may also be sensitive to the homologous proteins from oats.

Idiopathic Adverse Reactions

Adverse reactions can also be idiopathic. Although the mechanism of reaction is unknown, such reactions are not necessarily rare. For example, sulfite sensitivity has been estimated to occur in as many as 10% of the asthmatic population. Although the mechanism of this sensitivity is unknown, regulatory agencies have been able to establish labeling and usage limits to protect sensitive consumers, which have greatly reduced the number of reported reactions each year. Other idiopathic reactions can be considered as 'emerging' issues. For example, the syndrome known as 'pine mouth' (a transient metallic taste disturbance after eating pine nuts) has been reported at an increasing rate in the last several years.

Although the mechanisms behind idiopathic reactions such as sulfite sensitivity and 'pine mouth' are unknown, the fact that many individuals experience similar reactions to a single food or food ingredient suggests that the common biological mechanisms exist. In other cases, idiopathic adverse reactions appear to be unique to an individual. Such individual reactions can manifest through virtually any sign or symptom, but can usually be prevented through simple avoidance.

The Future

The application of advanced genomic and molecular technologies promises to have a significant impact on our understanding of the biological mechanisms that underlay all types of adverse reactions. This includes understanding both differences in consumers and differences in the foods that lead to such a variety of sensitivities and range of responses. Further, changes in food labeling regulations have made it easier for sensitive consumers (particularly allergic and gluten-sensitive consumers) to identify and avoid those foods that trigger reactions. Increased awareness should improve our ability to measure and characterize the public health impact of the sensitivities.

Risk Management Measures

Because there are currently no treatments or cures for food allergies, allergic individuals must practice complete avoidance to prevent adverse reactions. This means that these individuals and their care givers become avid readers of food labels. Under the food labeling laws and regulations of many jurisdictions, manufacturers are responsible for providing labels that are complete and accurate, listing all the food allergens that are present in plain language. Manufacturers can insure that their labels meet this standard using Good Manufacturing Practices, supplier controls, and allergen control programs. See Management of Allergens in the Food Industry. Sensitive consumers must also rely on information supplied by restaurants, food service sites (such as schools and hospitals), and retail establishments. See Management of Food Safety in the Food Service Sector. It is also important for physicians to educate allergic consumers on how to respond to the first signs of an allergic reaction, and how to use rescue medications such as epinephrine autoinjectors epi-pens.

The importances of these measures are illustrated regularly in news stories and medical reports of allergic individuals having severe reactions when exposed to hidden allergens. For example, in late 2010 a 13-year-old student with peanut allergy in a Chicago public school died after eating take-out Chinese food with hidden peanut protein at a school function. Because some allergic individuals are sensitive to very small low levels of protein even small exposures, such as from the use of shared kitchen utensils or through carry-over in frying oil, can lead to severe reactions.

OTHER SIGNIFICANT HAZARDS

Food-Related Choking

B Altkorn, G Rider, X Chen, and D Stool, Intertek, Oak Brook, IL, USA

Glossary

Asphyxia Oxygen deprivation caused by inability to breathe normally.

Asphyxia by ingestion Asphyxia caused by ingestion of food or a foreign body is the result of the distension of the anterior wall of the esophagus into the tracheal volume.

Aspiration Inhalation of food or other matter into the airway rather than the esophagus.

Bolus A mass of food that has been chewed or otherwise prepared for swallowing.

Choking Asphyxia caused by an object in the oral cavity or oropharynx.

Introduction

Foods are among the most common objects involved in choking and related injuries. Children constitute the largest susceptible subgroup for food-related choking, although other subgroups such as elderly adults and persons with certain psychiatric disorders experience elevated levels of risk. Risk of airway obstruction injury and fatality caused by food is a product of the potential hazard level of the foods, multiplied by exposure to these foods. The risks to the consumer are injury or death, and to the producer and distributer loss of brand value and costly litigation. The potential airway obstruction hazards of food are related to both the design and manufacturing quality of the products. The choking hazard level of many natural foods is inherent; however, the hazard potential of manufactured food products may be controlled and reduced through design. Exposure to choking hazard relates to the physical and cognitive developmental level of the consumer as well as marketing and societal factors. Exposure to foods that present a choking hazard may be mitigated through caregiver vigilance, labeling describing hazards, or packaging, which may mitigate or aggravate hazard manifestation.

Identification of Hazard Factors for Airway Obstruction by Food

The etiology of airway obstruction injuries from foods includes three components: exposure (to the hazardous characteristics), consequences (of contact with the hazard), and mitigation (of the effects of the hazard).

Injury and fatality data related to food and foreign objects may be analyzed to identify benchmark levels of hazard. Cognitive and behavioral foreseeable use and potentially hazardous characteristics should be assessed qualitatively or, preferably, quantified and subjected to comparison and analysis in order to determine potential risk of injury from food objects.

Creation of a Hazardous Condition

Consumer exposure to a food product with hazardous characteristics may create a hazardous condition for airway obstruction. The probability of this event must be determined. For example, food that is hard or elastic may be difficult to process into a bolus. Slippery food may be swallowed inadvertently before it has been masticated. Excessive amount of time (e.g., hard food) or insufficient amount of time (e.g., slippery food) taken to process a food in the oral cavity can increase the likelihood of a possible adverse event.

Probable exposure to the hazard may be determined using anthropometric data (e.g., the number of teeth), pediatric biomechanics, and foreseeable use analysis. The potential for the creation of a hazardous condition includes the evaluation of the impact of physical and cognitive development including the behaviors and capabilities of consumers on their abilities to assess hazardous product characteristics.

Direct Hazard

If a consumer is exposed to hazardous product characteristics, the severity level or potential consequence of this exposure must be evaluated. For example, consider aspiration of a food fragment. Analysis of the interaction of the size, shape, and consistency of the food with the anatomical characteristics of the airway may be conducted to determine the consequences, i.e., potential product-related injuries, based on the foreseeable behaviors consumers will use when interacting with products. To understand the severity of the direct hazard an understanding of the human anatomy may be used to effectively diagnose and demonstrate hazardous product characteristics.

To determine the level of hazard represented by a food involved in a potential choking, aspiration or esophageal obstruction incident, both product characteristics and

 doi:10.1016/B978-0-12-378612-8.00256-0

anatomical characteristics of likely consumers should be examined.

Mitigation of Hazard

The severity level of an airway obstruction hazard caused by food may be reduced by design characteristics that lead to reduced consequence or decreased time to effective treatment. For example, a food engineered to dissolve very rapidly will represent a reduced hazard for serious or fatal airway obstruction injury.

Injury and Fatality Data

Foods are the most common cause of choking, aspiration, and ingestion injuries throughout the world. Three demographic subgroups have particularly high incidence of food-choking injuries and fatalities: neurologically impaired persons, the elderly, and children. The first group includes persons with both permanent and temporary neurological impairment. Elderly persons may be at increased risk of food choking due to loss of motor control or loss of dentition. Children constitute the largest and best-studied susceptible subpopulation and reasons for their increased risk are discussed here in detail.

Approximately 75 children die from choking on food each year in the US, and approximately 10 000 children are seen for food choking incidents in US emergency rooms annually. Toys or consumer products, for example, can be designed to prevent choking by being too large to fit in the oral cavity and tough enough to resist releasing small parts. By contrast, foods must by definition be small enough to fit at least partially into the mouth and lend themselves to maceration or dissolution and subsequent swallowing. The specific foods associated with choking-related injury and fatality exhibit international variation according to local diet. However, the physical and rheological characteristics of foods appearing in injury and fatality studies remain remarkably constant, as do the demographics of persons involved in the incidents. In general, children less than 4 years of age represent most of the injuries and fatalities caused by food foreign object airway obstruction. This trend is demonstrated in Figure 1, which includes injury data collected from 48 children hospitals and fatality data from a 1984 paper by Harris *et al*.

Factors influencing the likelihood and severity of a choking injury include the physical properties of the food and the characteristics of the person consuming the food. Certain foods, such as nuts and seeds, appear with great regularity in injury data, but rarely cause fatalities. Others, including pliable cylindrical foods that can effectively plug the airway, are often associated with fatalities. However, the nature of the food is not the sole predictor of hazard. Anatomical and psychological factors can predispose population subgroups to injury or fatality from specific types of foods. For example, infants and young children have immature dentition that prevents them from grinding food into a smooth homogeneous bolus.

A study examining data related to foreign object injuries treated at 48 children hospitals throughout the world found nuts, meat, sunflower seeds, carrots, chicken (and chicken bones), popcorn, hot dogs, fish (and fish bones), hard candy, and apples to be the 10 foods most frequently associated with injury (see Table 1). Fatality data compiled from a 1984 paper by Harris *et al.* indicate a somewhat different trend (Table 2). Hotdogs, hard candy, nuts, grapes, meat, cookies and biscuits, carrots, apples, popcorn, and peanut butter were found to be the 10 foods most commonly associated with fatal airway obstruction.

Although the data in Tables 1 and 2 provide epidemiological information on the risk associated with foods, they do not provide guidance on inherent hazard. The latter

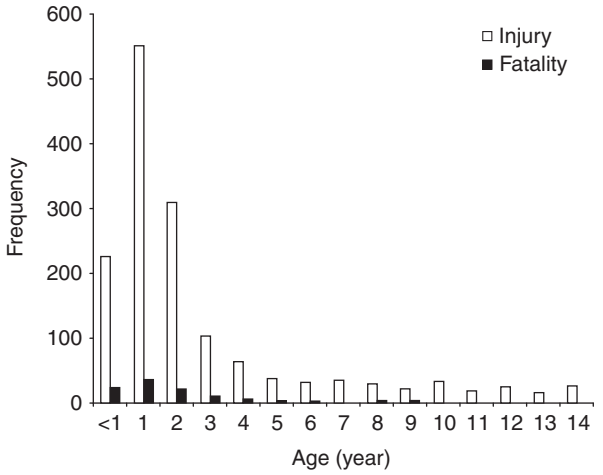

Figure 1 Airway obstruction by food injuries and fatalities by age (fatality data ends at 9 years).

Table 1 Foods associated with choking-related injury (1989–1998)

Food	*Number of injuries*
Nuts and peanuts	406
Meat	93
Sunflower seeds	66
Carrots	57
Chicken and chicken bones	54
Popcorn	44
Hot dog	41
Fish bones and fish	34
Candy	34
Apple	31

Table 2 Foods associated with choking-related fatality (1979–1981)

Food	*Number of fatalities*
Hot dog	17
Candy	10
Nuts and peanuts	9
Grapes	8
Meat	7
Cookies/biscuits	7
Carrots	6
Apple	5
Popcorn	5
Peanut butter	5

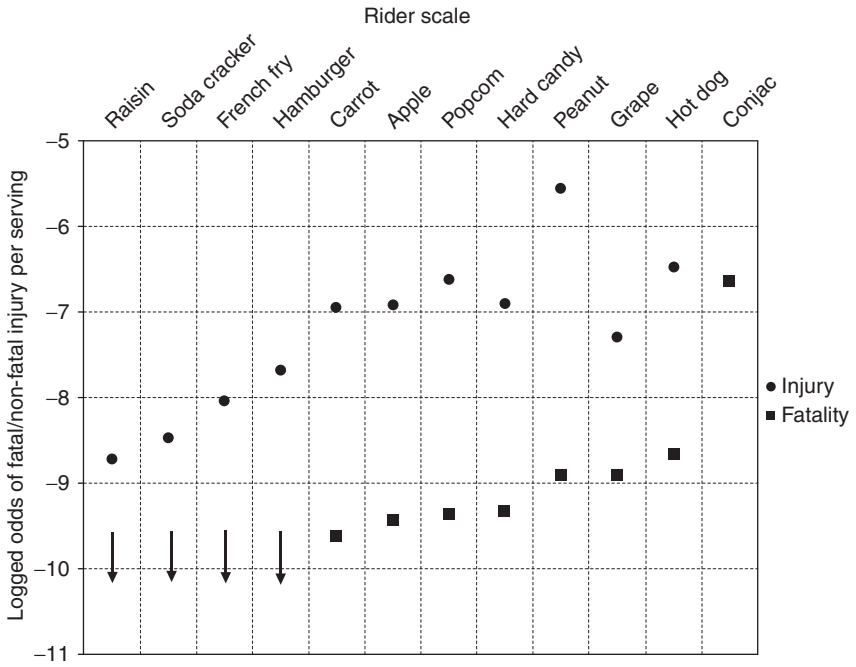

Figure 2 Rider scale: injury and fatality hazard levels of foods.

requires correction of the data for exposure to the foods in question. Knowing the percentage of individuals eating a certain type of food, and the typical serving size of that food when children eat, the annual number of servings can be estimated by dividing the product of percentage of individuals consuming, the population size, the daily consumption amount, and the number of days in 1 year by the typical serving size. Using data from the US, injury and fatality data were projected to serve as a national estimate on an annual basis. Finally, the ratio of injuries and fatalities to the number of annual servings was calculated. The results are plotted in Figure 2.

To create Figure 2, food intake information was acquired for children less than 3 years of age. It is presented in terms of the percentage of individuals consuming a certain type of food, and the daily consumption amount among the individuals who consume. In conjunction with the demographic information, the annual number of servings was estimated.

The ratio of injury and fatality statistics to the annual number of servings of a certain food was calculated as a risk indicator for that food. Raisins, soda crackers, and French fries were associated with risk indicators with low values, regardless of their high exposure level. In contrast, apples and grapes exhibited relatively high likelihood of injuries per serving. This may result from the hazardous characteristics associated with apples and grapes, which demand more advanced oral xmanipulation skills for young children.

Cognitive Development

Potential for airway obstruction is profoundly influenced by the feeding abilities developed at different ages. Newborn children cannot eat solid foods. Their oral cavities are a compact vertically moving structure and are instinctually capable of suckling. Indeed, ultrasound images of late-term fetus show suckling behaviors before gestation. These behaviors are innate or instinctual and are governed by robust hindbrain reaction to stimuli. Consumption of more solid foods is a learned behavior. As children age, they develop muscular coordination and oral fluency with more diverse textures, and their lower jaws gain transverse motility.

As children begin to feed themselves, personality and situational factors affect feeding. The feeding behavior of a child sitting quietly at a table with caregiver vigilance does not create the same hazardous condition as a child eating while running, laughing, or playing with a low level of caregiver vigilance. One child may nibble at food whereas another may prefer to shove large amounts of food into their mouth.

Adults may create a hazardous condition for airway obstruction injury related to food by consuming food while under the influence of drugs or alcohol, or in conjunction with other tasks such as watching television or driving. The elderly may suffer diminished oral perception and cognitive difficulty, leading to the creation of a hazardous condition for airway obstruction. In addition, those members of the population suffering from neurological deficits or developmental delay may have difficulty in handling any but the most benign food textures.

Injury Location and its Effect on Severity

The hazards associated with different types of foods are related to the anatomy of the human upper airway (Figure 3).

Of the majority of foreign objects which are not immediately fatal, approximately 65% lodge in the esophagus

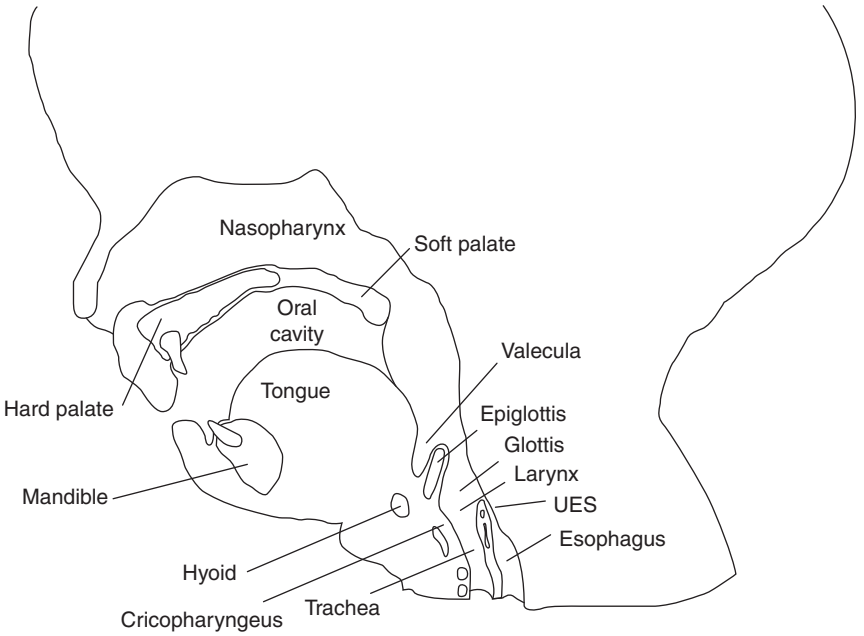

Figure 3 Anatomy of the upper airway.

(ingestion), usually at the level of the crico-pharyngeus. Foreign objects aspirated below the epiglottis make up 26% of injuries (aspiration). Objects lodged in the posterior oral cavity or orophaynx are referred to as choking incidents and make up 5% of incidents (choking). Objects inserted into the nasal passages make up 4% on foreign object incidents (insertion). These locations have a profound effect on severity of injury. Although choking incidents make up only 5% of all incidents, they account for 25% of foreign body incidents resulting in severe injuries including permanent brain damage.

Physical Development

Newborns suffer relatively few airway obstruction events, both because any objects introduced into their oral cavities are likely placed there by a caregiver, and because the laryngeal inlet has not yet lowered into the mature position. Newborn humans can suckle and breathe simultaneously due to this structure.

Dental Development

Incisors erupt at approximately 12 months of age. Incisors are teeth at the front of the upper and lower jaws used to scrape or tear food objects into smaller particles. Canine teeth erupt at 16–21 months of age. Canines are adjacent to the incisors and are used to tear or cut food objects into smaller particles. Molars erupt at 15–24 months of age. Molars are used to crush food objects into smaller particles.

Primary dentition is replaced in the same order by secondary dentition beginning at approximately 4 years of age for incisors, through maturity and full skull development for molars. As indicated in Figure 1, food injuries and fatalities begin before the eruption of incisors but peak at ages 1 and 2 years. This is consistent with a picture in which incisors and canines allow children to tear relatively large pieces from foods but young children lack the molars necessary to process these pieces into easily manageable boluses.

The elderly may be edentulous, and may employ dental appliances. Consequently, this segment of the population may have greater difficulty processing foods for proper bolus formation.

The Swallowing Process

Most of the process of eating is a learned skill. Although a child readily puts most things in its mouth, the ability to distinguish food from any other material has to be taught, and even then it is several years before the whole range of foods can be consumed. Our mastery of the complex set of mechanical actions involving tongue, teeth, and swallowing is so complete that we do not consciously note what we are doing or how we do it. Being able to bite and chew food efficiently is influenced by the sensory properties of the food and its placement in the mouth. Biting and chewing food is a multisensory task that requires a high level of coordination of all parts of the mouth. The degree of skill is determined by sensory awareness and discrimination and integrated coordination of the jaw, lips, cheeks, and tongue.

Airway obstruction from food objects may be caused by premature or inadvertent swallowing. To understand how airway obstruction from food objects occurs, we must first understand the mechanism of successful swallowing.

Swallowing can be roughly divided into four phases: oral preparatory, oral, pharyngeal, and esophageal. The first phase and first half of the second phase are voluntary. If a problem is sensed during these phases there is a possibility of aborting the swallow and preventing potential injury. The second half of the oral phase is involuntary, as are the pharyngeal and

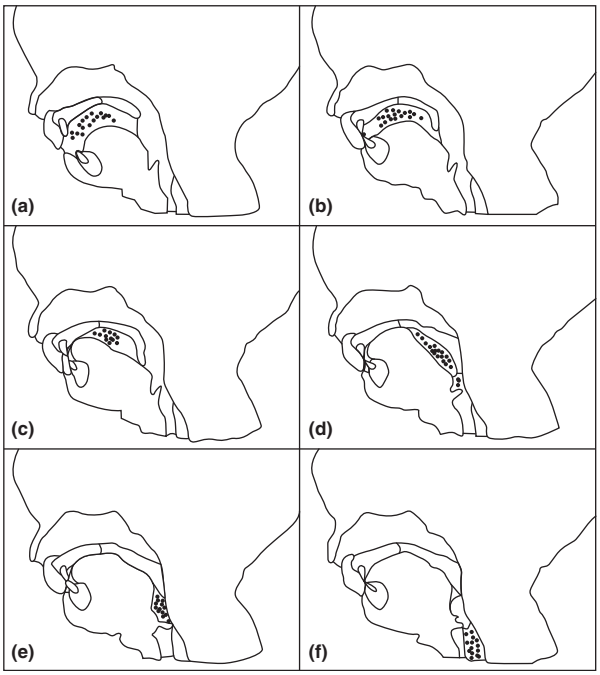

Figure 4 Phases of swallowing: (a) oral preparatory, (b) oral, (c) oral, (d) pharyngeal, (e) pharyngeal, (f) esophageal.

esophageal phases. Once these stages are reached it is impossible to stop or alter the swallow. Figure 4 illustrates the swallowing process, and the swallowing phases are explained in more detail below.

Oral Preparatory Phase

The oral preparatory phase is the initial stage of oral food manipulation in which food is chewed and manipulated into a bolus suitable for swallowing. The length and quality of this phase vary dramatically with the physical properties of the food and the quantity of food taken into the mouth. For infants consuming liquid food no chewing is involved and the oral preparatory phase occurs quickly. As children mature they begin eating thicker liquids and solid foods, and the oral preparatory phase requires more time. For these children and adults, the oral preparatory phase requires execution and synchronization of several highly complex motions. The tongue must effectively detect and sort food particles according to size and move the larger food particles toward the teeth where they can be processed into smaller pieces. In some cases, this task is made even more complicated if additional food is added to the mouth before swallowing. Once the food has been adequately chewed and mixed with saliva, the bolus is moved into a position between the tongue and hard palate. In this position, it is possible to voluntarily initiate a swallow. During the oral preparatory phase, the soft palate is moved into a lowered position by the palatoglossus muscle to help prevent parts of the bolus from prematurely entering the pharynx. The larynx and pharynx are relaxed during this phase and breathing through the nose is possible.

Oral Phase

The oral phase begins with a voluntary peristaltic motion of the tongue that moves the bolus toward the back of the oral cavity. As this phase progresses, the bolus stimulates nerves at the back of the oral cavity that trigger involuntary actions including movement of the bolus into the pharynx and closing of the nasopharynx to prevent reflux of the bolus into the nose. The oral swallowing phase is rapid, generally requiring less than a second.

Pharyngeal Phase

The pharyngeal phase begins as the soft palate elevates to close off the nasopharynx. This phase involves a number of complex coordinated motions. As the bolus enters the pharynx, the pharyngeal muscles constrict to force the bolus through the pharynx. At the same time the larynx is closed to keep food from entering the airway. The epiglottis is brought down over the glottis and the bolus moved toward the upper esophageal sphincter (UES), which is the opening to the esophagus.

In a normal pharyngeal swallow the entire bolus must proceed through the pharynx and the UES whereas the airway is protected against aspiration of the swallowed material. This requires precise coordination between motions of the bolus laryngeal closure that protects the airway.

Esophageal Phase

The esophageal phase consists of a weak involuntary peristaltic wave that moves the bolus through the esophagus and into the stomach. The peristaltic wave propagates at approximately 2–4 cm s^{-1} and terminates when the food passes through the gastroesophageal junction.

At birth, the greater pressure in the esophagus is the principal means of preventing reflux of stomach contents. However in the first few weeks after a term birth, closure at the gastroesophageal junction takes over in preventing reflux. At this point, esophageal swallow peristalsis is much the same in infants, children, and adults.

Mechanism of Injuries from Food

Several characteristics influence a foreign object's chance of penetrating the defenses of the mouth and pharynx (Figure 5).

Foreign objects that are small, thin, smooth, or slick when wet may prematurely slip through the oral cavity and enter the pharynx. Foreign objects that are round or cylindrical and pliable or compressible most effectively form a plug in the airway. Highly viscous foreign objects will also mold to the airway. A large bolus or foreign objects mass is more likely to block the airway at the pharynx and cause asphyxia. Foods that are ingested and lodge beyond the UES may distend the wall of the esophagus into the volume of the airway along the length of the trachea. When premature or inadvertent foreign object penetration occurs, a gag and or cough reflex may be triggered.

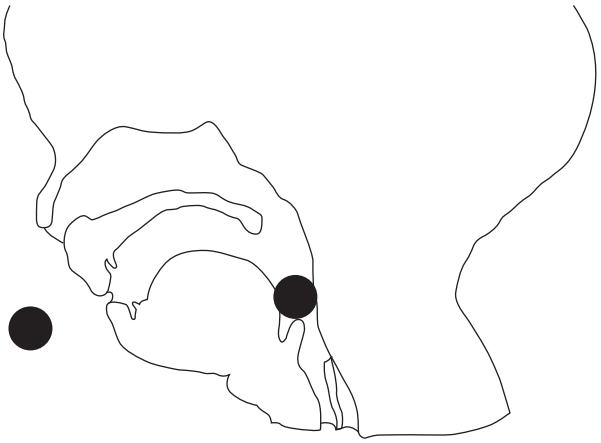

Figure 5 Obstruction of the oropharynx.

Smooth, slick, and pliable food-like objects are less likely to trigger a timely gag reflex than textured or sharp objects.

Gagging and coughing is frequently followed by rapid deep inhalation as the victims attempt to regain their breath. This action may draw the object downward leading to physical impaction and obstruction. This consequence is facilitated by the temporary expansion of the pharyngeal and laryngeal chambers that occurs during vigorous inspiratory effort. This reaction is more intense in infants than older children or adults. Pliable conforming objects are less likely to be expelled from the airway than rigid objects.

Protective Mechanisms

The body has several protective mechanisms to prevent choking-related injury. Gagging and productive coughing are vigorous hindbrain reflexes that may remove foreign objects from the airway. The gag reflex includes anterior and inferior jaw movement, tongue extension, and spasm of the stomach and esophagus. The purpose of these actions is to expel food objects sensed as noxious by the nervous system. A productive cough may expel foreign objects which enter the trachea or bronchial tree. Very small foreign objects or particles may be removed from the airway by muco-cilliary action. The cilia or hair cells lining the lung passages carry particles upward to the laryngeal inlet, where a productive cough can carry them out of the airway. These reflexes come into play after a foreign object has penetrated the defenses of the oral airway.

Evaluation of the Hazard Levels of Foods

The choking hazard associated with a given food is largely associated with its physical properties. Physical property measurement can be approached in two ways: sensory and mechanical evaluation. Sensory evaluation uses the human senses of taste, smell, touch, and sight to measure food properties. These evaluations can range from informal quality checks to trained test panels to very sophisticated consumer tests. Sensory evaluations have proven to be difficult to maintain consistency; therefore, these evaluations are often correlated and compared to objective physical measurements. Few physical property measurements have ever been shown to be correlated with sensory evaluations. Complete assessment of the physical properties of foods involves interactions between the material properties of the food and its structure, complex stress states, and interactions with lubricated oral surfaces. It is, therefore, hardly surprising that attempts to correlate sensory assessments and physical property measurements are often inconclusive.

It is also possible to use rheological techniques to measure quantities that contribute to food hazard. Commonly measured quantities include the following:

- Lubricity or 'slipperiness': Slippery objects are more difficult to control in the mouth, potentially creating a hazardous condition. Very slippery objects may initiate a premature swallow before the food is processed into a bolus that is safe to swallow.
- Hardness: Hard objects are difficult to process into a bolus. The longer a food takes to process into a bolus that is safe to swallow, the greater the potential that the food will prematurely enter in to the pharyngeal phase of the swallow cycle. Foods that are hard generally require more developed dentition and oral fluency to process. Therefore, the softer a food, the more suitable it will be for children who have not yet developed their full dentition.
- Dissolvability: Objects which rapidly break down in the presence of heat or moisture, and particularly in saliva with the presence of enzymes, may be easily formed into a bolus that is safe to swallow. Objects which dissolve slowly create a hazardous condition due to the greater amount of time required for bolus formation, and a direct hazard if they enter the airway and remain in a solid state.
- Surface roughness or texture: Roughness and increased surface area provide improved oral manipulability. Smoother foods may be more difficult to manipulate in the oral cavity.
- Friability: Objects which easily break into small soft pieces are more easily formed into a swallow-safe bolus. The development of teeth is critical to determination of age appropriateness of foods. In general, multiple fragments increase mouthing difficulty. This is especially true for fragments that have diverse material properties. Multiple fragments which are homogenous in characteristic pose a lower level of difficulty, but may still become scattered in the oral cavity and potentially provoke a gag reflex.
- Size: Oral sensors can discriminate the size of solid materials, but children may make poor decisions as to what they can successfully swallow. Objects that pass into the airway have a direct hazard in proportion to the area of the airway they obstruct.
- Shape: Spherical or cylindrical shapes will occlude the airway if they are the diameter of the airway. Analysis of injury and fatality data indicates that foods that retain these characteristics in the environment of the oral cavity and oral airway such as hot dogs, hard candy, and grapes are particularly hazardous, especially for young children and infants. By contrast, 'one dimensional' objects such as coins are less likely to effect a complete airway blockage.

- Packaging: In some cases, packaging can increase the risk associated with food products. In particular, package designs that promote the transit of foods to the rear of the oral cavity rapidly may create a hazardous condition for premature or inadvertent swallow, leading to the potential for airway obstruction injury.

Prevention of Food-Related Choking

Choking is an inherent hazard associated with food, although food-choking incidents are highly preventable. In the case of un- or minimally-processed foods such as fruits, nuts, seeds, fish, or vegetables, caregiver discretion and vigilance are needed to reduce choking risks. Caregivers can limit access to hazardous foods or modify their physical properties to reduce hazard. In the case of manufactured food products, manufacturers can design or redesign foods to avoid shapes, sizes, textures, and other characteristics that increase choking risk. Furthermore, developmental appropriateness needs to be taken into greater consideration. A food of benign hazard to adults may be challenging to young children. Appropriate warning labels can aid in proper product selection and safe consumption.

Public education is another key component of choking prevention. Pediatricians, dentists, and other healthcare providers should provide choking-prevention counseling to caregivers and consumers. Enactment and enforcement of safety legislation can also serve to reduce risk by eliminating particularly hazardous foods or mandating labeling that increases hazard awareness.

OTHER SIGNIFICANT HAZARDS

Physical Hazards in Foods

M Edwards, Campden BRI, Chipping Campden, UK

Glossary

Container glass Jars and bottles used to pack food and beverage products, made from soda lime glass.

Extraneous vegetable matter (EVM) Intrinsic (qv) plant material such as fragments of pea pod or pea leaf included in peas.

Extrinsic foreign material Derived from any origin other than the plant or animal product that has been contaminated; *cf.* intrinsic foreign material.

Heat-resistant glass Sometimes known as borosilicate glass, it is resistant to cracking as a result of heat shock because its coefficient of expansion is much less than that of ordinary soda lime glass. Originally developed for railway signal lamps and typically used for domestic glassware such as casseroles for use in ovens and microwaves.

Intrinsic foreign material Derived from another part of the plant or animal product that has been contaminated; *cf.* extrinsic foreign material.

Lead glass A type of glass in which lead replaces the calcium content of a potash glass. Lead glasses may contain 18–40% lead oxide. To qualify as lead crystal, the glass must contain at least 24% lead oxide. Many cheaper items of glassware are available with lower lead oxide contents.

Potash glass A variety of soda lime glass types with an increased potassium content, resulting in greater clarity. Used for higher quality domestic glassware.

Soda lime glass Used to make ordinary domestic glassware such as drinking glasses and sweet bowls, also container items such as jars and bottles, and sheet glass used for windows, picture framing, horticultural glasshouses, vehicle windows, etc.

Struvite Magnesium ammonium phosphate, a clear, colorless crystalline material occasionally found in canned fish products such as salmon, tuna, or crab. The material is harmless and can be dissolved in dilute acid. Because of its appearance, it is sometimes mistaken for glass, giving rise to consumer complaints.

Toughened glass Glass that has undergone a controlled heat treatment to prestress the glass, such that when it breaks, instead of forming shards with sharp points, it shatters into many small fragments. Used for some windows and domestic glassware.

X-ray microanalysis A laboratory analytical technique where the sample is bombarded with electrons, typically in an electron microscope, and the energies of the X-rays released can be analyzed to determine the elements present in the sample.

Foreign Matter Complaints in the Food Industry

Foreign matter incidents constitute the biggest single cause of consumer complaints received by many food manufacturers, retailers, and enforcement authorities. The accidental inclusion of unwanted items can occur in even the best-managed processes. Foreign matter in foods is therefore a matter of concern to all food manufacturers and retailers. The publicity given to a range of food issues, including contamination incidents of glass in food products, concerns about *Salmonella* and other microorganisms in a range of foods, and more recent issues such as bovine spongiform encephalopathy (BSE) and genetically modified (GM) foods, have left consumers very aware of the safety of what they eat. This has been encouraged by increased media emphasis on consumer rights, and, unfortunately, a burgeoning culture of personal injury claims. Therefore, any measures that can be taken to lessen the incidence of foreign matter in foods will be of importance to food manufacturers, retailers, and enforcement authorities and will benefit consumers.

Foreign matter may be defined as something that the consumer perceives as being alien to the food. The perception of the consumer is important, because not all foreign matter is, in fact, alien to the food, though all may have the potential to result in a consumer complaint. Hence, foreign matter can range from items that are clearly alien to the food, such as fragments of glass, metal, or plastic through items that are related to the food, such as fragments of bone in meat products, to part of the food itself, such as crystals of sugar or salt that are mistaken for glass.

It follows from this definition that the range of possible foreign matter is virtually limitless. One distinction which can be made is between intrinsic and extrinsic foreign matter. Intrinsic foreign matter includes items that are related either to the raw materials used in the food product itself or to packaging materials used with the product. Examples of these might include fragments of bone in a meat product, fruit stalks in dried fruit, or pieces of plastic from the food packaging. Extrinsic foreign matter includes items that are not so related, which become incorporated in the product flow from an external source. Examples of these might include stones

accidentally harvested with a field crop or metal nuts lost from food processing machinery.

Hazards Caused by Foreign Matter

Foreign matter may be unpleasant for the consumer to find, but the vast majority of incidents do not pose any real hazard. Of the few that do, potential hazards can be grouped into several classes:

Physical Hazards

Hard objects such as glass fragments, metal, and bone pose the biggest food safety concern because they can cause injuries such as cuts, broken teeth, choking, and intestinal perforation. There is a risk of cuts or lacerations to the hands during food preparation and to the mouth, esophagus, stomach, or intestines. There is also a risk of chipped teeth, broken dental fillings, and damage to prosthetics (dentures).

The possibility of choking due to obstruction of the upper airway is greatest in young children up to 3 years old. Objects causing such choking are common items such as toys, coins, or food, but very rarely foreign matter in food as such. Objects may become lodged in the upper esophagus and cause choking by compression of the trachea. Aspiration – the inhalation of foreign matter into the lungs – may result in partial lung collapse, secondary infection, or destruction of lung tissue from retained foreign material.

From American studies, approximately 80% of reported foreign matter ingestions occur in children, and 80–90% of such ingested foreign objects will pass through spontaneously over the following 4–7 days. It was estimated that only 1–5% of ingested foreign objects resulted in actual injury. Sharp objects accounted for approximately 10% of ingested foreign matter, but a disproportionate number of injuries. Of foreign objects which had to be removed surgically, 37% were in the airway and 63% were in the upper digestive tract. In a review of United States Food & Drug Administration (FDA) consumer complaints of foreign materials in food, the most frequently reported injury was mouth or throat laceration. In the FDA review, glass was the foreign material most frequently reported as causing illness or injury.

There are three main factors which determine whether or not an object may be hazardous. The most obvious factor is probably the size, but opinions differ on precisely what size of object may present a hazard. For example, the United States Department of Agriculture (USDA) Food Safety Inspection Service indicated that bone particles of less than 10 mm are unlikely to pose a food safety hazard. Bone particles from 10 to 20 mm may cause discomfort, but would be a low risk for a food safety hazard, whereas bone particles greater than 20 mm have the potential to be a food safety hazard and may cause injury to consumers. However, they also stated that each instance should be considered on a case-by-case basis, irrespective of size.

The Consumer Product Safety Commission (CPSC) concluded in 1995 that spherical objects less than 1.75 in. in diameter are dangerous to children under 3 years old due to the risk of choking, ingestion, or aspiration. CPSC uses a small-parts test fixture (a cylinder) to judge other nonspherical objects for choking hazard.

The FDA Health Hazard Evaluation Board concluded that in cases of foreign materials examined over a period of 25 years (1972–97), 56% of objects measuring 1–6 mm might pose a limited acute hazard. For objects greater than 6 mm, only 2.9% were judged to present no hazard.

The FDA/Office of Regulatory Affairs (ORA) Compliance Policy Guide gives some criteria for direct reference seizure:

- Hard or sharp objects measuring 7–25 mm across in ready-to-eat products not requiring additional preparation.
- Criteria are also given for recommending legal action:
  - objects 7–25 mm across in products requiring additional preparation,
  - objects less than 7 mm and intended for special-risk groups, and
  - objects greater than 25 mm in length in all products.

The second factor is shape. Spherical or cylindrical objects present a greater risk for choking, whereas slender and sharp or pointed objects (e.g., fish bones) present a greater risk of laceration or perforation.

The third factor to consider is the consistency of the object. Rigid objects such as coins caused most choking deaths in 3 years and older children, whereas conforming objects such as balloons caused more choking deaths in children under the age of 3 years.

Illness Associated with Foreign Matter

Illness complaints from the ingestion of foreign matter include nausea and vomiting, diarrhea, headache, fever and dizziness, and chest pain. These may be due to chemical hazards, microbiological contamination, or a psychosomatic response to the belief that foreign matter has been ingested.

Chemical Hazards

A very few foreign objects may represent possible chemical hazards to a person consuming them. Examples include certain berries such as those of members of the nightshade family, which may be accidentally harvested with field crops such as peas, or ergots accidentally harvested with cereal crops.

Concern is sometimes expressed by complainants finding medical tablets or capsules in their food, but there are very few tablets or capsules that would cause serious or lasting harm to anyone accidentally consuming a single tablet or capsule. Similarly, concern is sometimes expressed regarding items such as dead rodents or slugs reported from food products, which may have been killed by commercial pesticides. However, the toxicity of such materials is expressed in milligram per kilogram body weight, and so the absolute amount of pesticide required to kill a rodent or a slug is many times smaller than that required to harm a human being, simply by virtue of the large difference in body weight.

Contamination of food with ingredients from other recipes, such as nuts, may also present a risk of causing an allergic reaction. Most food companies take great care to prevent cross contamination of this type in the factory, but accidental

cross contamination by consumers in self-service outlets may be a significant risk.

Biological Hazards

Again, some consumers finding potential biological hazards in food products, such as blood, used wound dressings, or condoms, have expressed fears that diseases such as AIDS may be transmitted to them by such means. In fact, most of these diseases are quite difficult to transmit indirectly by such means, and if the offending item has been subjected to heat processing along with the food, any infective agent is in any case likely to have been killed.

The Control of Foreign Matter

The control of foreign matter in food products has to be seen within the commercial environment in which it takes place. The approach to foreign matter control must, therefore, be chosen in relation to the risks and costs involved. The choice of method will be influenced both by the size of the enterprise and the impact the cost will have on the commercial viability of the business. For example, a low cost manual system may be the correct solution for a small operation, whereas a larger company might install some form of an automated machine. A low cost manual system may be the appropriate solution when the problem is short term. Control methods may include physical barriers like screens on windows and doors and a stream of air (curtain) at entrances. Pest exterminators should be employed when it is considered that there is a risk of an invasion of insects, birds, or rodents. Metal detectors are often installed at food production plants, but are not always turned on or are not sensitive enough to detect small fragments. The choice of equipment will depend on the technical problem to be solved, the cost of the equipment, the particular foreign matter hazard, and the risk involved. Assessment of the risk will involve not only the legal position but also the publicity risk to the business of a foreign matter incident.

Sources of Foreign Matter

It is important to be able to identify foreign objects and to locate the source as far as possible, in order to determine when, where, how, and why the object got into the food. This can help to identify patterns in the incidence of foreign matter, which can then be used as part of a strategy to reduce the numbers of occurrences. If the source is shown to be in the raw materials, measures can be taken to prevent the incorporation of foreign matter, or means of removing them may be introduced. Alternatively, a different supplier may be sought. Results may identify where manufacturing practice could be improved, in which case they should be incorporated in a hazard analysis and critical control points (HACCP) system. The identification may indicate that the problem is with the consumer, but even in this case it may be possible to make improvements, such as modifying the pack design or amending the instructions for opening a pack to reduce the chance of packaging materials becoming incorporated with the product. Foreign matter discovered during food processing frequently becomes the subject of dispute between the company finding the foreign matter and their suppliers, and production may also be held up or product quarantined until the source of the foreign matter is identified. Rapid and accurate identification of the foreign matter in such a case is vital to resolution of the problem.

Insects and Other Invertebrates

Many food companies dealing in a broad range of food products, but particularly those involved with fresh produce, regard complaints about insects and other invertebrates as one of the most important foreign matter problems. One of the main reasons for this is undoubtedly the difficulty of detecting and removing these creatures on a production line, particularly in fresh produce.

Insects reported as foreign matter can be divided into two broad groups: those that have some specific connection with the particular food product and those that do not. The former group generally consists of insects that feed either on the food product or on something closely connected with it. It may include field pests such as caterpillars, which feed either directly on the crop itself or on its leaves, or storage pests, which infest the harvested or fully manufactured product during storage. It may also include insects such as flies that lay their eggs directly on the surface of meat during preparation. The second group of insects includes a wide range of species that have no particular interest in the food concerned, and have become associated with it quite accidentally. This may include insects harvested inadvertently with a field crop or those alighting on the food while it is being prepared or consumed.

In all of these cases, the accurate identification of the insect is crucial to the correct identification of the source of the problem. Insect fragments include heads or parts of legs, rarely whole insects, and can only be identified through referring to an identification key. Field pests are generally well studied and documented, and so their habits and requirements are well known, as are suitable control measures. Similarly, storage pests and those insects that feed on fresh meat are well understood and their requirements in terms of access to food, temperature, and so on are fully documented. For example, some adult female flies will actively seek out meat on which to lay their eggs, whereas males of the same species, which feed on plant sugars, will have no interest in meat. However, figs are fertilized by a small wasp that is considered to be a part of the fruit and is not extraneous, although a consumer finding the insect may not share this view! Control measures for storage pests should be implemented in all well-run storage facilities, but this may not always be the case in domestic kitchens. An infestation of psocids, which are very small insects that are relatives of booklice, may begin in a bag of flour and rapidly spread to the rest of a domestic pantry. A discovery of maggots feeding on meat may be particularly revolting. However, accurate identification of the growth stage reached by the larvae, together with knowledge of the temperature at which the meat has been stored, should enable the analyst to estimate the age of the larvae and hence the approximate time at which the eggs were laid.

The most widely reported insects in food products appear to be those which become associated with the food by accident. These include a wide range of insects that live within field crops and are accidentally harvested with them, and those that live around food processing sites which either fly in accidentally or are attracted to lights at night. Many moths become associated with foods in this way, but other insects are also attracted to windows, such as the aptly named window gnats. These can be controlled by suitable insect screens and insectocutors in factories. However, many insects appear to become associated with food products while being prepared or eaten by the consumer, particularly with the increasing popularity of snacking and eating on the move. Many day-flying insects such as flies, shield bugs, and others have been reported in this way. The source can sometimes be confirmed either by their day-flying habits or by relating the time of year when the insect is on the wing to either the time of discovery or the time of manufacture of the product.

Very few insects or other invertebrates represent a real hazard to the consumer. Larger insects may present a potential choking hazard, but very few will cause any chemical or biological hazard. The presence of pest species may cause significant losses of harvested or stored product, representing an economic loss to the owner, and may also be an indication of a breakdown in hygiene.

Plastic Materials

With the increasing use of plastics in everyday applications, it is not surprising that many food companies regard plastics as one of the most important causes of foreign matter complaints. Their common use is exacerbated by the technical difficulty of detecting plastics on the food production line. Although fragments of the final packaging materials of a food product can sometimes form the source of a foreign matter complaint, items such as plastic gloves, plastic sacking, or twine used in packing the raw materials appear to be a more common source. Similarly, cardboard boxes in which fish is frozen on ship can be a source of complaints of pieces of card in fish products. Plastics used on the production line such as parts of piping or machinery can sometimes find their way into the products as a result of breakages. However, fragments of consumer equipment are also common sources, pieces of kitchen equipment being especially common. These can include fragments of plastic pepper grinders, pieces of casing from food mixers and blenders, and fragments broken from domestic electrical plugs. Complainants often mistake clear colorless plastic fragments for glass, and in some cases these result from the substitution of plastics such as Perspex for glass, for safety reasons.

The main hazard caused by plastic materials is a physical one, sharp edges presenting a risk of cuts or lacerations, and larger fragments being a potential choking hazard.

Metals

A wide range of metal fragments is still reported from food products, despite the widespread use of metal detectors and magnets on food production lines. However, the efficiency of these measures usually means that most of the reported foreign bodies consist of quite small pieces of metal which have somehow evaded detection. The type of metal involved is usually an important indication of the source of the problem. Pieces of wire often form the cause of complaint. In flour and bakery products, pieces of broken sieve may be the origin, whereas in other products, the cause may be fragments of electrical wire from repairs, either in the factory or the consumer's home, or pieces from a wire brush. Pieces of tinplate, aluminum, or tin-free steel used in the manufacture of cans or more particularly can ends are sometimes found. Can ends are a particular problem because they are stamped out of a flat sheet of metal, leaving behind a relatively fragile fretwork of waste metal, but a key feature in their identification is often the type and distribution of lacquer on the surface(s). Pieces of aluminum from baking trays, scraped from the surface by mechanical contact, may be the cause of complaints in bakery products. Similarly, fragments of stainless steel from food machinery are sometimes reported, and the precise composition of these steels can be helpful in tracing the source of the problem. Deteriorating bearings for moving parts may also shed minute fragments of metal coated with oil, and in cases like this the complaint will usually be of oil spots on the product rather than of metal. The detection of tiny metal fragments in the center of the oil spot, and their subsequent identification as metals suitable for bearings such as brass or bronze, will confirm the source of the problem. Parts of knives used on the production line are also sometimes found.

A source of metal fragments that is related strongly to either hard foods such as biscuits or crusty bread, or to sticky foods such as toffee, is dental fillings. This relationship with a particular type of food suggests strongly that, in most cases, the complainants themselves are the source of the problem. Experience shows that these are generally from badly diseased teeth or from poorly mixed fillings, both of which are more likely to lead to failure of the filling while the food is being eaten. Metal dental posts, used to secure large fillings or crowns, are also found, with or without the relevant filling or crown. Dental bridges have also been reported occasionally. Other dental samples, such as fragments of human teeth, or, surprisingly commonly, temporary crowns made of polycarbonate or polymethylmethacrylate, also occur.

As with plastics, the main hazard caused by metal fragments is a physical one, sharp edges presenting a risk of cuts or lacerations, and larger objects being a potential choking hazard.

Glass

Fragments of glass reported from food products are amongst the most important foreign objects, because of the emotive impact on the finder, the reputation of glass fragments for causing injury, and hence the potential for bad publicity. Indeed, although glass fragments can and do occasionally cause cuts to the mouth and throat, in many cases the actual risk is less than the consumer's perception of the risk. Larger fragments may present a choking risk.

Glass fragments reported from ready-to-eat/heat prepared meals often include a high proportion of heat-resistant glass from the rims of domestic items such as casseroles. The rims of

casseroles often have a characteristic chunky profile, and frequently carry scratch marks as a result of contact with the lid of the casserole. There is usually a groove caused by a mold parting line during manufacture of the casserole, which is difficult to clean and in a well-used item may carry a line of burnt-on food material from repeated use in an oven. Finally, the identification can be confirmed by X-ray microanalysis, which will show the characteristic elemental composition of a heat-resistant glass. In the case of heat-resistant glasses, it is often possible to identify the brand of glassware involved, because each type has its own characteristic composition. Similarly, some products, such as frozen peas, are sometimes microwaved in heat-resistant glass bowls. These items are occasionally subject to similar damage to that suffered by the rims of casseroles. Rim fragments fall into the bowl or casserole, and remain unnoticed when food is added. Bowls are often damaged by the use of a metal spoon or fork to scrape food away from the side of the bowl. This results in characteristic scratch marks in a line on or just below the rim, depending on its exact profile, and in further random single lines of scratching lower down on the inside of the bowl.

Ordinary domestic glassware made from soda lime glass, such as sweet dishes, may occasionally be broken in use, and sometimes fragments from these breakages may be found as glass fragments in food products. Glass fragments of this type may typically be found in products used in desserts such as canned fruit products, whipped toppings, and other products often served in ordinary domestic glassware. Although pieces from the rims of such items may be found, some fragments have been identified that clearly result from a completely smashed item, such as a piece of glass rod forming the stem of a sweet dish.

Container glassware such as jars and bottles is also made of soda lime glass. A common domestic source of fragments from glass jars is the scraping of the last remnants of a product such as jam or peanut butter from the bottom corner of a jar, using a metal implement such as a spoon or knife. If excessive pressure is applied, the spoon or knife can punch a small hole in the corner of the jar, producing a fragment of characteristic shape. This has a large area of external convex surface with sharp edges all round, presenting a risk of cuts to the consumer. The reverse side has large tapering fracture surfaces, with a very small central area corresponding to the internal manufactured surface of the jar. The fragment falls onto whatever is immediately beneath the jar at the time. The jar, being empty, is discarded without the consumer even being aware of the breakage. The fragment, when found, is then associated with whatever it fell onto, and the true origin is forgotten.

Fragments of glass are sometimes reported from cans of beer or other drinks products. Because a metal beverage can is not transparent, the glass fragment is generally discovered in the glass into which the product is poured, rather than in the can. Nevertheless, the complainant is often quite certain that the glass must have come from the can. In most cases, examination of the glass fragment indicates that it came from an ordinary domestic drinking glass, and it would appear that most of such instances are the result of a breakage in the home resulting in a glass fragment resting in the bottom of the glass, and only being discovered after the drink has been poured onto it. Often these pieces of glass include part of the rim, with its characteristic beaded edge.

From time to time, fragments of glass from lead potash or lead crystal glassware are reported from food products. These are often associated with the more expensive kinds of ready-made desserts, such as might be served up at a dinner party, when the best glassware is also being used.

Manufacturing Problems

The experience of analysts at Campden BRI over the years suggests that the vast majority of glass fragments, unlike many other types of foreign matter, originate from the consumer's own home. A particular exception to this is glass fragments reported from food products containing rice. These fragments have a characteristic appearance. They are of roughly the same size and shape as a rice grain, and they have heavily abraded surfaces due it having been tumbled with the rice grains in the polishing process, giving them an almost opaque appearance. This makes such glass fragments very difficult to separate from the rice by either automatic sorting machines or by hand. However, because of their rounded shape these glass fragments present no hazard in terms of cuts or lacerations, and are too small to cause a choking hazard. The only real cause for concern from a safety viewpoint might be the slight possibility of damage to teeth by biting on a hard object.

Another type of manufacturing problem is the breakage of glass jars or bottles on a filling line. This can result in fragments of glass flying some distance, with the consequent risk of glass getting into neighboring, unbroken jars or bottles. Good operating practices in factories should prevent potentially contaminated jars or bottles leaving the factory as a result of such breakages. Analysis of the glass fragments by X-ray microanalysis, and comparison of the results with data from the jar from which the fragment was reported, enables analysts to determine whether or not the glass fragment came from the same batch as the jar, and hence whether a breakage on a filling line is likely to be the cause of the problem. Experience from analysis of complaint samples suggests that the numbers of such incidents are much less than they used to be, indicating that good operating practices are having their effect.

Glass Introduced at Point of Sale

Glass fragments may be accidentally introduced into food products at the point of sale, particularly in sandwich bars and restaurants. Food products such as sandwiches sold from glass display cabinets are occasionally contaminated with glass fragments from the edge of the glass shelves used in these cabinets. These fragments frequently are part of a frosted edge of the shelf. Food served in restaurants may occasionally be contaminated with glass fragments from chips of the glassware used in the restaurant. These include items such as drinking glasses and sweet dishes, which inevitably become chipped as a result of repeated use. Most of the chips come from the rim, and the rim carries good evidence of having come from an article subjected to repeated use in the form of a series of fine scratch marks, caused when the glass is placed upside down on a storage shelf.

Objects Frequently Mistaken for Glass

Probably the most frequently encountered materials mistaken for glass are clear colorless plastics such as Perspex, polycarbonate, or polystyrene. Examples of salt and also sugar crystals being mistaken for glass are surprisingly common. Another material often mistaken for glass is struvite or magnesium ammonium phosphate, a clear, colorless crystalline material occasionally found in canned fish products such as salmon, tuna, or crab. The material is harmless and can in fact be dissolved in dilute acid. Other objects frequently mistaken for glass include glass-like minerals such as quartz and other silicates.

Plant Material

Plant material may be reported as foreign matter in many different forms. Extraneous vegetable matter, such as bits of leaf or stalk, is frequently found to be the cause of complaints in vegetables such as peas or beans, or fruits such as raisins or sultanas. Woody material from the center of roots of carrot or parsnip, or from the stem of cabbage, can result from overwintering root crops or from the use of older cabbage than the ideal. In the case of overwintering root crops, good crop husbandry, including roguing of older plants, has been found to be a very effective cure for the problem. Parts of other plants inadvertently harvested with crops can sometimes give rise to complaints: for example, the fruits of weeds such as woody nightshade are sometimes harvested with peas, and if still green and immature, are extremely difficult to separate from the crop. Fragments of true wood can occur from broken boxes or pallets, and are often identifiable by their softwood structure and sometimes the presence of paint. Fragments of hardwood may be pieces of manufactured articles such as furniture, but are more frequently found to be pieces of a branch or twig, probably also inadvertently harvested from the hedgerow at the edge of a field. Again, examination of the wood structure under the microscope can often help to identify the species and thereby isolate the cause of the problem. Most plant material is too soft to present a physical hazard, but pieces of wood may cause choking, and berries from deadly nightshade (*Atropa belladonna*), sometimes accidentally harvested with crops like peas, may be a poisoning hazard.

Other Foreign Matter

The possible range of foreign matter is almost limitless, and only a small range can be dealt with here. Stones, sand, and soil may be incorporated when soil-based crops are harvested, as well as tramp metal and other debris in the soil, and these can sometimes cause damage to teeth. Creatures living in fields of crops may also be inadvertently caught up in harvesting machinery, identifying them or their parts, to species level can sometimes be helpful in identifying their source. Similarly, the droppings of animals such as rabbits, mice, and rats need to be positively identified; sometimes agglomerations of plant material caught during harvesting in processing machinery can take on the appearance of droppings. Animal parts and droppings are important more in terms of the revulsion they induce in the consumer than any real safety concern. Many parts of food processing machinery and packaging have the potential to become foreign objects, as do a wide range of ordinary household items.

Holes in food containers such as cans or pouches caused either by accidental puncturing or by the consumer starting to open the product before changing their mind and returning the product to the store cupboard may result in the product becoming contaminated by mold spores or insect eggs. This can result in the development of a mold pellicle, a tough leathery layer on the product surface, or the hatching of insect eggs into larvae, both of these foreign matter types being discovered when the product is finally opened.

Deliberate Contamination

Although relatively rare, the deliberate contamination of food can be a serious problem, whether perpetrated within the factory, through the distribution chain or by the consumer. Deliberate contamination within the factory can often be identified by demonstrating a positive relationship between foreign objects retrieved from different packs carrying the same or similar batch codes, and these batch codes can also be used to identify the factory personnel who might be responsible for the deliberate contamination. Deliberate contamination through the distribution chain or by the consumer may often be more difficult to prove because the incident is often an isolated one. Examples of deliberate contamination for fraud purposes may include broken glass or a mouse in a bottle, and there may be factors that demonstrate clearly that the contamination must have occurred after the product was opened, such as an allegation of a live insect in a sealed pack of a fully heat-processed product. However, it may sometimes be possible to demonstrate a link between different occurrences if multiple attempts have been made. In one case, it was possible to show that the pieces of glass contaminating two own-brand products from different retailers were identical. They were produced in the same factory at two quite different times, but further investigation revealed that the complainant was the same person in both cases.

Conclusions

An analysis of the occurrence of different types of foreign objects in a variety of food products shows that the types of foreign matter can be related to the way in which the product is manufactured, packed, sold, or used by the consumer. It demonstrates that some foreign matter can be quite specifically linked to specific types of food product. In particular, it demonstrates the reason why the great majority of glass fragments do originate from consumers' homes. This is not surprising because most food companies operate strict "no glass" policies in their factories. In contrast, not only does the consumer have glassware in the kitchen where the food product is being used, but also in many cases the glassware is actually being used in conjunction with the food product. In these circumstances, it is not surprising that most of the glass fragments originate from end-use of the product rather than from its manufacture. This fact also explains why the number of complaints of glass fragments in food products remains stubbornly high. Although a

food manufacturer can reasonably be expected to take measures to prevent glass fragments getting into food in the factory, he cannot control the way the product is used by the consumer. In contrast, many other foreign matters can be very effectively controlled by suitable measures within a food processing system, including metal detectors, X-ray machines and magnets, mechanical separation methods such as sieving, flotation and gravity separation, automatic vision systems, and even visual inspection by factory staff.

H-C Langowski, Technische Universität München, Freising, Germany
J Wunderlich, Fraunhofer Institute for Process Engineering and Packaging, Freising, Germany

Glossary

Cleaning-in-place (CIP) A method for cleaning purposes, whereby the plant is cleaned automatically and without opening of pipes or other machine parts, prevents human failures, and allows reproducible cleaning results.

Colony-forming units (CFUs) A unit for direct quantification of microorganisms.

Critical control point (CCP) A point or step in a process that represents a critical point for hazard, which should be controlled with special care.

Hazard analysis and critical control points (HACCP) A concept for determination, elimination, prevention, and control of critical control points, helping to guarantee food safety.

Sterilization-in-place (SIP) It is a method for sterilization purposes, which is similar to CIP and commonly follows on CIP.

Ultra-high pressure treatment (UHP) Preservation method that uses high pressure (up to 600 MPa in industrial facilities and up to 1400 MPa in research facilities) instead of temperature.

Ultra-high temperature treatment (UHT) A sterilization method used for liquid and semi-solid foodstuffs using extremely short processing time (1–2 s) as a result of the used ultra high temperatures (>135 °C).

Introduction

Consumer demand for shelf-stable, high-quality food with a maximum degree of safety has been a focus in processing of liquid and semisolid foodstuffs. Food products should also meet the sensory and nutritional parameters, as specified by the consumer and legislative authorities. Thermal processing is one of the reliable methods to preserve the food. Aseptic processing and packaging is an established technique used for decades to process suitable low-acid food (pH > 4.5) products like milk and milk products, for example, puddings as well as nondairy desserts, fruits and vegetables juices, soups, sauces, and particulate foods. The word aseptic is derived from the Greek word *septicos*, which means the absence or

 doi:10.1016/B978-0-12-378612-8.00274-2

exclusion/elimination of microorganisms that cause spoilage. Aseptic packaging can generally be defined as the filling of a commercially sterile product, with its sterilization being achieved through adequate thermal treatment into a pre-sterilized container under aseptic conditions, followed by its hermetic sealing to prevent recontamination. The word 'hermetic' is a synonym for strictly 'air tight' and is the designation for the mechanical properties of the used sealing to prevent any kind of mass transport between the packed product and the environment like microorganisms, water vapor, or any further gas.

Typical examples of packaging of presterilized products are milk and other dairy products without a fermentation flora, like cream, puddings, and deserts as well as juices, soups, sauces, and foods with both small discrete particles and a minor amount of larger particles. Packaging of pasteurized products is a method for the packaging of products in which spore-forming bacteria cannot grow (as consequence of pH and/or water activity (a_w)); therefore, sterilization is not required for the microbiological stability of such products.

Aseptic packaging is absolutely different from conventional packaging technology, which allows a similar shelf life like retort processing or canning. In conventional packaging process, the product is filled into the previously cleaned packages, followed by extensive heat processing to achieve the desired commercial sterility. This is limited to packaging materials like tinplate, glass, and aluminum (Al)-foil laminates that can tolerate high temperatures (up to and higher than 127 °C), high pressures, and acidic conditions too. The containers are commonly metallic, making them expensive and prone to corrosion. More importantly, the duration of the heat treatment, dictated by the rate of heat transfer, leads to degradation of nutritional and organoleptic properties. A comparison of the two technologies can be observed in Figure 1.

Significance and Advantages

Strict regulations on food safety by regulatory and advisory bodies in the area of food process hygiene have compelled the food industry to maintain the uniformity in the quality standards. The main reason for framing such regulations was the reports of outbreaks of foodborne disease due to poor hygiene during the processing. Aseptic packaging has been around for 100 years, with the first aseptically packaged food (specifically milk in metal cans) dating back to 1913 in Denmark markets. Over the years, new techniques like heat–cool filling systems in 1933 and can sterilization with superheated steam at 210 °C in 1940 were developed. The first commercial aseptic packaging machine developed in 1950 was based on similar principles but with limited market due to high cost of the equipment and cans. The establishment of laminate paperboard cartons by Tetra Pak®, Sweden led to the first commercial successful product in 1961, with a huge market to

date. The main focus was to develop a system that allows the economical production of products with long shelf life at ambient conditions. The progress in processing technology in the past decades has made aseptic processing a commercial viable and successful technique – UHT short-time processing is a specific example.

The numerous advantages of aseptic packaging, which will be discussed in the following text, can be summarized in three main aspects:

- The usual food containers are unsuitable for in-package sterilization; this method uses economical, light and highly protective packaging materials like paper and special plastic foils, the preferential container design in terms of material choice for optimized protection of liquid foods.
- Extension of product shelf life at ambient conditions by aseptic packaging. For example, commonly pasteurized milk is stable for approximately 5–8 days under refrigerated conditions, whereas aseptically processed and packed milk is stable for up to 6 months at ambient conditions.
- Possibility to use high-temperature-short-time (HTST) processing for heat-sensitive products in order to preserve nutritional, sensory, and other quality attributes without increased costs.

All these aspects clearly reflect the significance of aseptic packaging for contemporary foods. High consumer acceptance for aseptic products may be demonstrated in terms of shelf life extension without both refrigeration and addition of chemical preservatives. More than 90 billion liters (2009) are aseptically packed with an estimated increase of 30% (113 billion liters) by 2013. The main markets are Western Europe wherein dairy products, especially milk, have been the main product.

Basics of Sterilization

Sterilization is a process that should eliminate virtually all colony-forming units (CFUs) of any kind of microbe present in the food product. Thus, a sterile product should be free of any CFU, and microbial spoilage may be caused only by re-infection or recontamination from the surrounding environment. Autoclaving in hermetically sealed containers at 121.1 °C and 2.013×10^5 Pa pressure for longer than 15 min is the only technique that is considered to guarantee sterile conditions. This results in the virtually complete destruction of all CFUs in the initial product, but also leads to a significant reduction of its nutritional and sensory properties. For aseptic packaging, high-temperature short-time (HTST) processing is used, especially UHT, to preserve the nutritional and sensory properties besides achieving a commercially sterile product. In such a case, the reduction of CFUs follows a logarithmic function as shown in eqn [1].

$$\log S(t) = \log\left(\frac{N_t}{N_0}\right) \qquad [1]$$

The equation shows the time-dependent survival rate $S(t)$ as a function of cell count after a defined treatment time t (N_t) in comparison with the cell count exactly at initial time $t=0$ (N_0). This shows that S cannot exactly reach zero level, an acceptable low number of CFU of relevant microorganisms (bacteria, yeasts, and molds) being able to contaminate, multiply or survive in the product and being harmful to the consumer or product quality) is achievable, which ensures the microbial stability of the closed product over a defined period of storage time (in general, approximately 3–6 months at ambient conditions). Hence, the number of active cells is reduced to an amount of 1 CFU per 1000 l or lower. This means that the risk per package to include one CFU equals 1:1000. If, sometimes required, the risk for a microbiological failure of package should be less than 10**5 to achieve higher food safety. But the advantages first become clear by looking on the z values of microbes and desirable quality factors. Typical z values for microbes have been approximately 10 °C until the proposal of typical values for quality factors C_0 to compare the heating effect on appropriate compounds. It is similar to the F_0 value, with the change that the reference temperature is 100 °C:

$$C_0 = 10^{(T-100)/z}\, T \qquad [2]$$

Equation [2] reflects that the high temperatures show less effect on the degradation of quality factors due to their increased z values. UHT processing at temperatures of 130–150 °C for very short heating times of 2–6 s has very low thermal effect on food but it is quite effective for microbial degradation. Owing to this fact, such methods are often described as 'mild' methods. The only problem with UHT processing is that several heat resistant enzymes like proteases, lipases, and peroxidases are still active after high heat treatment, which tends to deteriorate the food quality. This may lead to quality defects like off-flavors and age gelation during storage.

Aseptic Processing

The aseptic process comprises of several steps, which must be fulfilled to achieve a shelf-stable product (Figure 1). The critical cleaning and safety concerns may be briefly described as:

- Sterilization of all installations before their operation in the aseptic section of the product processing. This usually includes the sterilization of product and the package, pipes and tubing for product, sterile air and gas, as well as filler, and other relevant machine zones. The industry premises are frequently disinfected to minimize contamination risks.
- Sterilization of all media entering the system. They are generally air, gases, and water for cleaning, heating, and pneumatic applications.
- Sterilization during closure of packaging materials as well as containers.
- Sterilization and cooling of the product before filling in the package.
- Securing a sterile environment in the whole system during filling and sealing.
- Guaranteed sealing quality to obtain hermetic packages.

It is clear by this above enumeration that aseptic processing is complex due to interactions between many compounds in

the process line. Modern processing plants allow a high level of control and automation, making aseptic processing highly cost efficient and handling of food much easier.

Product Processing

In the aseptic packaging process, the plant design is based on the principles of sterilization as already discussed. UHT processing is commonly carried out in four major steps for the presterilization of the product.

1. Preheating of the product to a defined temperature.
2. Final heating to sterilization temperature.
3. Temperature holding over a defined period of time.
4. Instant adequate cooling at ambient or chilled conditions to avoid product damage.

The processing steps should be held as short as possible to reduce the quality losses through thermal processing. Different types of plants have been developed that fall into two classes. Class one is the indirect heating approach, whereas the second type is direct heating through steam infusion into the product.

1. Indirect heating in closed heat exchangers, with separate product and heat exchange by a heat-conducting surface. This category has three main types available in the market:
   a. Scraped surface heat exchangers.
   b. Plate heat exchangers.
   c. Tubular heat exchangers.
2. Direct heating by steam as heating media rapidly heats the product to the desired temperature. The steam is rapidly injected to achieve the desired consistency in the 'sterile' product. The product is precooled before being filled into an aseptic package. It can be of two types:
   a. Steam infusion (product is injected into the steam flow).
   b. Steam injection (steam is injected into the product flow).

Both systems have their advantages and disadvantages. Direct methods deliver better product quality through high temperature and short heating time. Indirect methods require longer heating time, which may also affect the food quality and material buildup on the heating surface. Their advantage lies in the enormous cost efficiency through energy saving and lower installation as well as repair costs together with a higher throughput than direct processing plants. In addition, they are easier to handle because dilution by condensing steam is not problematic. Today, most companies use indirect heating methods and direct systems have almost disappeared from the market.

New Technologies for Product Sterilization

Several new potential techniques had come up in the past in which heat is not used for killing of microorganisms. Owing to the physiological properties of microorganisms, factors like pressure, electricity, and radiation can also lead to their cellular death. Some of them are:

- Radio heating frequency.
- Microwave heating.
- Ohmic heating.
- Pulsed electric fields (PEFs).
- Ultraviolet (UV)-radiation.
- Pulsed light.
- Ultrahigh pressure (UHP).

Some of these processing technologies (UHP and PEF) are already in use and show promising results in terms of product quality. They are limited in use due to high operational costs in comparison to UHT processing. Moreover, sterility issues are still a concern, with the use of such technologies.

Packaging Technology

For aseptic packaging, the package has to fulfill a series of criteria that are mandatory to ensure the safety and quality of the packaged product:

- Food safety: The most important function of aseptic packages is to ensure that the product sterility is maintained over extended period of time at ambient temperatures; especially, the package should avoid or prevent recontamination. In addition to this, the packaging material must be free of any substances that may raise safety concerns and must be stable under the product conditions, for example, pH, temperature, oxygen, etc.
- Shelf life: The shelf life of a product can be defined as the time span after which a consumer does not accept the product. This might be due to the product's color or smell as well as its taste. Technologically, such products are still consumable as the degradation of appropriate compounds is commonly caused by light or atmospheric oxygen but not always in aseptic packaging.
- Physical protection: A package must be strong enough to ensure the protection of the product, even after minor physical damages like drops or hits. This is very important to guarantee the safety of the product. It also makes transportation and handling easier, faster, and cheaper.
- Product containment: This is the main function of a package to prevent the hazards of contamination. Liquid foods must be contained in packages with adequate tensile properties to avoid leakages.
- Nutritional protection: Standing in direct relation with the shelf life of a product, nutritional protection is of major concern today for the consumer acceptance of a product. The effects that also lead to color degradation reflect the depletion of nutritionally important substances like vitamins, omega-fatty acids, and antioxidants. Carotenoids are one of the best examples; through oxidation, they degrade from deep red bioactive pigments to colorless and biological inactive substances.

All these examples together reflect the importance of packaging and the difficulties, which have to be realized by an aseptic package. Therefore, the right packaging material, sterilization method, and sealing are required, together with an intelligent package design to accomplish all requirements.

Packaging Materials

Packaging materials for aseptic packages must fulfill a series of requirements before they are commercially used:

- It must withstand sterilization conditions.
- It must be inert to the product and should not allow the migration of any substances from the package to the product.
- It must protect the product from environmental influences like light and oxygen.
- The physical integrity must be ensured.
- It must be cheap and easy to handle.

A brief overview about the materials used in aseptic packaging is presented in Table 1. A series of packaging systems consisting of such materials are available on the market. They can be segregated into five major groups, which can be further classified into subgroups (Table 2). Laminated paperboard cartons are the most widespread ones, being composed of several materials with diverse properties.

Composite Materials

Most of the packaging systems used for aseptic packaging consist of several materials with different functions. The improvement in bonding and development of vapor deposition technique had led to the development of composite materials. These composites unify the properties of several materials, thereby forming an effective and cost efficient barrier against environmental influences. Figure 2 shows a composite material such as the Tetra Pak-laminated paperboard cartons wherein up to six layers provide total protection against factors like microorganisms, light, moisture, oxygen, and smell from outside and the loss of liquid and flavors from inside. The most famous ones are Tetra Pak aseptic cartons, which consist of three basic materials, forming a six-layer sandwich. The use of composite structures allows the use of cheap packaging materials on the outside and the high quality film in contact with the liquid food. A very good example is the paperboard layer, which helps in the mechanical stability of the package but has no other protective properties. The paperboard layer (providing high stability at low cost) is often combined with very thin layers of PE (sealability, liquid and flavor barrier) and Al foil (light, odor, gas and microorganism (MO) barrier), so that all the desired packaging properties can be imparted.

Package Sterilization

Package is also presterilized in the similar fashion as described above to achieve the sterility necessary to prevent the microbial contamination from package. Therefore, the package has to fulfill a series of requirements before it is considered for aseptic packaging:

- Should be compatible with the aseptic treatment or sterilization.
- The residues should not pose any health hazard.
- Should have no adverse effects to the product.
- Safe for personnel working with the method.
- Reliable and economical.

Several techniques can be used in package sterilization. The sterilization technique depends on the requirements of the packaging material and product as shown in Table 2. The techniques can be separated into three main groups: (1) sterilization by heat; (2) sterilization by chemical agents; and (3) sterilization by radiation (Table 3).

Sterilization by Heat

Heat sterilization is performed mainly by 'moist' or 'dry' heat. For 'moist' heat, temperatures of approximately 121–129 °C with pressure are used, whereas 'dry' heat requires temperatures from 176 to 232 °C for longer duration. The high temperatures with long heating times limit this technique to metallic packages or packages out of plastic laminates that can withstand much heat. The sterile air used for this process is commonly sterilized at temperatures ranging from 260 to

Table 1 List of functional attributes of several packaging materials being used for aseptic packaging

Material	*Barrier property*				*Durability*		
	Oxygen	*Moisture*	*Light*	*Seal quality and adhesion*	*Stiffness*	*Tear*	*Puncture*
Linear-low density polyethylene		X		X		X	X
Low-density polyethylene		X		X			
High-density polyethylene		X	X	X	X	X	X
Polystyrene					X		
Polypropylene		X				X	
Polyvinylidene chloride	X	X					
Ethylene vinyl alcohol	X						
Polyamide (Nylon)						X	X
Ethylenacrylic acid				X			X
Paperboard			X		X

Table 2 Available aseptic package systems in the market

Packaging system	*Materials*	*Subcategories*	*Properties*
Cartons	Laminate of polyethylene, paperboard, and aluminum foil (for detailed construction seal, see **Figure 3**)	Form-fill-seal	● Commonly sterilized by hydrogen peroxide (H_2O_2) in deep bath, wetting systems as H_2O_2 aerosol, H_2O_2-steam or in combination with UV. ● Directly formed in the filling machine ● Continuous filling of product until sealing ● Filling without headspace possible
		Prefabricated	● Folding is carried out under nonsterile conditions ● Filling machine must consists of several separate areas ● Commonly sterilized by hydrogen peroxide (H_2O_2) in deep bath, wetting systems, as H_2O_2 aerosol, H_2O_2-steam or in combination with UV ● Residual peroxide might be a problem ● Filling only with headspace
Cans	Tinplate; electrolytically chromium-coated steel and aluminum; and composites of foil, plastic, and paper with metal ends	Metal cans	● Available in volumes from 125 ml to 22 l ● Superheated steam is used to guarantee aseptic conditions during filling ● Filling with headspace ● Resistant against nearly all heat conditions
		Composite cans	● Similar to metal cans ● Sterilization by hot air at 143 °C for 3 min
Bottles	Glass, high-density polyethylene, and polypropylene (PP)	Glass	● Can be sterilized with all methods ● Risk of breaking ● No more commercially used today ● Weak or no light protection
		Plastic	● Material can be mixed with pigments for light protection ● Available as nonsterile, and single station systems (blowing, filling, and sealing in one step) ● H_2O_2 or peracetic acid (PAA) for sterilization ● Only headspace filling possible
Sachets and pouches	Laminate of low-density polyethylene, a center layer of ethylene vinyl alcohol (EVOH), and carbon black	Form-fill-seal	● Production is similar to laminated cartons ● Material is presterilized by bathing in H_2O_2
		Lay-flat tubing	● Blown polymer film tubes ● Only transversal seal required
Cups	High impact polystyrene, PP, polyvinylidene chloride, and EVOH	Preformed	● Sterilization by H_2O_2 or a combination of both
		Form-fill-seal	● One step process ● Sterilization by H_2O_2, saturated steam ● Often used for puddings

320 °C. The advantage of this technique is that it is simple in use, effective, easy to control, and cost effective. However, the application field is limited to packages consisting of heat sensitive materials. This process is also compatible with multilayer laminated packages. The heat that is required to melt the raw materials is high enough to guarantee the sterilization of the material. To prevent recontamination, the final forming is carried out in the aseptic packaging machine.

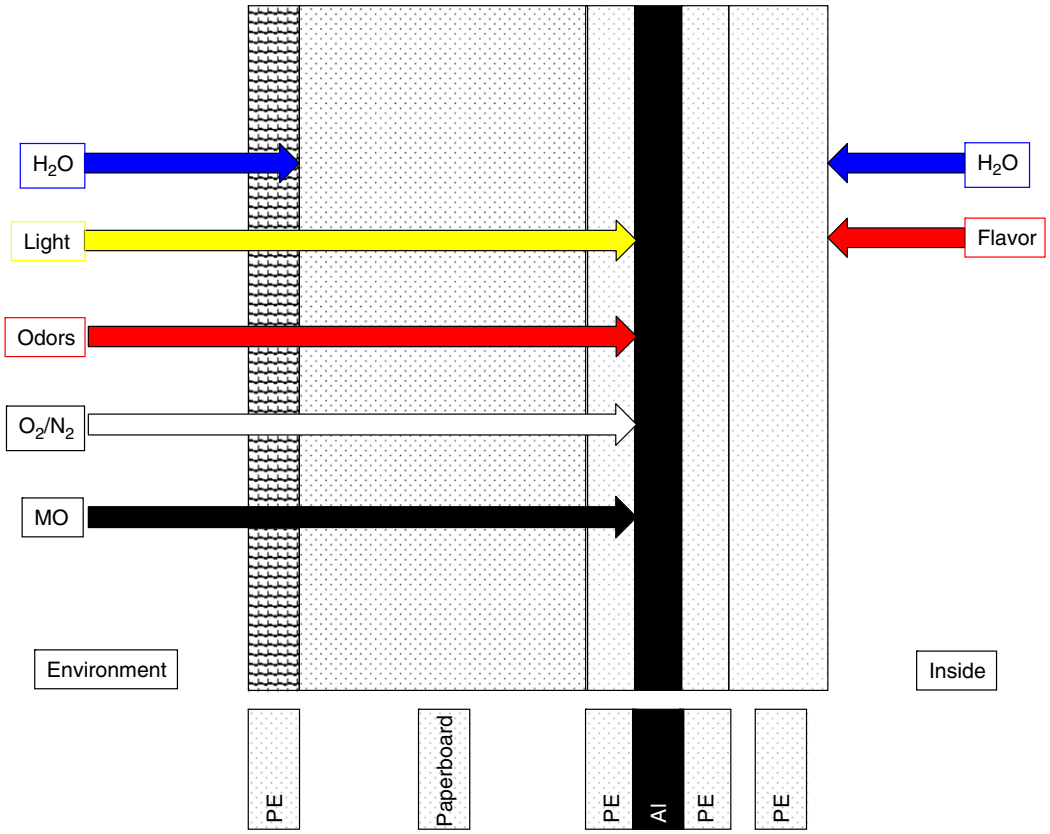

Figure 2 Schematic material stack like that used in laminated paperboard cartoons (Tetra Pak). PE, polyethylene.

Sterilization by Chemical Agents

Chemical agents are often used for package sterilization. The type of chemicals being used depends largely on the product meant to be packaged. Hydrogen peroxide (H_2O_2) at concentrations of 30–35% and peracetic acid (PAA) is are widely used. The typical temperatures for sterilization with H_2O_2 are from 60 to 90 °C for fluid H_2O_2 and above 90 °C for H_2O_2-steam, being much lower than 'dry' heat and still lower than 'moist' heat. All materials are not resistant against all chemicals, so it is very important to pay attention as to which chemical is suitable for the packaging material. Three different techniques are available for wetting, depending on whether prefabricated containers or raw material is used, as well as shape in case of prefabricated containers.

- Dipping/rinsing: The package is passed through a bath of H_2O_2 that contains a wetting agent to ensure a uniform wetting of the surface. After the bath, the liquid is mechanically removed and the package is dried and activated by hot air.
- Spraying/aerosol: H_2O_2 is sprayed on prefabricated packages. Hot air is used as carrier gas by which the sterilization effect of H_2O_2 is enhanced. New technique uses vaporized H_2O_2 mixed with hot air of 130 °C instead of liquid droplets.
- Rinsing: This process is quite similar to the dipping but it is much more suitable for prefabricated containers with an intricate shape. H_2O_2 or a mixture of H_2O_2 and PAA are sprayed in the container. In this process, the container is drained and then dried with hot air.
- Steam/aerosol: This is also applied to the packaging materials to achieve the desired sterility.

Sterilization by Radiation

Sterilization with radiation has the advantage of not involving the use of heat or chemicals, thereby not only offering chemical-free materials but also allowing the usage of heat-sensitive materials for packaging. But depending on the type of radiation, the material penetration must be considered so that shadowing effects may result in a worse sterilization. The disadvantage with the use of radiation is discoloration of the packages. Two types of radiations are used: γ-Radiation: This technique has been in use for a long time. Owing to the high penetration of γ-rays, packages are treated in bulk with doses of approximately 1.5 Mrad. The disadvantage with this technique is its low consumer acceptance.

A relatively new approach is electron beams. They have good penetration, together with good consumer acceptance and high sterilization effects. Until now, equipment size and cost have limited the use of such systems, but appropriate plants are in development and with time these problems may be solved. Some of the prototypes have already appeared in the market.

Table 3 Overview of different methods for package sterilization

Method	*Application*	*Advantages*	*Disadvantages*
Superheated steam	Metal containers	High temperature at atmospheric pressure	Less effective than saturated steam due to microorganisms higher resistance
Dry hot air	Metal or composite containers	Same like superheated steam	Same like superheated steam
Hot hydrogen peroxide	Plastic containers and laminated foils	Fast and efficient	Highly depending on used temperature and chemical reagent
Hydrogen peroxide/ultraviolet (UV) light combination	Plastic containers (preformed cartons)	Increased effectiveness of hydrogen peroxide through UV light	Chemical reagent
Ethylene oxide	Glass and plastic containers		Cannot be used where chlorides are present or where residuals would remain
Process heat from coextrusion	Plastic containers	No chemicals used and environmental friendly through energy recovery	
Radiation	Heat-sensitive plastic containers	Can be used to sterilize heat-sensitive packaging materials	Expensive, risk of radiation source, and requires specially trained staff

Source: Adapted and modified from Ansari MIA and Datta AK (2003) An overview of sterilization methods for packaging materials used in aseptic packaging systems. *Food and Bioproducts Processing* 81: 57–65.

Filling Systems

Filling is the most critical part in aseptic packaging process. It combines the sterilized product with sterile package. Before the product is filled, the system is commonly degased to prevent any kind of undesirable oxidative reactions. This process commonly takes place in a tube, in which the product is exposed to vacuum until it flows through the tube. The degased product is then stored in a cooled tank. This tank system allows both sterilization and filling processes to be carried out independently of each other. For the purpose of filling, the product is initiated into the filling machine by sterile air, which expels the product out of the tank. The whole filling process is carried out in a hermetically sealed sterile environment. This is required to avoid product contact with the surrounding air during the filling process in the package. If no sterile air is used, microbes will be 'filled' in the package, thereby destroying the achieved sterilization.

Sealing

Sealing is the last step in the aseptic packaging process. It has to guarantee the package integrity by sealing it hermetically to maintain sterility during appropriate storage time. The seal must be strong enough to survive physical stress during handling and distribution in order to maintain the sterility of the product. The most commonly used technique is heat sealing. The package material is heated to an appropriate temperature; the sealing material begins to melt and easily flows in all cavities, forming a total closing. This is supported by the application of pressure on the sealing by a pair of jaws, which is usually fitted with a heater. The most widely used sealing material is PE, which constitutes the outer and inner layer of composite packages. It is melted by sterile hot air or by a short electrical impulse as indicated in the Figure 2. PE is easy to melt, very strong, and has better sealing properties than other polymers in forming the hermetical seal, an important requirement for the package integrity. The only disadvantage of PE is its permeability to gases, which may lead to oxidation and water loss.

Safety Aspects

In the light of the previous sections, it is apparent that aseptic packaging is a highly complex process. The process is prone to a series of contamination risks, the most important ones being schematically represented in Figure 3. For better understanding, the risks may be separated into three different groups as listed below in enumeration, whereby all can be viewed in their relationship:

1. Risks associated with prepackaging.
2. Risks with packaging.
3. Postpackaging risks.

Each group can be further divided into several subgroups for characterization of individual risks. The sum of all individual risks can be used as an indicator for the safety of the process. Thereby it can establish a factor R_{con} (eqn [3]), which allows the estimation of risks going out from the process.

$$R_{con} = \sum_{i=1}^{n} RSG_i \qquad [3]$$

where, risk per subgroup (RSG) is percentage of the associated risks from one subgroup. These values need to be summarized due to safety concerns and R_{con} should be as low as possible. A similar approach is the calculation of the microbial contamination rate (CR) from various sources.

$$\sum_{i=1}^{n} CR_i = CR \leq x \qquad [4]$$

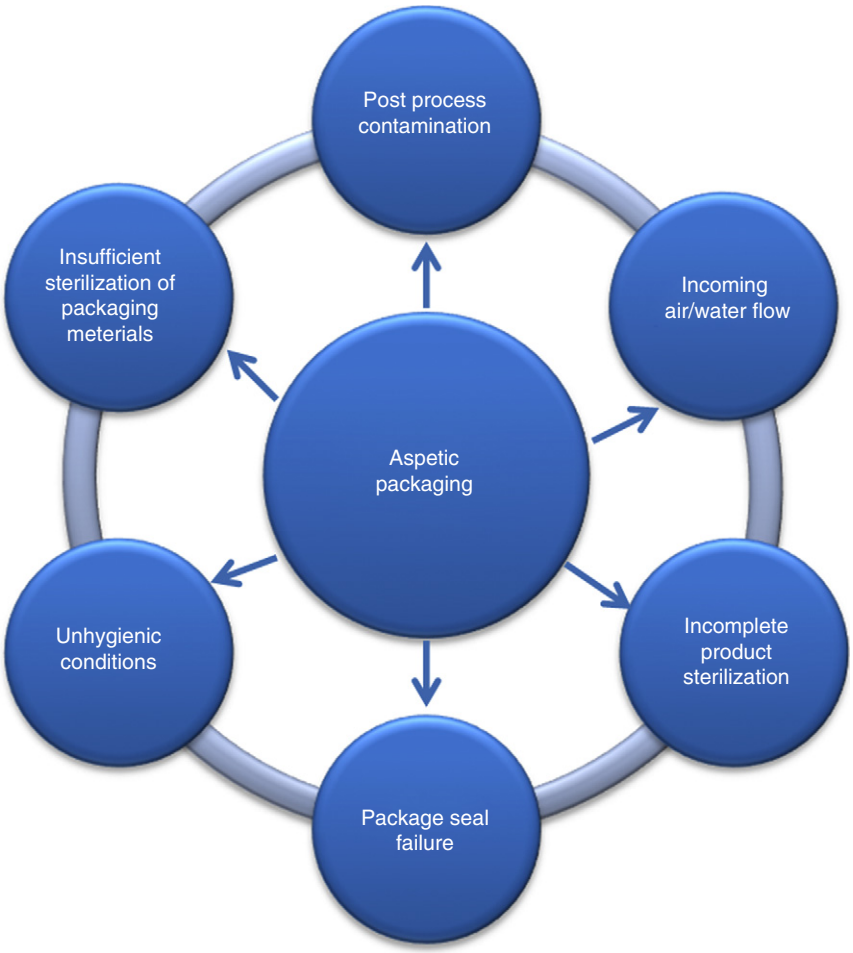

Figure 3 General risks affecting aseptic packaging processing.

where CR_i is the contamination risk resulting from an individual source and x represents the acceptable CR. Like R_{con}, the total CR is the sum of the individual CRs, which are contributed by various sources. Overviews of various sources for RSG as well as CR are listed in Table 4. The advantage of R is that this factor is much more segregated than CR in not being limited to considering the microbial contamination risk alone, and this segregation is important for extremely sensitive products like baby nutrition wherein heat sterilization is used to reduce the allergic risks resulting from several proteins like β-lactoglobulin. Separating appropriate risks into small subgroups helps to detect critical control points (CCPs) and establish an effective hazard analysis and CCP (HACCP) concept, so that contamination risks can be held in an acceptable range.

Table 4 List of various contamination sources for RSG and contamination rate (CR)

RSG	*CR*

Storage	

Insufficient Plant Sterilization

Methodical cleaning and sterilization of processing plants provide the basis for aseptic packaging. Cleaning-in-place (CIP) and sterilization-in-place (SIP) allow for reproducible results with a highest degree of reliability. The application of these techniques depends largely on plant design. Poor plant design results in product deposition in the plant, providing a nutrient for microbes, which can contaminate the product. Moreover, biofilms cause a problem in being hard to be removed by CIP, so they form a perfect and protected environment for pathogen microbes. The practice shows that CIP

followed by SIP is often used with plants that are not completely suitable for such processes.

Under Processing

Extended processing can result in quality and nutrient loss, whereas under processing is associated with high food safety risk. To maintain product quality at low price, both heat processing and package sterilization times are held as short as possible. This procedure requires a lot of time for process optimization in order to obtain the required commercial sterility. Therefore, it is important to specifically adjust the processing conditions for each product due to minor differences in viscosity, flow rate, and particle concentration, which may otherwise cause major differences in the sterilization process. Also, factors such as temperature differences in heat exchange media, concentration of sterilization chemicals, and the age of radiation sources may result in risks during aseptic processing.

Filling and Sealing

The storage of the presterilized product in storage tanks before filling is associated with a high level of risks. Low number of heat-shocked microorganisms survive, as could be the case in commercial sterile products, can start to grow with storage time. This may also happen due to insufficient product heating. They may completely contaminate whole product in the tank. In this perspective, the thermocouple in the flow diversion value needs frequent check on its sensitivity for recording the desired product temperature so as to avoid the microbial survival in the product. Until filling, the requirement of a hermetically sealed packaging plant is difficult to implement, but is done in all aseptic systems. The incoming flows like product, sterile air, and packages or packaging material must be brought through an airlock or hermetically closed pipes in the plant. Especially, the sterile air might cause problems due to air filter damage. If unnoticed, this will allow spores/microbes to survive in the pipes behind the filtering and sterilization system. They would grow and spores may be transported by the airflow in the plant to enable their entry into the packages. The final point in the aseptic chain of risks is the sealing step. If the sealing temperature is not high enough or the applied pressure is too low, the sealing will not be strong enough to prevent microbial migration to the product, thereby leading to postpackaging contamination. Additionally, it will not be strong enough to survive physical state use during transportation and storage, thereby leading to damaged packages.

Risk Prevention

The ways to prevent hazards or risks in the aseptic packaging processes are widespread, ranging from automation and plant design to employee trainings. In case of plant design, the European Hygienic Engineering and Design Group provide a series of guidelines that are quite helpful for the right design of processing plants. An additional approach is establishing a good working HACCP concept, together with routine testing. Table 5 provides a series of CCPs and possible methods to evaluate and prevent any kind of risks. A variety of destructive as well as nondestructive methods are available in the market, especially for testing. Package integrity is one of the most

Table 5 Overview of several critical control points requiring to be monitored in an aseptic packaging process

Process	*Processing steps*	*Parameter that should be monitored*
Product sterilization	Processing plant, pipes, and storage tanks	Sufficient cleaning and sterilization (refer Table 3), well functioning, sensor are correctly working, and no leakages
	Standardized product	Product parameters (viscosity, composition, density, particle size, etc.) are into specified ranges and microbial contamination is not too high
	Sterilization process	Humidity, temperature, concentration, pressure are correct, and depending on the used method
	Cooling	Temperature of chilled product
Package decontamination	Processing plant	Equal to product processing
	Decontamination step	Temperature, time, quantity dosed, concentration, residual amount energy, etc. depending on the used method
	Decontaminated material	Remaining colony-forming unit of relevant microorganisms on material surface, damages of material surface, recontamination until storage in packaging machine
Cooling and storage	Storage of sterilized product	Sterilization of storage tanks, contamination of stored product, temperature, and storage time
Filling	Processing plant	Equal to all others, sterility of incoming process flows and air, and hermitical sealing
	Package filling	Needle contamination, pressure, filling height, speed, and temperature
	Sealing	Time, temperature, pressure, positioning, and pack seal integrity

Biopreservation

F-K Lücke, Hochschule Fulda – University of Applied Sciences, Fulda, Germany

Glossary

Bacteriocins Peptides, ribosomally synthetized by bacteria, that specifically inactivate (inhibit or kill) other (mostly close related) bacteria.

Biopreservation Use of microorganisms, enzymes, or natural antimicrobials to protect foods against deterioration caused by microorganisms and/or against growth of pathogenic microorganisms, without major changes in their sensory properties.

Endolysins Bacteriophage-encoded proteins attacking bacterial cell walls.

European Food Safety Authority (EFSA) European reference body for risk assessment on food and feed safety, animal health and welfare, nutrition, plant protection, and plant health.

Generally recognized as safe (GRAS) Status of a substance that is generally recognized, among qualified experts, as having been adequately shown to be safe under the conditions of its intended use, or unless the use of the substance is otherwise excluded from the definition of a food additive (quoted from the US Food and Drug Administration (FDA)).

Qualified presumption of safety (QPS) A tool for safety assessment tool for microorganisms added to food and feed (quoted from EFSA).

Definitions and Scope

In the broad sense, biopreservation may be defined as the use of biological systems (microorganismss and their metabolic products, enzymes) to improve food safety and to extend the shelf life of food and feed. In this sense, biopreservation has a long tradition. For example, milk is preserved by conversion into sour milk products and cheeses, and meat is processed into shelf-stable sausages by a combination of microbial fermentation and drying. Likewise, animal feed may be preserved by ensiling. Obviously, the resulting products are completely different from the original raw materials. In the strict sense, the term 'biopreservation' is used for the use of biological processes that change the sensory properties of a food as little as possible.

The term 'biopreservation' may also be extended to the use of biological systems to protect humans, livestock, and plant crops from colonization by pathogens. This aspect is not discussed further in this article. Biopreservation of animal feed, and possible use of bacteriophages, are also not covered. For an extensive treatment of these aspects, the reader is referred to the book edited by Lacroix and the literature on probiotics.

It should also be remembered that frequently, mechanisms other than microbial activity, limit the shelf life of food. These factors include the activity of food enzymes, the action of oxygen, recrystallization of starch in bread, and loss of turgor in fruit and vegetables. For example, use of oxygen-scavenging enzymes to extend shelf life may also be termed as 'biopreservation.' However, in this article, the term 'preservation' is limited to inhibition of microorganisms, following the definition of 'preservatives' as 'substances which prolong the shelf life of foods by protecting them against deterioration caused by microorganisms and/or which protect against growth of pathogenic microorganisms' (European Union (EU): Regulation No. 1333/2008).

Interest in biopreservation is triggered by various factors:

- Increased awareness of regulatory authorities and consumers on the importance of food safety.
- Increased recognition of the responsibility of food industry to ensure safety of its products.
- Increase in the number of susceptible individuals in the population, especially in industrialized countries, and thus the need for more stringent hygiene standards.
- The need for increased stability in food quality in order to prevent food loss due to spoilage.
- Consumer demand for increased convenience, for example, less frequent shopping, while still expecting 'fresh' and 'natural' food without chemical additives. Hence, retailers urge their suppliers to extend their shelf life and to cut the list of additives on the label ('clean labeling').

Generally, current food regulations do not require the use of enzymes and microorganisms to be labeled. Hence, it is tempting to add microorganisms or enzymes that form antimicrobial compounds *in situ*. However, the regulations were set up with the assumption that the consumer knows that,

for example, yogurt and cheese are made by the action of microorganisms. Whether this holds true for novel use of biological systems is, at best, doubtful. Current trends in legislation will be treated in a separate section of this article.

Mechanisms of Biopreservation

Viable microorganisms may be added to the food to be preserved. In contrast to 'starter cultures', these 'protective cultures' should only minimally change the sensory properties of the food. They may act by competitive exclusion (occupying binding sites, competing for nutrients) or by excreting antimicrobial compounds. Such compounds may be main products of energy metabolism (usually organic acids), other low-molecular mass compounds, or ribosomally synthesized peptides, namely, bacteriocins.

Lactic and acetic acids are the main metabolic products of lactic acid bacteria and essential for the safety and stability of various fermented foods. Other organic acids (such as propionic acid, phenyllactic, and *p*-hydroxyphenyllactic acids, 3-hydroxy fatty acid, 2-pyrrolidone-5-carboxylic acid) are formed in low amounts but have some inhibitory activity, particularly against fungi. This could be exploited to extend the mold-free shelf life of certain cheeses and of bread. Some neutral metabolites (e.g., diacetyl, hydrogen peroxide, reuterin, certain cyclic dipeptides) have a wide spectrum of antimicrobial activity. However, most of the compounds mentioned have an impact on the sensory properties, and it is difficult to select strains that form a 'cocktail' of these compounds that optimally suits the food to be preserved. For example, the aroma of diacetyl may be tolerated in some dairy products but definitely not in meats or juices.

Bacteriocins of interest to food preservation include small, heat stable, hydrophobic cationic peptides formed by Gram-positive organisms. Class I bacteriocins are also called lantibiotics and comprise posttranslationally modified peptides making pores into the cytoplasmic membrane. Of these, nisin (formed by strains of *Lactococcus lactis*) has been approved as an additive to certain foods (see section Legal Aspects). Within the Class II bacteriocins (not modified after translation), compounds with effect against *Listeria* are of interest. Of these, pediocin PA-1 is formed by commercially available cultures of *Pediococcus acidilactici* and *Lactobacillus sakei*, and leucocin A/B are formed by a commercial culture of *Leuconostoc carnosum*. Their main mode of action is also the permeabilization of the membranes. Application of bacteriocins or cultures producing them appears attractive because they have no effect on sensory properties and are readily destroyed in the upper intestinal tract, which may eliminate concerns about spread of resistance genes and resistant organisms. Moreover, it may be argued that bacteriocin-forming bacteria are present in traditional fermented foods. However, use of bacteriocins in food preservation has limitations: Their inhibitory spectrum is small and restricted to Gram-positive organisms, unless sublethally injured by other preservation techniques, Gram-negative bacteria are protected against these bacteriocins by their outer membrane. Another consequence of this specificity is that the susceptibility of the target strains may vary. Moreover, bacteriocins may be inactivated by food components such as membrane lipids or proteases.

Search for protective cultures was usually focused on lactic acid bacteria isolated from foods because these organisms have a favorable reputation for safety, and are competitive in many foods. However, for foods that have to be stored in the presence of oxygen (such as shredded vegetables), or other foods in with lactic acid bacteria are poor competitors, use of other microorganisms is also considered. However, this has limitations because it will be easier to obtain a generally recognized as safe (GRAS) or qualified presumption of safety (QPS) status for lactic acid bacteria than, for example, Gram-negative bacteria dominating the flora of ready-to-eat vegetables and fresh unpackaged meat.

Alternatively, one may cultivate food-grade microorganisms outside the food, in suitable food-grade media such as milk, isolate the compounds and add them to food. The advantages of this approach are that the producer organism need not to be competitive in the food to be preserved, and control of the levels of the antimicrobial compounds in the food is easier. For example, *Lactobacillus reuteri* forms a broad-spectrum antimicrobial compound, reuterin, with potential as a food preservative, but the bacterium is found in the gastrointestinal tract and in sourdoughs and competes poorly in foods like meats and cheeses. However, legal approval is generally required before these antimicrobials compounds can be used as food additives. Hence, much research and development are under way on the antimicrobial effect of natural food components such as essential oils from herbs or lactoferrin from milk, and the isolation and application of them. However, this is not covered by the term 'biopreservation' as used in this article, and the reader is referred to recent reviews.

Certain enzymes may also be used for biopreservation. Lysozyme, a muraminidase degrading bacterial cell walls, is already being used as a substitute for nitrate in some cheeses, in order to inactivate clostridia. Specific bacteriophages or their endolysins acting on the cell wall of the target organisms may be used to inactivate specific microbial species, for example, *Listeria monocytogenes*, or to eliminate certain biofilms. Lactoperoxidase is naturally present in raw milk and can oxidize thiocyanate ions in the presence of hydrogen peroxide generated by lactic acid bacteria (or added as such). The antimicrobial effect of the reaction product (hypothiocyanate) can be used to stabilize raw milk during transport under poor refrigeration.

Antimicrobial peptides are also part of the host – defense system of higher organisms and raised much interest in pharmacy. Whether or not they are useful in food preservation remains to be shown.

Applications

Meat, Poultry, and Fish

Raw Unprocessed Meat, Poultry, and Fish

When unprocessed or minced meat, poultry, and fish are stored in air or in oxygen-permeable packaging material, it is spoiled by Gram-negative bacteria, and relevant pathogens are Gram-negative, too. Lactic acid bacteria compete only poorly.

Therefore, very high levels of protective cultures or biopreservatives would have to be added to obtain a relevant effect. This is not a realistic option. However, lactic acid bacteria are favored by reduced oxygen, elevated CO_2 tension, and the presence of fermentable carbohydrates. On chilled red meat packaged under vacuum or under modified atmosphere (20–30% CO_2), use of selected strains of well-adapted psychrotrophic lactic acid bacteria may extend shelf-life by suppressing other lactic acid bacteria and *Brochothrix thermosphacta* that cause off-odors.

Fermented Meats

The main microbial hazards associated with fermented meats are salmonellae and shigatoxin-forming *Escherichia coli* (STEC). Growth of these bacteria is well under control by appropriate formulations (salt, curing agents, sugar, starter cultures, ripening temperature). The same applies to *Li. monocytogenes*; however, no outbreaks of listeriosis could hitherto be traced to the consumption of fermented sausages, so the risk should not be overestimated. The growth of *Staphylococcus aureus* is also well controlled by present technology.

Sausage fermentation usually reduces the counts of salmonellae, STEC, and *Li. monocytogenes* by 1–3 log cycles, depending on the strain, the pH, and the duration of drying and aging. It is desirable to accelerate the death rate of these pathogens further. Use of bacteriocin-forming lactic acid bacteria has been shown to reduce *Li. monocytogenes* counts by 1–2 additional log cycles (as compared to a non-bacteriocinogenic control culture with similar acidification rates) in various types of sausages, and anti-*Listeria* protective cultures (containing bacteriocin-producing *Pediococcus* and/or *Lactobacillus* strains) are commercially available. Cell-free preparations of bacteriocins (e.g., enterocins) have also been used successfully to inactivate listeriae. However, use of bacteriocins (including nisin) is not permitted for meats in the EU.

As outlined above, bacteriocins have some effect on Gram-negative bacteria only if the outer membrane of these organisms is damaged by additional stress factors. Some effect against these organisms may only be expected if a bacteriocin-forming starter is combined with other preservation methods.

For fermented sausages developing a surface flora (e.g., Italian-style salami or French 'saucissons'), surface inoculants (molds, yeasts) antagonistic against mycotoxigenic molds and/or *S. aureus* are useful.

Other (Nonfermented) Processed Meat, Poultry, and Fish Products

The main microbial hazard to be controlled in nonfermented ready-to-eat meat, poultry, and fish products is *Li. monocytogenes* because this organism grows at refrigeration temperatures, even in the range of water activity (usually 0.96 and above) and pH values (usually 5.8 and above) typical for these products. Heat treatment such as hot smoking of fish normally inactivates listeriae but also spoilage organisms which would otherwise compete with these organisms. *Li. monocytogenes* may be present in the processing environment, especially for fish, and it is difficult to avoid recontamination of the products during further processing. Hence, the 're-addition' of food-grade bacteria should be considered that inhibit (or even kill) listeriae while not causing spoilage. The feasibility of this approach has been demonstrated by various research groups, using selected strains of *La. sakei* or *Le. carnosum* that only minimally change the sensory properties of the products, provided that the content of fermentable sugar is below 0.1% (which means that no sugar should be added to the product). The antagonistic effects may be increased by using bacteriocin-forming strains and/or of bacteriophages specific for *Li. monocytogenes*. The inoculum size is critical for the desired effect. Preparations of *La. sakei* (with and without ability to form bacteriocin) and *Le. carnosum* (bacteriocin-former) are commercially available. Nevertheless, the prevention of recontamination by listeriae during handling, slicing, and packaging operations should have priority, and growth potential of *Li. monocytogenes* may also be reduced by the addition of small amounts of sodium acetate or other acidulants.

In lightly preserved fish and seafood, *Carnobacterium* species contribute to spoilage. However, some strains of carnobacteria have little spoilage potential and an antagonistic effect against other spoilage bacteria and *Li. monocytogenes*. Bacteriocinogenic *Carnobacterium* strains have an even stronger effect and have potential in suppressing *Li. monocytogenes* in particular on cold-smoked salmon and similar products, which are frequently contaminated by this organism. An antagonistic strain of *L. lactis* has also been patented.

For lightly preserved fish and seafood, nonproteolytic strains of *Clostridium botulinum* are a hazard to be controlled, especially if fish has been grown in poorly managed aquaculture or caught in areas with high prevalence of spores of this organism (such as the Baltic Sea). For control of spore formers, the 'fail-safe' approach could be an option.

Milk and Dairy Products

To improve the safety of dairy products, biopreservation systems inactivating *Li. monocytogenes* are of interest. Under insufficient hygienic conditions, this organism may contaminate the surface of cheeses, especially those ripened by a surface smear applied after lactic fermentation. Many bacteriocins are effective against listeriae, but adding bacteriocins or bacteriocin-forming lactic acid bacteria to the milk may interfere with the fermentation of the milk. Hence, a more promising approach is to test microbial consortia in surface smear for anti-*Listeria* properties, to select the strains (staphylococci, coryneforms or yeasts) responsible for this effect, and to develop strongly antagonistic smear cultures. In the future, use of endolysins specific to listeriae may also be an option.

There are cultures on the market that have been selected for antagonistic activity against lactate-fermenting clostridia during cheese ripening. Lysozyme, an enzyme degrading bacterial peptidoglycan, also falls within the definition of 'biopreservatives' and is a permitted additive to prevent 'late-blowing' of cheese by clostridia. Commercial antifungal cultures combine strains of *Lactobacillus rhamnosus* or *Lactobacillus paracasei* with a strain of *Propionibacterium freudenreichii*, and propionate as well as various other low-molecular mass compounds contributes to the inhibitory effect. Cell-free preparations

with metabolic products of *P. freudenreichii* ssp. *shermanii* have been on the US market since decades under the brand name MicroGARD®.

Vegetables and Fruit

There is an increasing market for minimally processed vegetables and fruit, either ready to eat (for salad bars etc.) or ready to cook. Hazards to be controlled include Gram-negative pathogens (salmonellae, STEC) and *Li. monocytogenes*. Shredding of vegetables and fruit, damages the mechanical barriers against microbiological colonization and also causes enzymatic browning and texture changes resulting in a very short shelf life. Moreover, these products cannot be packaged and stored in the absence of oxygen. The safety of sprouts is especially difficult to ascertain because conditions needed for seed germination also favor the growth of bacteria. For all these reasons, use of protective cultures and biopreservatives is considered as an option. It was shown that certain Gram-negative aerobic bacteria isolated from fresh produce can inhibit the growth of pathogens on iceberg salad and sprouts. Application of bacteriocins to these products also had some effect against listeriae. However, it will be difficult to get approval of Gram-negative bacteria as protective cultures under the GRAS/QPS scheme, and, generally, it is difficult to preserve them, which is essential for developing cultures for commercial use.

Vegetables (especially cabbage and cucumbers), can be fermented by lactic acid bacteria to give products like sauerkraut, Korean-style kimchi, and pickles. Also, most table olives are produced by a lactic fermentation. Even though starter cultures are not generally used, the resulting products have a good record of safety. However, lactic acid bacteria with strong antagonism against microorganisms causing sensory deficiencies or spoilage, or forming biogenic amines could be useful. This applies particularly to table olives because the lye treatment for debittering also reduces the levels of 'spontaneous' lactic acid bacteria on the olives, which leads to poor fermentation and to problems due to growth of certain *Propionibacterium* and *Clostridium* species. Bacteriocin-forming lactic acid bacteria have been isolated from fermented vegetables and olives, and shown to be useful in pilot-scale experiments.

Other Foods

In food service operations, there is a trend to uncouple cooking from serving. Meals are normally not stabilized by low pH and/or low water activity, and, for culinary reasons, the times and temperatures of cooking are usually not sufficient to inactivate spores of psychrotrophic spore formers such as nonproteolytic *C. botulinum*. To inhibit this bacterium, a strict maintenance of the chill chain is needed, and the storage temperature must be below 3 °C if the storage time exceeds 5 days. This is not always ascertained, especially if cook-chill meals are marketed through retails. One option to improve the safety of these products is to add protective cultures that grow rapidly and acidify the product under conditions of temperature abuse. This 'fail-safe' approach has also been suggested for inhibition of *C. botulinum* in bacon, and for delicatessen salads.

Since most bacteriocins of Gram-positive bacteria are heat-stable, and some of them – including nisin – are also effective against spore-forming bacteria, it was considered to add them to food to be canned, in order to reduce the intensity of the heat treatment. However, there are problems with stability of bacteriocins especially in meats and other foods rich in fat and membrane constituents. Hence, a 'botulinum cook' is still necessary for low-acid shelf-stable canned foods, even with bacteriocins added. Rather, it may be considered to use heat stable bacteriocins to aid inactivation of thermophilic (e.g., *Geobacillus thermophilus*) and acidophilic (e.g., *Alicyclobacillus* spp.) spore formers in canned vegetables and fruit products, respectively. These organisms may cause spoilage, but are no threat to human health.

Legal Aspects

In general, additives are defined as food ingredients that are not consumed as food, and must be included into a positive list (as provided in the annexes of official regulations). This applies – with certain exceptions – also to metabolic products of microorganisms such as bacteriocins. Nisin has been approved as a food additive in the EU (for semolina and tapioca puddings, clotted cream and certain cheeses), and in the US, nisin and pediocin PA-1 have GRAS status and are permitted to be used in various foods. The required wordings in the list of additives differ between countries. This is the main reason why poorly defined preparations of metabolic products from food-grade microorganisms such as MicroGARD® are being used in the US but not to any extent in the EU.

As indicated above, there is a trend in food legislation to cut certain 'privileges' of microorganisms and enzymes as food additives. Positive lists of food-grade microorganisms (e.g., the QPS list of the European Food Safety Authority (EFSA), GRAS list of the Food and Drug Administration (FDA)) and enzymes (as stipulated in Regulation 1332/2008 of the EU) are being developed, and, for example, the EU regulation on provision of food information to consumers (as of July 2011) generally requires labeling unless the culture and/or enzymes are just 'carried over' with some ingredient, and/or are no longer active in the final product. Extensive approval procedures and labeling requirements will hamper the implementation of biopreservation procedures in commercial practice. Moreover, use of protective cultures for unfermented food will result in higher microbial counts and their possible misinterpretation by food inspectors.

It should also be mentioned that the interest in systems killing *Li. monocytogenes* is, to a great extent, powered by regulations interpreted to require 'zero-tolerance' for *Li. monocytogenes* in ready-to-eat food, and specify decimal reductions of pathogens, which are difficult to achieve by conventional fermentation methods. The EU (in its Regulation No. 2073/2005) and the Codex Alimentarius Commission standard CAC/GL 61-2007 (amended in 2009 in ALINORM 09/32/13) require zero-tolerance (i.e., absence in 25 g) for *Li. monocytogenes*, only in food that support growth of this bacterium, and in infant food, whereas in other foods not

supporting growth of *Li. monocytogenes*, a maximum level of 100 g^{-1} is tolerated.

Concluding Remarks

Use of biopreservation techniques may contribute to the safety and quality of perishable food but cannot replace good hygienic practice in food processing. For example, avoiding cross-contamination is the most important measure to avoid problems with *Li. monocytogenes* in meat and cheeses. In many fermented products (including dry sausages), *Li. monocytogenes* does not grow, and use of listericidal cultures for such products does not reduce the risk to public health but merely the risk that viable *Li. monocytogenes* cells are found in the final product, with subsequent problems in explaining this to customers and public health authorities.

Although there is plenty of scientific information on bacteriocins formed by food-grade bacteria (more than 11 000 hits for 'bacteriocins and food' in the SCIRUS® database, accessed July 2011), there are to date, rather few examples for commercialization of bacteriocins and cultures producing them. More attention should therefore be given to combining the effects of bacteriocin-forming cultures and other intrinsic and extrinsic factors affecting microorganisms, and on other mechanisms of biopreservation.

FOOD TECHNOLOGIES

Chilling

SJ James and C James, The Grimsby Institute of Further & Higher Education (GIFHE), Grimsby, UK

Glossary

Conduction, thermal Mechanism for heat transfer. The process of heat transfer through a solid material/medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

Convection, thermal Mechanism for heat transfer. The process of heat transfer through a liquid or gas by means of circulating currents caused by changes in density.

Hazard A biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effect.

Heat transfer coefficient Coefficient used in thermodynamics to calculate heat transfer, typically by convection or phase change, between a fluid and a solid.

Pasteurization A form of heat treatment that kills certain vegetative bacteria and/or spoilage organisms in milk and other foods. Temperatures below 100 °C are used.

Radiation, thermal Mechanism for heat transfer. Electromagnetic radiation generated by the thermal motion of charged particles in matter. All matter with a temperature greater than absolute zero emits thermal radiation.

Refrigeration May be defined as the process of removing heat from any substance to: (1) render colder – reduce temperature, (2) change its state – for example, water to ice, (3) maintain its state – preserving foods, storing ice.

Retail An operation that stores, prepares, packages, serves, or otherwise provides food directly to the consumer for preparation by the consumer for human consumption. This may be freestanding markets, sections in grocery or department stores, packaged, chilled, or frozen and/or full service.

Shelf-life The period during which the product maintains its microbiological and chemical safety and sensory qualities at a specific storage temperature. It is based on identified hazards for the product, heat or other preservation treatments, packaging method, and other hurdles or inhibiting factors that may be used.

Introduction

There is no strict definition of what constitutes a chilled food, although some countries provide legislative requirements for particular chilled foods. In general, a chilled food is any food in which the temperature of the food is reduced to, and maintained at, a temperature below that of the ambient temperature, but above the temperature where any of its water content will change from a liquid to a solid (i.e., begin to freeze). With fish and meat the maximum chilled shelf-life will be achieved at a temperature close to their initial freezing points. However, for some foods, such as bananas and other tropical fruit, the optimum temperature can be as high as + 14 °C.

Chilling is often preferred over other food preservation methods, such as smoking, drying, salting, or canning, because it produces no significant changes in the texture, taste, smell, or appearance of the food and maintains the original 'fresh' quality characteristics of the food.

Temperature is the principal controlling factor for the safety of chilled foods. Temperature is particularly important in such foods in slowing, or inhibiting, the growth of pathogenic bacteria.

Chilling Process

Chilling is a process of removing heat from a food and can only be achieved by four basic mechanisms: radiation, conduction, convection, or evaporation.

Conduction requires a good physical contact between the food to be chilled and the cooling medium, and this is generally achieved only with foods that can be shaped into regular shapes, such as blocks of meat or fish.

Radiation does not require any physical contact but a large temperature difference is required between the surface of the food being cooled and that of surrounding surfaces to achieve significant heat flow. In primary chilling, radiation is only important in the initial stages of the process in a system where the food is not surrounded by other products. Again, in the initial stages of the chilling of cooked food products (e.g., pies and other pastry products, meat joints, baked cakes, etc.), radiant heat loss can be substantial if the products are surrounded by cold surfaces.

Evaporation from a food surface reduces yield and is not desirable in most food refrigeration operations but can be useful again in the initial cooling of cooked food products and

Table 1 Generation times for foodborne bacteria in raw meat

Bacteria	*Temperature (°C)*	*Time (h)*		*References*
		Lag	*Generation*	
Salmonella spp.	12.5		6.79	Mackey *et al.* (1980)
Clostridium perfringens	12		11.5	Lund *et al.* (2000)
Escherichia coli O157:H7, pH 5.7	12	16.2	6.0	Walls and Scott (1996)
E. coli O157:H7, pH 6.3	12	2.78	3.9	Walls and Scott (1996)
Salmonella spp.	10		13.87	Mackey *et al.* (1980)
Salmonella Typhimurium	10	45	9.65	Smith (1985)
Yersinia enterocolitica	10		12.73	Logue *et al.* (1998)
E. coli SF	8.2	40	6.9	Smith (1985)
B. cereus	5		8.3	Lund *et al.* (2000)
Y. enterocolitica	5		16.53	Logue *et al.* (1998); Lund *et al.* (2000)
Listeria monocytogenes	4		22.8	Lund *et al.* (2000)
L. monocytogenes	4		9.3	Pawar *et al.* (2000)
E. coli O157:H7	2		No growth	Ansay *et al.* (1999)

is used in the immediate postharvest cooling of many fruits and vegetables. However, as soon as the surface of the food is close to that of the cooling medium then any heat loss due to evaporation is minimal.

Convection is by far the most important heat transfer mechanism employed in the majority of food chilling systems. In most cases, refrigerated air is the transfer medium; however, in some cases brine or a cryogenic gas can be used. The rate of heat removal depends on the following:

1. Surface area available for heat flow.
2. Temperature difference between the surface and the medium.
3. Surface heat transfer coefficient.

Each combination of product and cooling system can be characterized by a specific surface heat transfer coefficient whose value depends principally on the thermophysical properties and velocity of the medium. Typical values range from 5 W m^{-2} K^{-1} for slow moving air to 500 W m^{-2} K^{-1} for immersion in an agitated refrigerant.

Heat must also be transferred from within the food to its surface before it can be removed. In a solid food this will be via conduction; whereas in a liquid this will mainly be via convection. Most foodstuffs are poor conductors of heat and this imposes a severe limitation on attainable chilling times for either large individual items or small items cooled in bulk.

Effect of Chilling on Food Safety

The principle of chilling as a preservation process is the basis that all biological systems are controlled by enzymatic reactions including those that control microorganisms and cause quality degradation and that the rate of these reactions is directly related to temperature. Reducing temperatures below the optimum growth range of a microorganism increases its generation time. The main group of microorganisms of concern in chilled foods are psychrophilic pathogens. These organisms can grow at temperatures below 0 °C, and some reportedly have an optimum growth temperature as low as 10 °C. The optimum temperature growth range of mesophiles is 25–30 °C and with many the minimum growth temperature is approximately 10 °C. Because most chilled food is kept below this temperature mesophiles are not usually of concern in chilled distribution. However, mesophilic pathogens, such as *Staphylococcus aureus* and *Bacillus cereus*, are also of concern when food handlers and producers fail to chill foods properly or when adequate temperatures are not maintained during storage and handling. In addition, some mesophilic microorganisms are psychrotrophic and can grow on refrigerated foods.

Although microorganisms can grow at low temperatures, they grow more slowly as the temperature is reduced. Thus the generation time for a pseudomonad (a common form of spoilage organism) might be 1 h at 20 °C, 2.5 h at 10 °C, 5 h at 5 °C, 8 h at 2 °C, or 11 h at 0 °C. As temperatures are reduced below 10 °C, fewer strains can grow and cause spoilage. In general, food will spoil approximately four times as fast at 10 °C and twice as fast at 5 °C, as at 0 °C. In the usual temperature range used for the storage of chilled meat and meat products, −1.5 to 5 °C, there can be as much as an eight-fold increase in growth rate between the lower and upper temperatures used (Table 1). Storage of chilled meat and meat products at -1.5 ± 0.5 °C would attain the maximum storage life without any surface freezing of the product. Chill temperatures also have a marked effect on the type of spoilage microflora present on food by altering the microbial community. For example, raw milk stored at temperatures close to 0 °C tends to putrefy because of the activity of pseudomonads, rather than to sour due to the activity of lactic acid bacteria.

The essential characteristics of pathogenic microorganisms can be found in numerous texts. There is a certain degree of conflicting data concerning the importance of various pathogens with regard to safety of specific foods and the effect of specific temperatures or packaging atmospheres on their growth or inhibition. Pathogenic bacteria such as *Salmonella* spp., *L. monocytogenes*, *Clostridium botulinum* type E, psychrotrophic *B. cereus*, *Aeromonas hydrophila*, and *Y. enterocolitica* are of particular concern in chilled foods because they are capable of growth at low temperatures (Table 2). Many of the organisms that compete with pathogens at ambient temperatures will not grow at low temperatures, thus low temperatures may

Table 2 Minimum and optimum growth temperatures for pathogens associated with foods

	Minimum temperature (°C)	*Optimum temperature (°C)*
Campylobacter spp.	30–32	42–45
Arcobacter spp.	15	37
C. perfringens	12	43–47
B. cereus mesophilic	10–15	35–40
C. botulinum proteolytic	10	35
Shigella spp.	7–10	37
S. aureus	7	35–40
Pathogenic *E. coli* strains	7	35–40
E. coli O157:H7	6–7	42
Salmonella spp.	5	35–43
B. cereus psychrotrophic	4–5	28–35
Vibrio parahaemolyticus	5–10	30–37
C. botulinum non-proteolytic	3	30
A. hydrophila	−0.1 to 1.2	15–20
L. monocytogenes	−1 to 0	30–37
Y. enterocolitica	−2	22–30

preferentially favor the growth of pathogenic organisms. Pasteurization may also favor the outgrowth of surviving spores of psychrotrophic strains of *C. botulinum* and *B. cereus* by destroying competing microflora, a particular concern in vacuum packaged pasteurized foods ('sous vide' products), and ready-to-eat (RTE) products. However, most will not grow, or produce toxins, below 4 °C, with the exception of *L. monocytogenes*, *C. botulinum* type E, psychrotrophic *B. cereus*, *A. hydrophila*, and *Y. enterocolitica*.

Investigations into the effect of different storage atmospheres on pathogenic growth at low temperatures appear to show that carbon dioxide (CO_2)-enriched atmosphere produce the greatest inhibitory effect on psychrotrophic pathogens (*Y. enterocolitica*, *A. hydrophila*, and *L. monocytogenes*). García de Fernando *et al.* (1995) concluded that "at a normal meat pH (i.e., 5.5) and at a low temperature (e.g., 1 °C) the growth of psychrotrophic pathogens is stopped when the CO_2 concentration is 40%." However, high pH meat (≥ 6) and/or higher storage temperatures will support growth of such pathogens.

The bacterial safety and rate of spoilage depends on the numbers and types of microorganisms initially present, the rate of growth of those microorganisms, the conditions of storage (temperature and gaseous atmosphere), and characteristics (pH, a_w) of the food. Of these factors, temperature is by far the most important. In the context of food safety the safest practical chilled temperature will be the lowest that can be used without significantly affecting the quality of the food. In many cases this will be as close to the freezing point of the food as practically possible. Maintaining temperatures and the integrity of the whole of the chill chain is vital to ensure the safety and quality of chilled foods.

Effect of Chilling Rate

Whether 'rapid' chilling offers any clear advantages to product safety will depend on what biological hazards (pathogens, etc.) are present, at what numbers they are present, and whether they are on, or in, the food in question, and how 'rapid' the rate is in comparison with other rates. There is no definition of 'rapid' and 'slow's rates. Size of product will also have a big effect on relative rates of chilling, because conduction through the product will become the rate-limiting factor as product size increases.

There are instances where excessively rapid chilling rates, or too low a chilling temperature, can cause quality problems in foods. For example, a serious defect known as 'woolly texture' can be produced in rapidly cooled peaches. Substantial textural problems due to a phenomenon known as 'cold shortening' can occur in rapidly chilled meats (particularly beef and lamb), although electrical stimulation before rapid chilling will mitigate this problem.

Few countries provide legislative requirements for chilling foods that specify chilling rates. For example, European legislation requires that red meat carcasses be chilled to a maximum temperature of 7 °C and poultry carcasses to a maximum temperature of 4 °C. No time limits on achieving these times have been set. There are very little data on the effect of current commercial chilling rates and conditions on changes in bacterial numbers during the process. In most cases no change or a small reduction (0.5 to 1 $\log_{10}$ cfu cm^{-2}) in number of organisms on the surface has been measured. Current European legislation for foods of animal origin places importance on core meat temperatures, because microbial contamination is primarily a surface phenomenon there is an argument to be made that surface temperatures are far more important than deep temperatures. This is the basis behind the controls in the Australian Export Control (Meat and Meat Products) Orders 2005 and their Refrigeration Index (RI) model. The central idea of the RI model is to measure the performance of the chilling process until all the sites of microbiological interest are at or below 7 °C and calculate the risk of *E. coli* growth from temperatures measured during chilling.

Although there are few legislative requirements, there are many guidelines and recommendations for chilling cooked/pasteurized food products (Table 3), particularly RTE products that can be eaten cold. Inadequate cooling of such products has been identified as potential safety risk, as there is always the possibility that some microorganisms, particularly spores, will not be killed by the cooking/pasteurization process. Therefore most guidelines recommend that cooked products should be cooled as quickly as possible through the temperature range 63 to 5 °C or less to minimize risk of spore germination and outgrowth. There is particular concern with vacuum packaged pasteurized foods (termed by some as refrigerated processed foods of extended durability, and including 'sous vide' products) that conditions (low oxygen and destruction of competing microflora) may favor the outgrowth of surviving spores of psychrotrophic strains of *C. botulinum* and *B. cereus*. Consequentially lower storage temperatures (<3 °C) are recommended for these products and/or more severe heat processes. With RTE products, there have been concerns over the possible presence and outgrowth of spores of psychrotrophic *B. cereus*. Although many of these guidelines were initially produced specifically for cook-chill catering operations, in many countries, the producers of chilled ready meals for retail sale use them.

Because prolific histamine-forming bacteria are predominately mesophilic, rapid cooling of at-risk fish species (such as tuna and mackerel) immediately after catching is recognized as the key control for reducing histamine formation in such fish, as is the maintenance of adequate temperature control during the rest of the cold-chain.

Similarly prompt and rapid cooling of other seafood, particularly fish and shellfish that are eaten raw, such as oysters, is an important control for *V. parahaemolyticus*. The maintenance of tight temperature control during the rest of the cold-chain is also very important with *V. parahaemolyticus* because it is capable of growth at temperatures as low as 5 °C, and is known for rapid growth and generation times as short as 12–18 min.

Chilling Operations

Chilling systems for foodstuffs will contain many, if not all, of the following unit operations:

- Preparatory treatment; conditioning, waxing, cooking, pasteurizing, blanching, etc.
- Chilling; primary or secondary.
- Storage.
- Transportation.
- Retail display.
- Domestic storage.

During the preparatory treatment there can be a range of temperature responses, from a large gain to a small decrease in the temperature of the product.

During chilling there is a substantial decrease in the mean temperature of the product. Within a correctly designed cold-chain there should be no significant change in mean product temperature during storage, transport, retail display, or domestic storage.

From a food safety-based approach, prepacking the food before chilling will lower the risk of contamination/cross-contamination during the chilling process, however, it will significantly reduce the rate of cooling, and this may allow the growth of any microorganisms present. Provided the cooling media (air, water, etc.) and refrigeration equipment used are kept clean, no one cooling method can be said to be intrinsically more hygienic, or safe, than any other. For example, although there has been much debate concerning the safety of chilled water-cooling versus blast air chilling of poultry carcasses, reviews of published data have found little evidence of any difference microbially between poultry cooled by either method. Similarly there appears to be no evidence of a difference between spray chilling versus blast air chilling of red meat carcasses. Although some pathogens, such as campylobacters and arcobacters, may show sensitivity to air chilling; immersion and spray chilling may result in some physical removal (washing off) of microorganisms. In addition the use of antimicrobials, such as chlorine or ozone, in chilled water immersion/spray systems has been shown in some studies to reduce microbial contamination and subsequently may improve food safety. Such substances, however, are not permitted in all countries (notably the European Union) at present.

The potential for the fans used in air chilling to disseminate molds and bacteria has been identified in a number of reviews as a potential hazard, but very little work has been carried out to evaluate whether this is in fact the case. Similarly, condensation in the chiller has also been identified as a possible source of cross-contamination during chilling and storage (particularly of unpackaged foods). EU legislation regarding the chilling of foods of animal origin specifies that "during the chilling operations, there must be adequate ventilation to prevent condensation on the surface of the meat." However, there appears to be little published data to support such a control. It is however prudent that chillers should be properly constructed and maintained. The design of chillers should be such as to provide for effective cleansing and disinfection.

Chilling Systems

Moving Air

Air is by far the most widely used method of chilling food as it is economical, hygienic, and relatively noncorrosive to equipment. Systems range from the most basic in which a fan draws air through a refrigerated coil and blows the cooled air around an insulated room, to purpose-built conveyerized blast chilling tunnels or spirals. Air chilling is slow but versatile especially when there is a requirement to cool a variety of products.

The cooling time of the product is reduced as the air speed is increased, thus air distribution is very important. Conveying the product through the cooling system overcomes the problem of uneven air distribution because each item is subjected to the same velocity/time profile. The refrigeration capacity and air conditions can also be varied throughout the length of the tunnel. Using higher air temperatures in the latter stages can avoid surface freezing.

Immersion/Spray

As their names imply, these involve dipping product into a cold liquid, or spraying a cold liquid onto the food. When water is used as the heat transfer medium the process is often called 'hydrocooling.' This produces high rates of heat transfer due to the intimate contact between product and cooling medium. Both offer several inherent advantages over air cooling in terms of reduced dehydration and coil frosting problems. Clearly if the food is unwrapped the liquid has to be 'food safe.' Any uptake of the cooling medium, whether 'food safe' or not, by the product may present problems both in terms of flavor changes and the requirement for periodical replacement of the medium.

Hydrocooling is probably the least expensive method of achieving rapid cooling in small products. The product to be cooled is immersed in, or sprayed with, cool water, either at ambient or near 0 °C. Where permitted, the water is often treated with a mild disinfectant, such as chlorine. Practical systems vary from simple stirred or unstirred tanks to plants where the product is conveyed through agitated tanks or under banks of sprays. Hydrocooling is very effective for chilling fruit and vegetables, however, not all crops can tolerate wetting.

Spraying with ambient or chilled water is also an effective method for initially cooling cooked products that can withstand wetting, i.e., hams, sausages, chubs, etc. Spray bars are either fitted in the batch cookers or in separate cooling cabinets. Spray chilling of meat carcasses is widely practiced in the USA and used for poultry in Europe.

Chilling with crushed ice or an ice/water mixture is simple, effective, and commonly used for fish cooling. Cooling is more attributable to the contact between the produce and the cold melted water percolating through it than with the ice itself. Ice has the advantage of being able to deliver a large amount of refrigeration in a short time as well as maintaining a very constant temperature, 0 to -0.5 °C (where sea water is present). Ice may also be used for cooling fruit and vegetables, however, as with hydrocooling, ice is only applicable to vegetable and fruit produce that can tolerate wetting, such as watercress, broccoli, and some other brassicas. Large poultry carcasses, such as turkeys, are also often initially cooled by immersion in an ice/water mixture, with the carcasses being conveyed through a tank of ice/water using Archimedean screws.

Vacuum

Solid products having a large surface area to volume ratio and an ability to readily release internal water are amenable to vacuum cooling. The products are placed in a vacuum chamber (typically operating at between 530 and 670 N m^{-2}) and the resultant evaporative cooling removes heat from the food. Evaporative cooling is quite significant, the amount of heat released through the evaporation of 1 g of water is equivalent to that released in cooling 548 g of water by 1 °C. Suitable products, such as lettuce, can be vacuum cooled in less than 1 h. In general terms, a 5 °C reduction in product temperature is achieved for every 1% of water that is evaporated. Because vacuum cooling requires the removal of water from the product prewetting is commonly applied to prevent the removal of water from the tissue of the product.

Plate Heat Exchangers

In a plate cooling system product is essentially pressed between hollow (horizontal or vertical) metal plates containing a circulating refrigerant. Cooling rate depends on product thickness, good contact, and the conductivity of the product. Thus the need for regularly shaped products with large flat surfaces is a major hindrance. Air spaces in packaging and fouling of the plates can have a significant effect on cooling time.

Jacketed Heat Exchangers

Batch coolers for liquid foods can range in capacity from 100 to 10 000 l with the foodstuff usually contained in a stainless steel vessel. The cooling medium may circulate through the jacket of the vessel, through a coil immersed in the liquid, or both. Most vessels are provided with agitators to improve the rate of convective heat transfer and stop temperature stratification. One common method used to decrease cooling times of liquid products in a closed vessel is to apply a vacuum to produce evaporative cooling. Temperature stratification is a problem in unstirred vats whilst in agitated vessels the design and operation of stirrers is critical if breakdown of delicate solid product is to be avoided.

Belt Heat Exchangers

Belt systems consist of an endless steel belt (approximately 1 mm in thickness), the underside of which is cooled either directly with water, brine, or glycol sprays or by sliding over a stationary cold surface. Because only one side of the product is in contact with the cooling surface relatively thin products are required, such as hamburgers, fish fillets, or liquid and semi-liquid products such as purées and sauces. The main advantages of belt systems are: (1) continuous processing, (2) easy continuous cleaning and sanitation, (3) reduced evaporative losses, in comparison with air systems, and (4) the possibility of operating with several temperature zones.

Continuous Heat Exchangers

The majority of liquid foodstuffs require cooling after a heat processing operation such as cooking of sauces and soups, and pasteurization or sterilization of fruit juices, milk, and other dairy products. Milk is also cooled at the point of collection to maintain its quality. Unpasteurized 'freshly squeezed' fruit juices are cooled immediately after production. Fermented beverages are often cooled during primary and secondary fermentation, and before storage. Multiplate coolers are extensively used for liquid foods. They have the highest available heat transfer surface, lowest material requirements, maximum efficiency (up to 90% heat recovery in counter current mode) and are very flexible in operation and easy to clean. Scraped surface heat exchangers can have advantages in the cooling of very viscous liquid foods and where surface fouling is a potential problem.

Cryogenic

Cryogenic cooling uses refrigerants, such as liquid nitrogen or solid carbon dioxide, directly. Owing to very low operating temperatures and high surface heat transfer coefficients between product and medium, cooling rates of cryogenic systems are often substantially higher than other refrigeration systems. Avoiding surface freezing of the product is the main problem in using cryogens for chilling. Forced gas cooling is the only method that can be employed when surface freezing has to be avoided. However, the system tends to be inefficient.

Chilled Storage

Most unwrapped meat, poultry, fish, fruit and vegetables, and all types of wrapped foods are stored in large rooms with circulating air. To minimize weight loss and appearance changes associated with desiccation air movement around the unwrapped product should be the minimum required to maintain a constant temperature. With wrapped products low air velocities are also desirable to minimize energy consumption. However, many storage rooms are designed and constructed with little regard to air distribution and localized velocities over products. Horizontal throw refrigeration coils are often mounted in the free space above the racks or rails of product and no attempt is made to distribute the air around the products. Using a false ceiling or other forms of ducting to distribute the air throughout the storage room can substantially reduce variations in velocity and temperature.

Controlled atmosphere storage rooms were developed for specialized fruit stores. In addition to the normal temperature control plant these stores also include special gas-tight seals to maintain an atmosphere that is normally lower in oxygen and higher in nitrogen and carbon dioxide than air. An additional plant is required to control the carbon dioxide concentration, generate nitrogen, and consume oxygen. The optimum atmosphere must be determined experimentally for the specific product being stored. There is growing use of controlled atmosphere and modified atmosphere retail packs to extend the chilled storage and display life of red meats, poultry, fish, and vegetables. Because the packs tend to be large and insulate the products efficient precooling before packaging is especially important if product quality is to be maintained. Provided that temperatures during chilled storage are sufficient to prevent or inhibit the growth of any pathogens present on the food in question, in general the food will spoil before there is significant growth in pathogens would be a cause of concern.

The safe storage life of chilled foods depends on the control of all the preceding factors, but must be validated by challenge testing and/or modeling for each product and process under defined storage conditions. However, from a practical point of view, the lowest storage temperature that can be used without affecting the quality of the food will be the safest.

Transportation

Chilled foods are transported around the world and locally via a range of transportation systems. All these transportation systems are expected to maintain the temperature of the food within close limits to ensure its optimum safety and high quality shelf-life. It is particularly important that the food is at the correct temperature before loading because the refrigeration systems used in most transport containers are not designed to extract heat from the load but to maintain the temperature of the load. In the large containers used for long distance transportation food temperatures can be kept within $\pm 0.5\ ^{\circ}C$ of the set point.

Control of the oxygen and carbon dioxide levels in shipboard containers has allowed fruits and vegetables, such as apples, pears, avocados, melons, mangoes, nectarines, blueberries, and asparagus, to be shipped (typically 40 days in the container) from Australia and New Zealand to markets in the USA, Europe, Middle East, and Japan. Even longer shelf-lives (over 20 weeks) can now be achieved for meats, particularly beef and lamb.

Air-freighting is increasingly being used for high value perishable products, such as strawberries, asparagus, and live lobsters. Although air-freighting of foods offers a rapid method of serving distant markets, there are many problems because the product is usually unprotected by refrigeration for much of its journey. Up to 80% of the total journey time is made up of waiting on the tarmac and transport to and from the airport. During the flight the hold is normally between 15 and $20\ ^{\circ}C$. Perishable cargo is usually carried in standard containers, sometimes with an insulating lining and/or dry ice but is often unprotected on aircraft pallets.

Overland transportation systems range from 12 m refrigerated containers for long distance road or rail movement of bulk chilled or frozen products to small uninsulated vans supplying food to local retail outlets or even directly to the consumer. The rise in supermarket home delivery services where there are requirements for mixed loads of products that may each require different storage temperatures is introducing a new complexity to local overland delivery.

Retail Display

The temperature of individual consumer packs, small individual items, and especially thin sliced products responds very quickly to small amounts of added heat. All these products are

commonly found in retail display cabinets and marketing constraints require that they have maximum visibility. Maintaining the temperature of products below set limits while they are on open display in a heated store will always be a difficult task.

The required display life and consequent environmental conditions for wrapped chilled products differ from those for unwrapped products. The desired chilled display life for wrapped meat, fish, vegetables, and processed foods ranges from a few days to many weeks and is primarily limited by microbiological considerations. Retailers of unwrapped fish, meat, and delicatessen products, for example, sliced meats, pate, cheese, and prepared salads, normally require a display life of one working day. The introduction of humidification systems can significantly improve display life of unwrapped products.

Average temperatures in chilled retail display cabinets can be varied considerably from cabinet to cabinet, with inlet and outlet values ranging from -6.7 to $+6.0\,^{\circ}C$, and -0.3 to $+7.8\,^{\circ}C$, respectively, in one survey. The temperature performance of an individual display cabinet not only depends on its design but also its position within a store and the way the products are positioned within the display area significantly influence product temperatures. External factors such as the store ambient temperature, the position of the cabinet, and poor pretreatment and placement of products substantially affect cabinet performance. Warm and humid ambient air and loading with insufficiently cooled products can also overload the refrigeration system. Even if the food is at its correct temperature, uneven loading or too much product can disturb the airflow patterns and destroy the insulating layer of cooled air surrounding the product. An in-store survey of 299 prepackaged meat products in chilled retail displays found product temperatures in the range -8.0 to $14.0\,^{\circ}C$, with a mean of $5.3\,^{\circ}C$ and 18% above $9\,^{\circ}C$. Other surveys have shown that temperatures of packs from the top of stacks were appreciably higher than those from below due to radiant heat pickup from store and cabinet lighting. It has also been stated that products in transparent film overwrapped packs can achieve temperatures above that of the surrounding refrigerated air due to radiant heat trapped in the package by the 'greenhouse' effect. However, specific investigations have failed to demonstrate this effect.

The display life of chilled foods depends on the control of all the preceding factors, but must be validated by challenge testing and/or modeling for each product and process under defined chill display conditions. It must be recognized that the integrity of the whole of the chill chain is vital to ensure the safety and quality of chilled foods.

Domestic Handling

Recommended refrigerator temperatures are in general below $8\,^{\circ}C$ throughout the world, with many countries (including the UK) recommending below $5\,^{\circ}C$. The numerous surveys on the domestic storage of refrigerated foods show remarkable similarities in consumer attitudes and handling of chilled foods and the performance of their refrigerators. Perhaps even more remarkable is that despite numerous recommendations on handling and storage temperat'ures, consumer use and the performance of refrigerators remain remarkably unchanged throughout the world over the past 30 years. Numerous surveys (Figure 1) show that mean temperatures range between 5 and $7\,^{\circ}C$, with 50–70% of domestic refrigerators operating at temperatures above $5\,^{\circ}C$. It is clear that many refrigerators throughout the world are running at higher than recommended temperatures. Because even these recommended temperatures are higher than the 0–$1\,^{\circ}C$ that is usually the recommended temperature range for storing fish and seafood, meat, and many chilled products the current situation is even more detrimental to maintaining the high quality life of chilled foods. Although there have been many surveys of refrigerators, how fridge temperatures, cleanliness, and consumer practices (e.g., over filling with warm products, use for cooling hot cooked foods) impact on consumer health remains to be fully assessed. The few studies that have assessed these factors do not appear to have demonstrated clear links between incidences of food poisoning and operating temperatures of cleanliness.

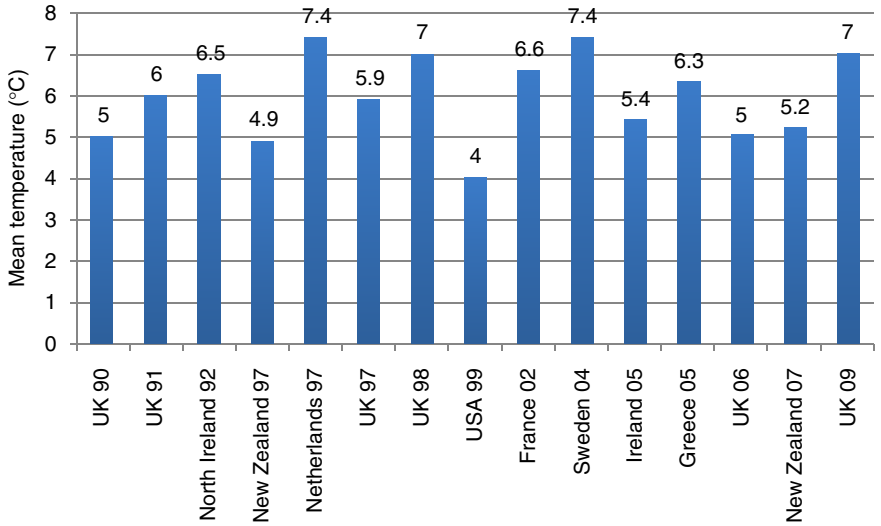

Figure 1 Reported mean temperatures recorded in surveys of domestic refrigerators throughout the world since 1990.

Temperature Measurement and Monitoring

Temperature measurement and monitoring is an integral part of any food cold-chain management system; as well as being, in many areas of the cold-chain, a legislative requirement. Monitoring the cold-chain requires detailed information on food product temperatures. Temperature monitoring includes both measurement and recording. Temperature measurement can be achieved using a variety of instrumentation such as bimetal style thermometers, thermistors, thermocouples, infrared thermometers, etc. Typically, in the food industry, temperature measurement is achieved using calibrated thermocouples and data loggers. Owing to the variety of available equipment, manufacturers and suppliers are best positioned to give advice to the food business on the choice of temperature measurement equipment for specific purposes and food products. Advice can also be found in numerous International and National recommendations and guidelines for chilled foods.

One possible aid in the future may be the widespread use of time temperature indicators (TTI) or integrators throughout the cold-chain. TTIs are simple devices that are capable of reporting a visual and straightforward summary of either the temperature (indicators) or time-temperature exposure history (integrators) of the product. Indicators show that a product has exceeded, positively or negatively, a given temperature Whereas Integrators monitor both time and temperature during a given period and show the cumulative effect of temperature fluctuations during the history of the product.

Conclusions

The safety of a chilled food depends on the numbers and types of microorganisms initially present, the rate of growth of those microorganisms, the conditions of storage (temperature and gaseous atmosphere), and characteristics (pH, a_w) of the food. Of these factors, temperature is by far the most important. In the context of food safety, the safest practical chilled temperature will be the lowest temperature that can be used without significantly affecting the quality of the food. In many cases this will be as close to the freezing point of the food as practically possible, i.e., between 0 and $-1\,^{\circ}C$. Maintaining temperatures and the integrity of the whole of the chill chain is vital to ensure the safety, and quality, of chilled foods.

In general, after initial chilling, as a chilled product moves along the cold-chain it becomes increasingly difficult to control and maintain its temperature. Temperatures of bulk packs of chilled product in large storerooms are far less sensitive to small heat inputs than single consumer packs in transport or open display cases.

If primary and secondary cooling operations are efficiently carried out then the food will be reduced below its required temperature before it is placed in storage. In this situation the cold-store's refrigeration system is only required to extract extraneous heat that enters through the walls, door openings, etc.

Even when temperature controlled dispatch bays are used there is a slight heat pickup during loading. In bulk transportation the resulting temperature rise is small and the vehicle's refrigeration system rapidly returns the product to the required temperature. Larger problems exist in local multidrop distribution to individual stores. There is a large heat input every time the doors are opened and product unloaded, small packs rapidly rise in temperature and the vehicle often lacks the refrigeration capacity or time to recool the food.

Temperature control during retail display is often poor due to the retailers' need to display as much product as possible in a way that is easily assessable to the consumer. Increasing energy costs may be the key factor that persuades retailers to reduce consumer access, i.e., install doors on chilled retail display cabinets, and hence improve temperature control.

At present domestic storage of chilled foods would appear to be the weakest link in the entire chill chain. However, despite all the many published surveys on refrigerator temperatures carried out in the past 30 years, how fridge temperatures, cleanliness, and consumer practices (e.g., over filling with warm products, use for cooling hot cooked foods) impact on consumer health remains to be fully assessed.

Cleaning and Disinfection Technologies (Clean-In-Place, Clean-Out-of-Place)

R Ryther, Ecolab, Eagan, MN, USA

Glossary

Chemical activity Cleaning factor using chemical agents to optimize cleaning time, temperature, and need for mechanical action.

Cleaning factors The use of time, temperature, chemical activity, and mechanical action in a balanced manner to ensure an optimized cleaning program.

Clean-in-place Clean-in-place is the automated cleaning of equipment with minimal dismantling of food production equipment before the cleaning and sanitizing operation.

Clean-out-of-place Clean-out-of-place is the removal of food production equipment or portions of the equipment as well as related food production tools to an external area for cleaning, sanitizing, and drying before reassembly.

Environmental surfaces Environmental surfaces are those external to food processing equipment within the food production facility. Cleaning and sanitizing of all environmental systems is generally accomplished manually but in some cases automated cleaning systems have been utilized.

Line circuit cleaning Automated cleaning process for transfer piping used to deliver raw materials and transfer out final food product in a food processing system.

Mechanical action Cleaning factor involving automated or manual application of physical force against a soil to be removed.

Sanitation standard operating procedure A protocol describing the sequence of steps for cleaning and sanitizing within a food processing facility including required quality inspections, corrective actions as well as required microbiological and allergenic verification testing.

Tank circuit cleaning Automated cleaning process for food processing tanks – usually performed in conjunction with a line cleaning circuit.

Cleaning and Sanitizing Operations in Food Processing Facilities

Effective cleaning and sanitizing, whether it is automated or manual requires an understanding of where soil and microbial cross-contact can occur in a food processing system. Cleaning and sanitizing procedures that inadvertently fail to remove soil from food contact surfaces can result in sources of microbial growth and the potential to contaminate subsequent food production. Developing effective cleaning and sanitizing procedures using optimized cleaning and sanitizing technology is critical to achieving a safe food production environment.

Food Production Facility Cleaning Based on Sanitary Design Principles

Despite the very broad range of food systems and very specialized equipment developed for many food production and packaging operations, cleaning and sanitizing systems should be designed using standard principles. An example of these principles adapted from the American Meat Institute is shown in Table 1.

Cleaning methods, manual or automated, cannot overcome poorly designed production equipment and facilities. For example, even sealed hollow areas in support structures or walls have been known to develop cracks and become microbial harborage points.

Types of Cleaning and Sanitizing Systems: Clean-In-Place (CIP), Clean-Out-of-Place (COP), and Environmental Cleaning

Cleaning systems for food plants are generally separated into three categories, CIP, COP, and environmental cleaning:

1. CIP is the automated cleaning of equipment with minimal dismantling of food production equipment before the cleaning and sanitizing operation.

Table 1 Ten principles of Sanitary Design

1.	Cleanable
2.	Made of compatible materials
3.	Accessible for inspection, maintenance, cleaning, and sanitation
4.	No liquid collection
5.	Hollow areas eliminated or sealed
6.	No niches
7.	Sanitary operational performance
8.	Validate cleaning and sanitizing protocols
9.	Separate processes wherever possible
10.	Meet personnel hygiene and sanitation requirements

Source: Adapted from American Meat Institute.

 doi:10.1016/B978-0-12-378612-8.00276-6

2. COP is the removal of food production equipment or portions of the equipment as well as related food production tools to an external area for cleaning, sanitizing, and drying before reassembly.
3. Environmental surfaces are those external to food processing equipment within the food production facility. Cleaning and sanitizing of all environmental systems is generally accomplished manually but in some cases automated cleaning systems have been utilized.

In all three categories, cleaning is usually followed by sanitizing although sanitizer chemistry and procedures will differ based on regional regulatory requirements. Methods used for cleaning and sanitizing can also vary significantly depending on the food type, food additives, and processing temperature used to make the food.

Cleaning Factors

Four factors are generally accepted as being important to ensure effective cleaning and sanitizing. Cleaning time, temperature, chemical activity, and mechanical energy all need to be defined for all cleaning and sanitizing programs and are described below:

1. Time to clean and sanitize is often misunderstood, especially when chemical cleaning is involved. Optimizing the time for a cleaning operation to ensure effective soil dissolution and emulsification (tying up soil in solution to avoid redeposition) is generally a high priority for food producers. Rushing a cleaning operation can result in poor cleaning and residual food cross-contact occurring on equipment. Improper use of cleaning chemistry, temperature, or mechanical action can result in an inordinately long cleaning time.
2. Temperature effects on cleaning and sanitizing will vary depending on soil type and water quality. A rule of thumb is that for every 10 °C increase, cleaning chemical activity doubles resulting in fatty soils, sugars and starches and many other types of food soils being more easily removed with increased temperature. High temperatures (>145 °F/65 °C) will kill microbes but if used properly, lower temperature cleaning and sanitizing programs can be used to achieve effective microbial kill. Increasing cleaning temperature in some cases will precipitate proteins or hardness ions (calcium or magnesium) and make it difficult to remove scale deposits.
3. Chemical activity is important as cleaning chemistry is built to dissolve soils from the surfaces to be cleaned and emulsify to avoid redeposition. A sanitizing step will kill or inhibit microbial cross-contact with surfaces after the cleaning step. Chemical activity is impeded when:
   a. Cleaning or sanitizing solutions do not reach the soils because of a lack of solution flow (dead zones).
   b. Chemical concentrations are too low (cannot dissolve soils) or too high (precipitate out or react with soils).
   c. Inappropriate chemical systems are used and are not effective at cleaning or sanitizing the food processing equipment.
4. Mechanical action is required to move soils away from a surface. In the absence of manual cleaning, automated cleaning systems generally rely on pressurized water or air to provide mechanical force for soil removal. The need for mechanical force can be minimized if temperature, time and/or chemical activity can be optimized to permit better soil dissolution but some force is always required to move the soil away from a surface to prevent soil redeposition.

Figure 1 CIP cleaning solution and sanitizing solution tanks: This single use CIP system includes two medium-sized tanks for detergent and rinse/sanitizer, a steam heat exchanger, and programmable logic controllers to automate the cleaning process. Image courtesy of Ecolab.

CIP Cleaning Background

In practice, a standard CIP system will recirculate cleaning solution automatically through enclosed food processing equipment such as tanks, ovens, fryers, conveyors, and cooling systems and the associated food transfer piping. Recirculating a cleaning solution permits measurement and control of temperature, flow rate, and chemical concentrations. Such a CIP operation, runs for a time period sufficient to ensure all surfaces are free of contaminants, is generally completely automated to (1) ensure consistent cleaning results, (2) minimize labor compared to manual cleaning, and (3) provide electronic documentation that a cleaning program was run as desired (Figure 1).

For a CIP system, the mechanical energy is provided by circulation systems. Liquid impingement on surfaces or turbulent flow through piping generally cannot match the mechanical energy provided by manual scraping and scrubbing. To overcome this mechanical energy deficit, the other cleaning factors, temperature, chemical activity, and time must be emphasized. As an automated, enclosed CIP system does not expose operators to chemical mixtures, stronger chemical activity and higher temperatures can be safely used in cleaning and sanitizing. Cleaning times can also be lengthened as labor can be distributed to other tasks while an automated CIP is in operation.

Food CIP systems and beverage (such as milk, beer, or soft drinks) CIP systems use essentially the same cleaning and

sanitizing solution transfer and spray technology but can vary greatly in the required chemical strength, water temperature, and cleaning time for removing light versus heavy, aged and/or burnt on food soils. Use of an automated cleaning and sanitizing CIP systems have advantages over manual cleaning in the following ways:

1. Reduces the amount of time and labor spent on sanitation operations (increasing food production run times).
2. Decreases the impact of sanitation operations on water consumption, energy utilization, and wastewater processing.
3. Reduces overall wear on process equipment because of decreased manual cleaning.

CIP – Line Circuit Cleaning

The line circuit portion of CIP cleaning is focused on ensuring proper turbulent flow at rates to provide mechanical 'scrubbing' by the cleaning solution. Critical to the success of cleaning line circuits is the removal of all 'dead zones' where cleaning solution cannot flow and residual food product can buildup and result in microbial cross-contact occurring within the equipment. CIP circuits can often be extremely complicated, especially when using a single CIP system to clean numerous circuits (sometimes simultaneously). Careful design of each CIP piping circuit, especially when new food processes are added to existing equipment is suggested to ensure elimination of these dead zones.

Optimizing time, temperature, and chemical concentration is important after ensuring optimum mechanical action based on solution flow rates. Flow rates will need to go up with increasing pipe diameter (see Table 2). Care must be taken where line circuits contain multiple pipe sizes as pressure/velocity drops will occur going from smaller to larger diameter piping and inadequate cleaning of the larger piping can result. It is common for tank and lines to be cleaned in the same CIP operation and optimizing both types of CIP programs in conjunction is required.

CIP – Tank Circuit Cleaning

The tank circuit CIP program relies on a spray device or spray ball to achieve mechanical action. At a minimum a tank cleaning spray device must be designed to ensure all tanks surfaces are reached by the cleaning solution. Fixtures within tanks such as mixing blades or drain valves on tank surfaces can block spray from reaching soiled surfaces. Multiple overlapping spray devices are often required to overcome such blockages. Flow rates out of a spray device typically are on the order of 3 gallons per minute per foot of circumference of a cylindrical tank.

Table 2 Minimum required clean-in-place (CIP) flow (various line sizes)

Line size[a]	*Desired velocity*	*Minimum flow rate*	*Drain capacity*[b]
1″	5 ft sec^{-1}	15 GPM	22 GPM
1.5″	5 ft sec^{-1}	24 GPM	40 GPM
2″	5 ft sec^{-1}	43 GPM	75 GPM
2.5″	5 ft sec^{-1}	69 GPM	115 GPM
3″	8 ft sec^{-1}	163 GPM	190 GPM
4″	8 ft sec^{-1}	288 GPM	350 GPM

[a]Assumes standard sanitary pipe.
[b]Maximum drainage through the pipe.
Table 2 shows flow rates in feet second^{-1} (ft sec^{-1}) and gallons minute^{-1} (GPM) for different CIP line sizes; courtesy of Ecolab Inc.

Single versus Multiuse CIP Designs

CIP circuits can be designed to be (1) single use with cleaning solution dumped directly to drain after completion of the CIP cycle or (2) reuse or multiuse systems. Multiuse CIP systems are often designed to recover final rinse water for use to make up subsequent cleaning solutions. Some or all of the cleaning solution itself can also be saved and reused to minimize chemical usage. In all CIP designs, any final rinse or sanitizing rinse would not be reused in that function but fresh final steps would generally be required by food processing regulations in most regions.

Single use systems, where all cleaning, sanitizing, and rinse solutions are used once, are simple to design and result in the highest level of sanitation. These single use systems would be required for food production equipment having very high soil loads or allergenic material. These single use systems avoid the potential for cross-contact of these soils types on equipment that would be possible with CIP solution reuse. Facilities with very limited space for additional equipment would also benefit from a single use CIP.

Recovery of rinse water is a popular choice for CIP as there is little chance of soil redeposition. Multiuse systems in which the cleaning chemicals are reused require a fairly complicated CIP design and a high level of understanding of the CIP circuit to avoid soil redeposition. There are many of these systems in use and some where automated make up water and cleaning chemical additions are balanced to achieve equilibrium and can run for weeks or months without the need to dump the cleaning solution.

COP Cleaning

COP is the cleaning of removable parts of food processing equipment after disassembly or any ancillary food production tools. Typically COP systems are open tanks where a given cleaning solution can be heated and recirculated. As with CIP systems, automation is possible with recirculation step (permitting the monitoring of solution temperature, chemical concentration, and flow rate) so that 'push button' COP systems are common. The use of numerous distribution headers in COP tanks are used to create turbulence to aid in soil removal via mechanical action.

COP cleaning and sanitizing programs require:

1. Appropriate tank design:
   a. Sized for application.
   b. That can contain shelves or hangers for parts to maximize number of parts loaded while still maintaining separation between parts to ensure full access to cleaning solutions.
   c. With a recirculation system and associated headers sized to ensure tank turbulence.

2. Cleaning solution chemistry, temperature, and cleaning time balanced to ensure full cleaning of the toughest to remove soils.
3. A rinse step to ensure removal of residual soil and cleaning solution.
4. A sanitizer step effective for kill of any residual microbial cross-contact on equipment.
5. Proper parts storage program to ensure complete drying and avoidance of cross-contact of microbial or allergenic soils onto these parts before reassembly.

Environmental Cleaning

Cleaning and sanitizing environmental surfaces (sometimes termed 'open plant cleaning') in a food production facility is a critical part of a full food safety program. Poor design of a cleaning program for environmental surfaces can result in microbial cross-contact that can migrate into food products.

Environmental cleaning in a food processing environment is the cleaning of equipment's external surfaces, walls, floors, ceilings, elevated walkways, drains, piping, and conduit in addition to ancillary equipment (such as motors, electrical boxes etc.) that generally cannot be cleaned by CIP or COP methods.

Typically, cleaning environmental areas of a food production facility is done manually by first removing food debris followed by wet cleaning and sanitizing steps. Emphasis is on removing as much soil as possible before a wet cleaning to limit the biological load on the wastewater treatment system. Environmental cleaning programs for food processing facilities should remove as much water as possible after the completion of cleaning and final rinse steps and return to as dry a state as possible before resuming food production. Focusing even wet cleaned areas on maintaining as dry a state as possible will help limit microbial growth in the environment, thereby reducing the potential for microbial cross-contact with food product.

Systems used to support environmental cleaning include:

Foaming or Gelling Systems

Cleaning and sanitizing with foam or gel based chemistry increases the dwell time of chemical on the surface to help dissolve soils for cleaners or provide increased microbial kill efficacy for sanitizers. Foam generators mix a chemical solution with air to create a foam or gel. This solution is then sprayed under pressure onto the surface to be cleaned. Often entire rooms and all accessible surfaces of the food production equipment are foamed (with chemically sensitive equipment wrapped before foaming).

High Pressure Cleaning Systems

High pressure air, water, steam, or particle blasting systems can be used for cleaning the exterior parts of equipment, floors, and some building surfaces when mechanical action is required for soil removal. Soil types dictate which type of mechanical action will be most effective. For example, particle blasting works best on brittle food soils whereas hot steam can clean by liquefying soils. Steam can also be used to sanitize surfaces (care must be taken that all surfaces are heated to an appropriate temperature for a reproducible time period to ensure the desired microbial kill).

Pressurized air or steam injection systems generally operate with nozzle pressures between 60–170 psi. Cleaning effectiveness is dependent largely on the force of the cleaning system against the surface which will be a function of operating pressure and nozzle design. It will be emphasized that high pressure air or water systems (especially centralized systems) must be free of microbial containing residues that could be dispersed into a food production environment. Additionally, high pressure cleaning procedures should never be used in rooms where food production is occurring and great care must be taken to avoid the transfer of residues from high pressure cleaning onto equipment already considered cleaned and sanitized.

Ancillary Cleaning Equipment

Programs should be developed for cleaning ancillary food production tools as well as ensuring that cleaning tools themselves have appropriate cleaning procedures to avoid the potential for microbial or allergenic cross-contact with these tools into the food product. Strategies often involve use of tool carts to carry cleaning equipment and are specific to areas and/or types of equipment to be cleaned. Carts and the cleaning tools they contain are then cleaned and stored in separate areas with appropriate drying before the next cleaning operation. Often cleaning tools are color coded for use specific to cleaning food contact versus nonfood contact equipment and are stored separately when not in use for cleaning operations.

Cleaning of Allergens

Food allergies affects as many as 6% of young children and 3–4% of adults. Exposure of some individuals to very small amounts of allergenic proteins can be life threatening. Moreover, food recalls because of cross-contact with allergens make up a significant portion of all food recalls. Control of allergens in any food facility that produces both allergen and nonallergen containing foods must be accompanied by a stringent allergen control program. Potential for allergen cross-contact with allergen free foods can include (1) mislabeled raw material entering the food process facility, (2) mislabeling of materials by facility staff, (3) allergen residues remaining on food production equipment or tools cross-contacting nonallergen containing foods and (4) mislabeling of a final product containing allergens. There are many manufacturers who have separate production equipment or even separate manufacturing facilities to avoid the potential for such cross-contact.

Cleaning of Facilities Producing Dry or Low Moisture Foods

Low moisture or dry food production areas are usually cleaned without water for the purpose of minimizing growth of microbial pathogens. Some of these low moisture foods include milled grains, bakery goods, cereals, chocolate, dry dairy, nuts, spices, and fried or baked chips. Food facilities that have dry

processing areas (in some cases the entire production facility will be dry) have been historically more concerned about pest issues than cross-contact of foods with microbial residues.

Unfortunately, recent food recalls involving food contaminated in dry food production facilities have increased the need to identify ways to provide sanitation breaks by these food producers in their facilities. *Salmonella* is the main concern in these environments because of its persistence on dry foods and in food manufacturing facilities. *Escherichia coli* O157:H7 is also of major concern in these dry areas.

For most dry food facilities, dry raw material delivery, storage, and internal facility transport systems are rarely cleaned completely and almost never sanitized. These businesses rely on low moisture to eliminate microbial growth and appropriate testing to ensure absence of any pest issues.

The presence of some residual food raw material or final dry product on production equipment has generally been considered acceptable especially as these residuals are usually 'fresh' because of continual 'push through' of new raw material or final dry product on those equipment surfaces. Yet, validation of a dry cleaning process can prove difficult as it must demonstrate an ability to remove detectable levels of microbial residues from the surfaces cleaned (much easier in wet cleaning using a wet sanitizer already proven to provide a sanitizing microbial kill if applied according to the manufacturers recommendations). Adding water these to environments, even with the use of heavy duty cleaners and water based sanitizers may still have a higher potential for cross-contact with microbial residues than if cleaned dry if residual water remains in hard to dry areas of the facility.

Cleaning and sanitizing in such dry cleaning include traditional sweeping, scraping, and vacuuming coupled with sanitizing with quick drying alcohol solution applied directly to surfaces or using sanitizing wipes. Sanitizing with steam and heat also provides low water alternatives to water based sanitizers. More unique sanitizing methods include flushing the systems with the new lot of the food product itself to remove any traces of the older product. Nonallergenic food material such as rice or salt might also be used to rinse out systems and then tested to demonstrate removal of microbial residues from food processing equipment. This flushing step effectively provides what would be termed a rinse in a wet cleaning operation and material used to flush can be sampled at different points in the flushing step for confirmation that potential for cross-contact from microbial and/or allergenic residues has been eliminated from the process. Efficacy of such a procedure must be validated to ensure complete elimination old food product and/or microbial residues from all surfaces being cleaned and/or sanitized.

Cleaning and Sanitizing Chemistry

Cleaning Chemistry

Chemical cleaners are required where dissolving and emulsifying soils are more efficient at cleaning food processing equipment than manual cleaning. Food soils of concern to most food processing facilities will vary depending on food type and additives, temperature and type of food processing as well the condition of the water used in food production and cleaning. To effectively clean these soils requires an understanding of the functions of different chemical components in a cleaning system. A comprehensive review of these technologies can be found in the work by Stenga (2010). The pH of a cleaning solution (i.e., the relative level of hydrogen cation, acidity or hydroxyl anion, alkalinity, in a solution) is a key factor in the cleaning ability for most food soils. The chemical structures of food soils such as fats and oils, proteins, sugars and starches as well as minerals all have some ionic features under some or all conditions. A cleaning solution must be built from components that maximize the breakdown of soil residues on food facility equipment and associated environmental surfaces whereas minimizing the amount of chemical used for cleaning. The goal of an optimized chemical cleaning system is to use the cleaning solution to wet the soil, dislodge it from a surface to be cleaned and then emulsify it (hold the soil in solution) so it will not redeposit.

When choosing the chemical cleaning system for a given food soil the cleaning time, cost, compatibility with equipment, safety of facility operators as well as regulatory requirements for wastewater discharge and environmental sustainability are all factors that must be considered to ensure an optimum system.

Sanitizing Chemistry

The US Environmental Protection Agency (EPA) defines antimicrobial agents as substances or mixtures of substances used to destroy or suppress the growth of harmful microorganisms whether bacteria, viruses, or fungi on inanimate objects and surfaces. Definitions of each type of antimicrobial agent are described in the EPA Fact Sheet on their website:

1. Sterilizers (also Sporicides) 'will destroy or eliminate all forms of microbial life including fungi, viruses, and all forms of bacteria and their spores.'
2. Disinfectants are used 'on hard inanimate surfaces and objects to destroy or irreversibly inactivate infectious fungi and bacteria but not necessarily their spores' (these require a final rinse if used on food contact surfaces).
3. Sanitizers will 'reduce, but not necessarily eliminate, microorganisms from the inanimate environment to levels considered safe as determined by public health codes or regulations.' Sanitizers used in food processing plants in the US generally are nonrinse agents, safe for food contact surfaces when used according to the product label requirements.

It is important to understand that for different food processing facilities, government regulations will differ based on region. An operator using sanitizers and disinfectants for direct and indirect food contact surfaces needs to follow regulations for both sanitizer and disinfectant products. For example, in the US, any antimicrobial or chemical sanitizer used on food or for treating food contact or other surfaces in a food production facility must be registered at the EPA. The US Food and Drug Administration (FDA) regulates the use of antimicrobial agents used on food or food contact surfaces. All

approved no rinse food contact surface formulations and associated usage levels used in the US are listed in the FDA 21 CFR 178.1010 Code of Federal Regulations. In some regions or applications may require a final rinse for all sanitizer chemistry applications.

Chemical sanitizers fall into a number of categories based on whether they are oxidative or nonoxidative. These chemical sanitizers can be delivered as liquids, gases, or in vapor/mist form depending on the application. A comparison of the different chemical sanitizers for stability, foaming, corrosivity, pH stability, and efficacy against microorganisms can be found in a review by Richter and Cords (2001).

Application of Sanitizers in Food Processing Facilities

A sanitizing operation is generally performed after a thorough cleaning operation for CIP and COP systems as well as for all environmental areas. Automated CIP/COP sanitizing would use a nonfoaming sanitizer whereas a foaming sanitizer would be used for environmental surfaces (see Sections CIP Cleaning Background and COP Cleaning) as foam provides contact time for vertical surfaces as well as a visual confirmation of sanitizer application. (In the case of sanitizers that are approved for no rinse applications, such foam would break and leave no visible residue.)

Any manual sanitizer application should not rely on mechanical action or scrubbing to assist the sanitizing operation (using the cleaning operation for such removal). If applicators, such as fabric or mop systems, are used for sanitizer application, care must be taken to ensure that these applicators are themselves thoroughly cleaned, sanitized, and stored separately from equipment used for cleaning operations to avoid microbial or allergenic residue cross-contact onto food production equipment during a sanitizing operation.

Cleaning Validation and Verification Technology

There are three main components to developing a cleaning program for any food production area:

1. A cleaning and sanitizing protocol usually termed a sanitation standard operating procedure needs to be developed that is based on the specific legal and safety requirements for the food processing business.
2. Validation of that cleaning and sanitizing protocol requires development of tests for every point in the cleaning process to prove that the process meets regulatory standards.
3. A Verification program needs to be instituted (usually consisting of a subset of the validation test methods) that will provide proof that the cleaning program continues to be effective over time.

There are numerous verification tests to determine the presence of allergen and microbial residues on food production equipment. The Association of Analytical Communities Research Institute provides a wide array of validated methods for both allergens and pathogens. These verification tests or similar validated tests should be used in a validation program to ensure elimination of the desired contaminant.

Sampling for microbial or allergenic residues is typically done using swabbing techniques on hard surfaces and analyzing the swabs using the various applicable allergenic or microbial detection methods. Other techniques include testing rinse water or using air sampling techniques.

Some allergen verification tests include highly sensitive tests that can detect allergenic proteins from a variety of allergens but especially focused on the top eight (peanuts, tree nuts, milk, eggs, soy, fish, crustaceans, and wheat) which represent at least 90% of the global cases of allergic reactions in humans.

The common bacterial tests include measurements of general bacterial populations such as total plate count, total viable count, standard plate count, aerobic bacteria, gram positive cultures, thermoduric count, coliforms, gram negative bacilli as well as more specific tests such as *E. coli* O157:H7, *Salmonella*, *Listeria*, *Cronobacter*, *Staphylococcus*, and *Campylobacters*. In addition yeast and mold tests are commonly used in food processing verification, especially for air quality assessments.

Verification tests can be general or specific. Common general tests demonstrate the presence of soil in areas of food production facilities and can be very sensitive. Use of general verification tests are based on the understanding that if no soil is detected, no microbial or allergenic residue is present. Such sensitive tests include total organic carbon which will detect any type of organic soil. Adenosine triphosphate (ATP) or ATP-based detection technology will detect any type of food or microbial residue (from cell ATP content) but is not specific to the sources of the ATP. The ATP from cells (living or dead) reacting with the luciferase enzyme is the basis of swabbing tests that are quick and semiquantitative, providing a light density based numeric output that can be used for comparative purposes for hard surface soils.

Numerous other fluorescence technologies have been employed for identifying pathogens, living from dead cells, at high sensitivity. Enzyme-linked immunoassays and enzyme-linked fluorescent techniques have been commonly used for automated detection of specific pathogens. There are numerous techniques for automated testing for specific pathogens and the technologies are getting better and more rapid. The ultimate goal for food processing facilities is obtaining test results rapidly enough to permit release of food product from a production facility with minimal need for keeping food product on hold.

Conclusions

Automated or manual cleaning and sanitizing requires an understanding of where soil and microbial residue might be present in a food processing system. CIP, COP and environmental cleaning systems and the associated cleaning and sanitizing chemistry and procedures for food production facilities is discussed. Developing effective cleaning and sanitizing procedures using optimized cleaning and sanitizing technology is critical to achieving a safe food production environment.

FOOD TECHNOLOGIES

Drying

CL Law, The University of Nottingham, Semenyih, Malaysia
HHH Chen, National Pingtung University of Science and Technology, Pingtung, Taiwan
AS Mujumdar, National University of Singapore, Singapore

Glossary

Dryer A unit operation that is used to remove water from solid substance.
Drying A process that applies thermal energy to remove water from solid substance.
Heat treatment A process where thermal energy is applied to food material.
Microbial inactivation Retard the growth of microorganisms.
Microwave A type of electromagnetic wave.
Photocatalyst A chemical substance that acts as catalyst after exposure to sufficient light.
Pretreatment Applying treatment such as osmotic dehydration and blanching before thermal drying.
Pulse combustor A chamber that combusts periodically at high frequency.
Superheated steam The steam whose temperature is higher than its saturation point.
Water activity Ratio of water vapor pressure in a substance to the water vapor pressure of pure water. It is used to indicate the amount of water available to microorganisms.

Introduction

Drying is one of the most important unit operations in food processing. It is applied to reduce the water content of food products including grains, fruits, vegetables, spices, meat, and marine products, biotechnological products, and agricultural products. Table 1 shows some typical food examples of these food categories which have been reported to undergo dehydration for the production of dehydrated food. Drying is performed in order to prolong the shelf-life of the products mentioned above by reducing the water activity to a level low enough to inhibit the growth of microorganisms, enzymatic reactions, and other deteriorative reactions. Figure 1 shows the critical water activity for the growth of various types of microorganisms. Low value of water activity inhibits the growth of microorganisms and prevents oxidation and enzymatic reactions. With reference to Figure 1, a dehydrated product with water activity lower than 0.6 is safe for long period of storage. Inhibition of microorganisms and prevention of undesirable reactions in turn minimize or avoid food wastage. In addition, drying is also applied to add value to the food products owing to some special characteristics that are only present in dried form, for instance, taste, texture, color, medicinal value, etc. Processing of the products mentioned above is usually subjected to various quality constraints, which are related to food safety, textural and sensory attributes, retention of bio-active ingredients, trade regulation, and consumer acceptance.

Table 1 Examples of dried food products available in the market

Category	*Examples of food products*
Fruits	Mango, guava, banana, longan, apricot, apple, strawberry, papaya, figs, grape, peach, plum, date, sapota, kiwi fruit, avocado, pineapple, prune, pear, persimmon, citrus peels, cherry, raspberry
Vegetables	Carrot, potatoes, pumpkin, garlic, tomato, chili, cassava, cauliflower, asparagus, bell pepper, eggplant, mushroom, spinach, onion, garlic, green beans, broccoli, celery, bamboo shoot, ginger, okra, artichoke, beet, cabbage, horseradish, japaleno, leek, peas, nuts, zucchini
Grains	Rice, wheat, maize, barley
Marine products	Fish, shrimp, squid, sea cucumber, jellyfish, cockles, mussels, sharkfin, fish maw, fish crackers, scallop
Meat products	Ham, beef, pork, sausages, meat jerky
Biotechnological products	Yeast, bacteria, proteins, amino acids, enzymes
Others	Pasta, noodles, cheeses, flavoring powders, juice mixtures, beverage extracts, soup mixtures

 doi:10.1016/B978-0-12-378612-8.00268-7

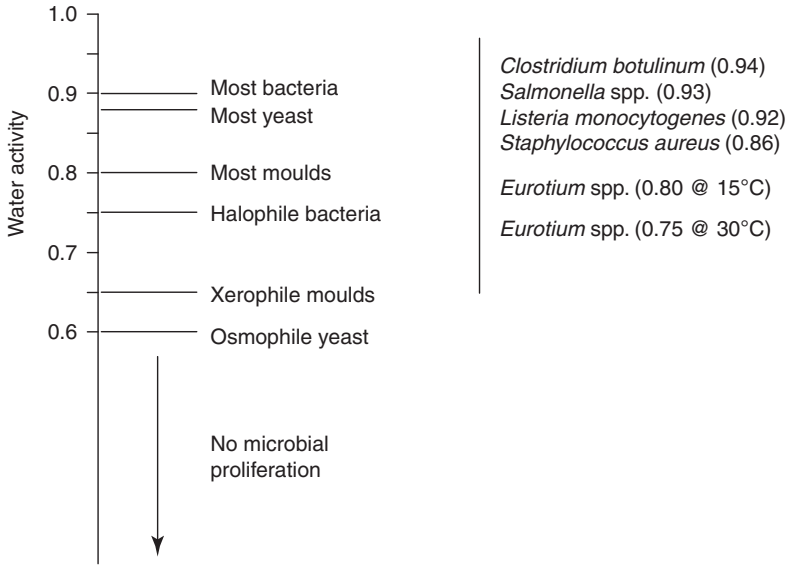

Figure 1 Water activity chart and susceptibility of food to spoilage by microorganisms.

Spoilage of food products due to microbial activities is a main concern. Further, degradation and spoilage of food products that are caused by microbial activity may produce microbial toxins and mycotoxins which bring adverse effect to human health. Contamination of microbial toxins and mycotoxins in food products is a serious concern with regard to food safety. Mycotoxins have been shown to be potent carcinogens, mutagens, and tetratogens.

Because the removal of moisture can only inhibit the growth of microorganisms and undesirable reactions, it cannot ensure food safety as rehydration of food may let the food product regain water which increases its water activity and thus makes it susceptible to spoilage by microorganisms and deteriorative reactions. As such, methods of eliminating contamination by microorganism are vital in processing of food products, including predrying, during drying, and postdrying.

Drying kinetics is seldom the sole parameter that affects product safety and guarantees low microbial count in the dehydrated products. This is due to the fact that the final microbial count is also dependent on the initial microbial count and drying temperature as well as the material being dried. Presence of nutrients like sugar will encourage rapid growth of microorganisms. Of course, shorter drying time is desirable in this aspect, but rapid drying may deteriorate product quality and cause problems such as cracking, surface hardening, surface discoloration, etc.

It should be noted that drying for a long period of time and at temperature of approximately 40 °C may lead to significant microbial proliferation and multiplication. In addition, initial microbial load of the drying material may also affect the final product safety and hygiene if improper processing method is used. Generally, drying at the shortest drying time may minimize the microbial proliferation; drying at high temperature may eliminate the microorganisms; however, drying at subzero temperature may inhibit microbial growth. Furthermore, pretreatment as well as practicing good manufacturing practice (GMP) during the predrying process may give a low initial microbial load which in turn ensures relative low final microbial load in the final product after drying.

There are more than 500 types of dryers reported in the literature and approximately 100 types are being used in various processing industries. Certain types of dryers permit elimination of microbial contamination during the process but many dryers do not. As such, they require pretreatment or posttreatment in order to eliminate the hazard and to meet stringent food quality requirement. In addition, dryers must be operated in a hygienic manner in order to avoid recontamination during the process.

This article elaborates drying from the food safety point of view in four main scopes namely:

- Classification of dryers.
- Description of dryers that have the inherent characteristics to permit sterilization, inactivation of microbial activity, and elimination of contamination during the process.
- Pretreatments that can be applied before drying, in order to minimize microbial load.
- Techniques that can be applied in a dryer to inactivate microbial activity.

Classification of Dryers

Dehydration of food products can be carried out by natural drying or in a mechanical dryer. Natural drying uses readily available sunlight and wind energy to realize the drying process.

Sun drying is a traditional drying method. It is applied in the drying of agricultural products, especially in many developing countries. Although the energy cost is free, its labor cost and requirement for space is high. A large space is

required to expose the drying material to sunlight, and the material needs to be mixed and spread from time to time to ensure uniformity and to avoid over-drying. Moreover, weather condition is a main constraint to sun drying; its availability is dependent on seasonal weather and thus not reliable. Further, the drying material is exposed to contaminating agents and insects thus posing hygienic issues.

Sun drying is often regarded as a method in eliminating microbial activity. This is a misconception. Drying is generally applied to remove water from drying material. If water activity of the dried material is below 0.6, it is safe for longer period of storage as most microorganisms cannot multiply or grow at this water activity level. However, drying does not eliminate or kill the microorganisms or spores. Some drying methods which are discussed in this article do have the potential to eliminate microorganisms, for example, superheated steam drying, pulse combustion drying, microwave drying, high temperature drying, etc., but sun drying does not. As a matter of fact, sun drying has some limitations with regard to product safety and hygiene. Sun drying is carried out in an open system, thus the drying materials are exposed to contaminants, microbes, and spores in the ambient air. It is highly dependent on the solar radiation intensity and local weather; thus, drying kinetics and product quality are not easy to control. Sun drying at temperatures of approximately 35–40 °C, in fact, provides an environment conducive to microbial growth. In fact, solar radiation does contain ultraviolet (UV) component in its spectrum which can kill microorganisms. However, this effect is confined to the line-of-sight surface only. Thus, microbes not directly exposed to solar radiation for long enough cannot be destroyed.

In addition, various pretreatments may eliminate initial microbial load which leads to low microbial count in the dehydrated material. These drying methods and pretreatments are discussed in detail in this article as well. Other drying methods which do not have the potential of eliminating microorganisms are discussed briefly in Tables 2–5. This is mainly because they are carried out at lower temperatures so as to safeguard quality parameters of the heat-sensitive material.

Solar dryer is an alternative to harness solar energy which eliminates the problems mentioned above. In a solar drying system, solar energy is transferred to heat storage agents such as water (medium which has high heat capacity), phase-change materials, etc. A heat exchanger is required where solar energy is transferred from the heat-storage agent to drying medium, normally air. Hot air is then supplied to a drying chamber. External heater is installed to supply supplement heat in case solar energy is not sufficient or not available.

In temperate regions, atmospheric air is dry (relative humidity is low). The air is a good drying medium for wind drying. However, this technique is not possible in tropical regions. It should be noted that a dryer or a drying system that works well in one place might not give the same drying performance in another area. Thus, selection of dryer is a not a simple task as the drying performance of a dryer is also dependent on weather condition and geographical location.

However, mechanical dryer has a wide range of dryers classified under different criteria. Figure 2 shows the classification of drying techniques. Generally, the mechanical drying system can be classified into four categories namely drying strategy, drying medium, handling of drying material, and mode of heat input. For the first classification which is with reference to drying strategy, dryers can be classified into subcategories in terms of the mode of operating parameters profile which include continuous mode (most common), intermittent mode, cyclic mode, stepwise mode, etc. For the second classification, drying medium such as hot air (most common), dehumidified air, superheated steam, combustor exhaust gas, inert gas, osmotic solution, etc., can be used in a drying system. With reference to the third classification, dryers are classified into different categories based on how the drying material is handled in a dryer. For instance, stationary (common), packed in a bed (common), conveyed on a conveyor (common), agitated in a rotary drum (common), fluidized, spouted, vibrated, pulsated in dryer, sprayed into fine droplets, or frozen and subjected to sublimation. Finally, dryers are also classified according to the mode of heat input namely convective, conductive, by radiation heat transfer, in microwave field, and high electric field.

Table 2 Description of dryer based on the first classification – drying strategy

Dryer/drying system	*Brief description*
Continuous	● Drying medium is supplied continuously throughout the process ● The most common strategy; most industrial dryers are continuous dryer, for example, oven, tray dryer, tunnel dryer, fluidized bed dryer, spray dryer, etc.
Intermittent	● Active drying and tempering (drying is stopped for a period of time) are carried out interchangeably and repeatedly in order to minimize product cracking; reduce operating cost; and enhance product quality ● This strategy can be applied to most dryers that are operated in continuous mode
Cyclic	● Operating conditions such as airflow rate, temperature, humidity, or operating pressure is varied individually or in tandem in cyclic mode ● It can be applied to most dryers that are possible in intermittent mode
Stepwise	● Operating conditions such as airflow rate, temperature, humidity, or operating pressure is varied individually or in tandem in two modes, namely step-up and step-down ● In step-down mode, operating condition is gradually decreased toward the end of drying and the reverse in step-up mode ● It can be applied to most dryers that are possible in intermittent

Table 3 Description of dryer based on the second classification – drying medium

Dryer/drying system	*Brief description*
Hot air	● Hot air is generated by contacting the air with heating element; burned with fuel in a burner ● Hot air generated from burning air–fuel mixture may pose contamination issue, thus it is generally not used in food processing. Instead, heating element is used ● Hot air makes contact with drying material, transfers heat to the material, and carries away water vapor ● The most common drying medium used in industrial drying which include oven, tray dryer, tunnel dryer, fluidized bed dryer, spray dryer, etc.
Superheated steam	● Superheated steam is generated by heating up steam generated from a boiler using a heat exchanger ● As it does not contain oxygen, oxidative or combustion reactions can be avoided, thus eliminating the risk of fire and explosion hazards ● Superheated steam can be used to replace hot air in almost all direct dryers such as, for example, oven, tray dryer, tunnel dryer, fluidized bed dryer, etc.
Dehumidified air	● Dehumidified air at low temperature can be generated from a heat pump system ● It is suitable for drying of heat-sensitive products and eliminates shortcomings in product quality that are caused by high temperature, for example, over-drying ● However, final moisture content is relatively high and drying duration is typically long unless combine with volumetric heating ● Low temperature processing environment can minimize microbial activity but not eliminate the hazard; may combine with other treatment processes ● Likewise, it can be used to replace hot air in almost all direct dryer
Exhaust gas	● Combustor exhaust gas is generated from high frequency combustor such as pulse combustor ● Complete combustion is normally achieved and the combustion is completed at extremely high temperature (700–800 °C) ● Drying time is within seconds or minutes ● Effective in eliminating pathogenic microorganisms such as *E. coli*, pseudomonas, coliform bacteria
Inert gas	● CO_2, N_2, organic vapor such as ethanol vapor can be used as a drying medium ● They are mainly used to eliminate oxidative reactions and to promote moisture removal rate
Osmotic solution	● Hypertonic solutions are used to remove moisture from drying material as well as microorganisms ● Sometimes it is applied as a pretreatment process before thermal dehydration

In addition, hybrid drying system can be introduced by combining variants in two different categories, for instance, combining superheated steam drying in the second classification with fluidized bed in the third classification gives superheated steam fluidized bed dryer; combining dehumidified air (heat pump drying) and microwave gives microwave heat pump drying.

Table 2 shows brief description about the different types of dryers with reference to the first classification in Figure 2 – drying strategy. The most common drying strategy is continuous drying where drying medium (can be any medium stated in Figure 2) is supplied to the drying system continuously and at constant profile throughout the entire process. Recent advancement reveals that the process can be conducted in intermittent, cyclic, or stepwise modes, mainly aims toreduce operating cost or enhance product quality especially in reducing product cracking and avoiding over-drying.

Table 3 provides brief description of dryers under the second classification – drying medium. The most common drying medium is hot air. Owing to the fact that hot air is detrimental to heat-sensitive product and may cause severe oxidative degradation, recent development in drying technology has introduced various types of drying media such as superheated steam, low temperature dehumidified air (heat pump drying), and inert gas to avoid thermal and oxidative degradation of bioactive compounds. In addition, extremely high temperature combustor exhaust air can also be used for rapid drying, which may eliminate the undesirable degradations that normally require relatively long period of time to cause significant deteriorative effect to the product quality. Further, osmotic solution such as sugar and salt solutions are excellent hypertonic solutions that can be applied to retard growth of microorganisms.

Drying medium at relatively high temperature (60–80 °C) may retard the growth of some microorganisms and enzymatic reactions. Nevertheless, certain types of microorganisms are resistant to heat and therefore hot air cannot eliminate the hazard completely. In this regard, precautionary actions should be taken in order to minimize the initial microbial load before drying. This can be achieved in two aspects namely pretreatment and hygienic drying practice. Both aspects will be discussed in the subsequent sections.

However, drying media at extremely high temperature such as superheated steam and combustor exhaust air are suitable for eliminating the hazard. Both superheated steam drying and pulse combustor drying are discussed separately in subsequent sections. In addition, osmotic solutions can also be applied to retard microbial growth.

Table 4 gives the description and illustration of types of dryers that handle drying material in different modes and states. Generally, thermal efficiency is low in conventional dryers, mainly due to poor contacting efficiency between solids and the drying medium. This results in low drying rate and long drying duration. If the drying material is stirred, mixed, agitated, fluidized, vibrated, pulsated, etc., intermittently during the drying process, the contacting efficiency between the material and drying medium is improved appreciably. This in turn enhances the drying efficiency.

Table 4 Description of dryer based on the third classification – handling of drying material

Dryer/drying system	*Brief description*
Stationary	● Drying material is placed on a tray in the dryer and subjected to drying medium ● Many industrial dryers are stationary dryers, for example, oven, tray dryer, tunnel dryer, freeze dryer (solids), etc.
Packed bed	● Particulate solids are packed in a drying column and form a bed of solids ● Drying medium is charged into the column from the bottom of the bed ● Solids are packed and in contact with each other. Certain solids surface is not exposed to the drying medium
Conveyor	● Drying material is placed on a conveyor and transported from inlet to outlet while contact with drying medium ● Impingement drying can be considered where a high speed drying medium is impinged to the material on the conveyor. Drying rate is typically high in impingement drying ● The drying system is operated in continuous mode and the material is stationary while it is being transported on the conveyor
Rotary	● Drying material is agitated in a rotary drum with the assistance of louvers ● Heat transfer can be achieved in two modes, namely convective and conductive ● Agitation of solids enhances the heat and mass transfer
Fluidized bed	● Particulate solids are placed in a fluidized bed column and forms a bed of particles ● Fluidizing gas stream is charged into the column from the bottom ● Gas passes through the bed of solids and suspends the particles in the gas stream, which expends the bed volume ● Sometimes bubbles are formed and therefore gives bubbling fluidized bed ● Good fluidization enhances contacting efficiency between solid and fluidizing gas which in turn enhances rate of removal of moisture
Spouted bed	● A powerful gas stream is charged into a bed of solids at the center region and therefore thrusting the solids into space above the bed of solids ● The solids falls on the bed surface after losing its momentum ● Thrusting and falling of particulate solids in a spouted bed gives a unique solids circulation and hence good contacting efficiency between solids and gas ● Suitable to dry coarse particles which are difficult to fluidized in conventional fluidized bed
Vibrated bed	● Vibration is applied to a bed of solids which gives pseudo-fluidization to coarse particles ● Suitable for fine and coarse particles which are difficult to fluidized in a conventional fluidized bed
Pulsated bed	● Bed of solids is divided into several parts ● Part of the bed of solids is fluidized bed intermittently and periodically ● It is also regarded as an intermittent dryer
Spray (liquid)	● Drying material in the form of liquid is sprayed into droplet and dried in the dryer ● Fine powder is formed and discharged from the bottom ● It may be combined with other types of dryers, for example, fluidized bed dryer
Freeze (liquid)	● Drying material in the form of liquid is frozen and subjected to sublimation for the removal water/solvent vapor ● A thin film is formed at the end of the process

Table 5 Description of dryer based on mode of heat input

Dryer/drying system	*Brief description*
Convection	● Drying medium makes contact with the drying material, transfers heat to the material, and removes moisture vapor ● This mode of heat input is the most common in industrial dryer as long as drying medium is applied ● Convective heat input may combine with conductive heat input such as heating plate/surface and volumetric heating such as microwave
Conduction	● Conductive heat transfer can be achieved by using hot surface, heating plate/rod, or inert solids that has high thermal inertia ● It can be applied in vacuum and freeze dryers where convective heat transfer is not possible or minimal. Some direct dryers also apply this mode to enhance heat transfer, for instance, internal tube fluidized bed dryer
Radiant (infrared)	● Infrared radiation transfer heat to the material surface by radiant heat transfer ● It can be combined with convective drying
Dielectric (microwave, radio frequency)	● Microwave generates rapid volumetric heating of the material by altering the electromagnetic field to interact primarily with the water molecules and ions in food materials ● It enables rapid removal of moisture and allows removal of internal moisture at initial stage of drying
High electric field	● Unlike microwave or radio frequency, heat is not generated in the material ● High electric field is applied across the drying material; particulate solids are usually negatively charged ● Water flows toward the direction of cathode

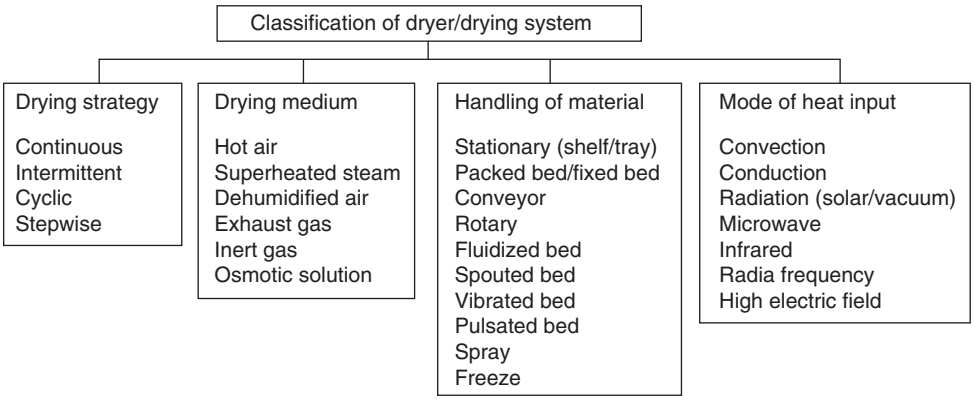

Figure 2 Classification of dryers.

Stationary dryers such as oven, tray dryer, tunnel dryer, freeze dryer, etc., are the most common dryers applied in the processing industry. Packed bed drying is common for drying of particulate solids. Further, the drying material can be conveyed on a belt dryer or agitated in a rotary dryer. Both conveyor and rotary dryers are also common in processing industry. To enhance solid–gas contacting efficiency, fluidized bed dryer can be applied to allow rapid heat and mass transfer and therefore higher rate of moisture removal. Further to this, the bed of solids may be spouted, vibrated, or agitated if the solids are difficult to fluidize in a fluidized bed. Pulsated bed is a variant of fluidized bed where part of the bed of solids is fluidized bed intermittently. It has the advantages of an intermittent dryer.

If the drying material is in a liquid form, it can be atomized and sprayed into droplets and dried in a spray dryer. Spray dryer is typically used to dry liquid, suspension, paste, etc., into dry powder. Alternatively, the material in the liquid form can be dried in a freeze dryer where the liquid is frozen and subjected to sublimation. Eventually, a thin layer of film is obtained. Both spray and freeze dryers are commonly used in processing industry.

Table 5 briefly explains the characteristics of dryers classified under the fourth classification – mode of heat input. Convective heat transfer is the most common mode in most industrial dryers. Conductive heat transfer is common in freeze dryer, rotary dryer, agitated fluidized bed dryer, and internal tube fluidized bed dryer and inert solids fluidized bed dryer. Infrared dryer transfers heat to the drying material in radiant heat transfer mode; dielectric drying (microwave and radio frequency drying) generates heat within the drying material using high-frequency electric fields. Both infrared and dielectric drying enable volumetric heating where the entire drying material is heated by the electromagnetic wave; this allows the removal of surface and internal moistures. Unlike convective drying, only the surface moisture is removed and the internal moisture has to migrate from the material core to the surface. One of the recent developments in drying technology is the development of hybrid drying where convective drying is combined with radiant heat transfer mode. For examples, convective microwave drying, microwave-assisted heat pump drying, etc.

Drying Techniques that have the Potential in Minimizing and Eliminating Microbial Load

Food contamination may occur in any process before drying. This may have an adverse effect on product hygiene and safety if effective microbial inactivation and decontamination method is not applied during drying or post drying. Therefore, the ability of dryers to inactivate bacteria may have considerable impact on the product hygiene and safety. In this regard, drying techniques that permit microbial inactivation and decontamination are worth to be considered when it comes to the selection of appropriate dryers. In General, factors that make microbial inactivation and decontamination in a dryer possible are high temperature processing, or low temperature processing, in a duration that is long enough to make the inactivation and decontamination effective. High temperature can denature proteins, thus eliminates microbes; low temperature inactivates microbial activity, hence stopping the microbes from multiplying. In addition, duration of operation must be long enough to realize the microbial inactivation and decontamination. Among the dryers that are described in Tables 2–5, superheated steam dryers, pulse combustor dryers, and microwave-assisted dryers have the inherent characteristics in eliminating microbial contamination during drying process.

Superheated Steam Drying

Superheated steam is steam heated to a temperature higher than its boiling point corresponding to the operating pressure. Figure 3 shows the schematic diagram of basic principle of a closed system superheated drying system. Saturated steam (100 °C, 1 bar) after heated to a superheated state at 110 °C, gaining 30 kJ kg^{-1} of energy, if it is used as a drying medium, absorbs moisture from drying material and transfers heat to the material until it reaches saturation. A major fraction of the exhaust steam must be recycled in order to maximize the energy efficiency. With reference to Figure 3, only 1% make-up steam is required and additional 30 kJ of heat is required to heat the saturated steam to superheated state. Thus, superheated steam drying system has high energy efficiency and it is normally conducted in closed system.

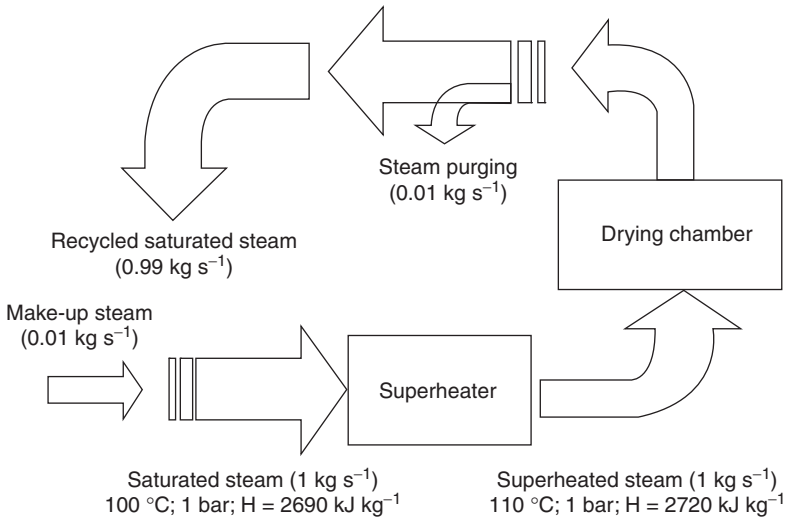

Figure 3 Schematic diagram basic principle of a closed system superheated steam drying.

Superheated steam can be used to replace hot air in direct dryers. As it does not contain oxygen, oxidative or combustion reactions can be avoided. Furthermore, it eliminates the risk of fire and explosion hazards. Superheated steam drying is a promising drying technique in processing industry as it also offers additional advantages such as low energy consumption and improved food hygiene. As the operating temperature of superheated steam drying is typically high, this drying technique permits pasteurization, sterilization, and deodorization of food products. In terms of microbial inactivation, moist heat is more effective than dry heat because proteins, which are important in maintaining cell viability, are more stable in the dry state. Therefore, superheated steam drying is effective in inactivating microbial activity. This is particularly important for food and pharmaceutical products that require high standard of hygienic processing.

It has been reported that surface sterilization could be achieved in fish products and cabbage after a short period of pretreatment with superheated steam. Abe and Miyashita (2006), Ono *et al.* (2006) and Cenkowski *et al.* (2007) after examining the effect of superheated steam drying on the vitality of *Fusarium* mycotoxin deoxynivalenol and with *Geobacillus stearothermophilus* spores concluded that the use of superheated steam drying is beneficial for reducing the contamination of foods.

However, superheated steam drying has deleterious effect on heat-sensitive compounds due to high operating temperature. As such, it is not suitable for the dehydration of biomaterials that contain high content of bioactive ingredients. Anyway, the operating pressure can be reduced in order to reduce the deleterious effect on bioactive ingredients.

Superheated steam has the ability to eliminate microbial activity, inactivate enzymatic reaction, and denature microbial proteins provided that the duration is sufficient to inactivate the microbial activity. This however gives drawbacks to product quality where long drying duration may result in problems such as over-dried, deteriorating product quality, etc. Constrain on both food safety and product quality poses a challenge to the processing industry if superheated steam drying is selected. Obviously, it requires optimization.

Like many other hot air dryers, the performance of superheated steam drying can be enhanced by combining it with other drying techniques such as microwave, fluidized bed drying, etc.

It has been reported that the exposure times required for 90% reduction in microbial population (D-values) of surrogate organisms *Clostridium sporogenes* (spores) and *Escherichia coli* at 300 °C were 0.33 and 0.10 min, respectively, in superheated steam fluidized bed dryer as compared to 54 and 1.12 min in hot air dryer. Whereas for the inactivation of the spores of thermophile *G.stearothermophilus*, 3.54 min in fluidized bed superheated steam drying compared to 228 min in boiling water.

Pulse Combustor Dryers

Combustible mixture of fuel and air is ignited and discharged periodically in a pulse combustor. The periodic combustion of fuel mixture and discharge of high-temperature exhaust gas results in periodic pressure oscillations. Liquid product is injected directly into the highly turbulent pulse combustor exhaust tailpipe; despite the ultra-high temperatures of the exhaust, rapid heat and mass transfer rates take place in the drying chamber. The highly turbulent flow in the chamber coupled with fine atomization allows drying to be accomplished within seconds or minutes. Although the operating temperature is extremely high, it is also suitable for highly heat-sensitive products because the duration is too short for thermal degradation to take effect.

Figure 4 shows the schematic diagram of typical pulse combustion dryer. The pulse combustor is mounted on a drying chamber. It can be a normal convective drying chamber or a spray dryer. The combustion gaseous product after being discharged from the combustor is mixed with product liquid and the mixture is then charged into the drying chamber. Rapid drying is carried out in the drying chamber

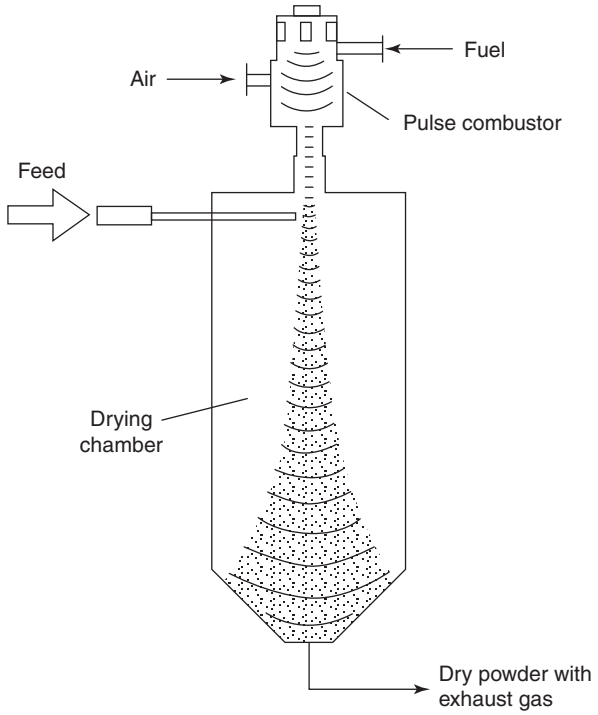

Figure 4 Schematic diagram of pulse combustion dryer.

where powders are formed and drops on the bottom of the chamber. The products together with the rapid moving gas stream exit the chamber and enter dust/powder separation system. The process has not been a commercial success yet, possibly due to problems of noise, scale-up, and capital cost.

Microwave Drying

Drying utilizing microwave energy is an attractive solution to many problems arising in drying of material that is based on the conventional, convective, and conductive heat transfer. Microwaves stimulate vibration and rotation of water and fat molecules as well as electrophoretic movement of ions for some depth inside the food, resulting in internal heat generation. Owing to the increase in vapor pressure, moisture from the interior of the product can be expelled. Microwave drying permits dielectric heating which heats volumetrically a drying material containing polar compound. When an alternating electromagnetic field is applied to a dielectric material, heat is generated. This allows the removal of internal moisture even at the initial stage of drying which is totally impossible for conventional convective drying that can only remove surface moisture. In conventional convective drying, the removal of internal moisture is dependent on the migration of internal moisture to the material surface and the evaporation of the moisture at the surface subsequently.

Microwave drying offers advantages which include rapid drying, high energy efficiency, uniform energy, and high thermal conductivity to the interior of the material, permits precise process control, space utilization, shorter drying time, short start-up and shut-down times, prevention of enzymatic reaction as well as microbial proliferation. However, it also gives some drawbacks which limit its application in food processing industry, for example, high start-up costs and relatively complicated technology compared with simple conventional convective drying, nonuniform heating patterns which are caused by focusing, corner and edge heating, inhomogeneous electromagnetic field, shape and composition of the drying material.

Daglioglu *et al.* (2002) dried tarhana dough (fermented product of yogurt–cereal mixture) inoculated with *Staphylococcus aureus* (10^4 CFU g^{-1}) in two types of dryers, namely hot air oven at 55 °C for 36 h and microwave oven (1500 W, 2450 MHz, 30% power level) for 10 min. It was found that microwave drying could completely eliminate *S. aureus* microbial population.

Because microwave offers the advantage of volumetric heating, as well as eliminating microbial proliferation, microwave drying is often combined with other drying techniques, for instance, microwave-assisted convective drying, microwave-assisted freeze drying, microwave-assisted vacuum drying, etc.

Microwave-Assisted Convective Drying

Microwave heating can, in principle, be coupled with any convective drying system such as fluidized bed or spouted bed. The drying time in a microwave assisted fluidized bed dryer can be 2–5 times shorter than in a conventional fluidized bed dryer, therefore resulting in higher drying efficiencies. However, the unique temperature leveling in microwave-assisted spouted bed helps to control product temperature and improve product quality as compared with microwave-assisted fixed-bed hot air drying methods.

Microwave-Assisted Freeze Drying

It is well known in the processing industry that vacuum freeze-drying can yield high-quality product, but its capital and operating costs are high and it requires a long processing time. Besides, microorganism count in freeze dried products sometimes exceed the permissible limit in food stuff. One of the ways to maintain freeze dried product quality and eliminate the drawbacks of freeze drying is to combine the freeze drying with microwave drying. In this regard, microwave does not only allow volumetric heating but also eliminates microbial activity during the drying process. This in turn improves the drying kinetics, meanwhile maintaining hygienic processing.

In an investigation on the sterilization effect of microwave-assisted freeze drying for the dehydration of cabbage, Duan *et al.* (2007) found that the change of standard plate count (SPC) treated by microwave-assisted freeze drying (MFD) is in the range of 2000 as compared to 14 000 in freeze dried (FD) cabbage and 15 000 in fresh cabbage. Further, it was reported that FD took 15 h whereas MFD required only 6 h to reach final moisture content of 6%.

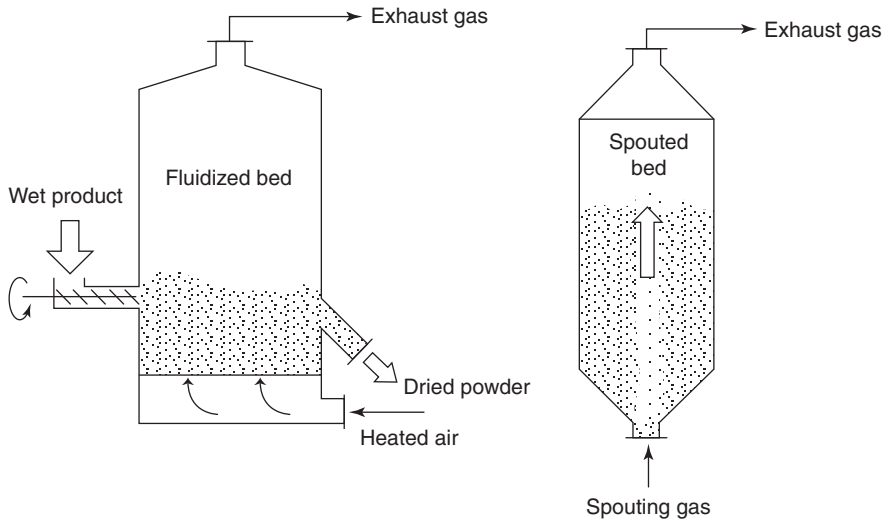

Figure 5 Schematic diagrams of a typical fluidized bed and a typical spouted bed.

Microwave Vacuum Drying

In vacuum drying, oxidative reaction is prevented as atmospheric air is not present in the dryer. Drying temperature is typically low as vacuum reduces the boiling point of water or solvent, thus reducing thermal stresses and overdrying that is caused by high temperature drying. This in turns improves color and texture of dried products. As drying medium is not present in the vacuum drying, convective heat transfer is not possible. This in turn results in relative long drying duration. Combination of vacuum drying and microwave drying gives the advantages offered by both vacuum and microwave drying, for example, minimization of oxidative reaction and rapid drying rate. Therefore, unwanted changes in sensory attributes and nutrient loss due to long drying times or high surface temperature can be prevented, and temperature-sensitive substances like vitamins, colors, and flavors may be retained. Vacuum microwave drying has been recognized as a good method for production of high-quality dry food materials.

It has been reported that vacuum microwave could reduce microbial population of fresh parsley leaves and grated carrots in a shorter time and at a lower final temperature as compared to traditional hot air drying. To further maximize the elimination of microbial load, it has been suggested to apply two-stage drying strategy, microwave drying in the initial stage of drying for a short period of time (e.g., 5 min) followed by vacuum microwave drying.

High Temperature Drying

Drying operated at high temperature (e.g., more than 80 °C) could minimize microbial activity but not eliminate the microbial activity entirely. In addition, the effect in minimizing the microbial activity is dependent on the duration of the application of high temperature drying. Often, the duration required to make the minimization of microbial activity to be effective tends to cause over-drying and therefore produces undesirable product quality. Hence, optimization is often required to maximize both aspects.

It (fixed constant maximum grain temperature 62 °C, retention time 10.5 min) of bread grain could reduce surface dwelling yeasts and filamentous fungi (especially the deoxynivalenol-, nivalenol-, and zearalenone-producing *Fusarium culmorum*) if compared to continuous hot air drying, albeit both drying methods gave the same drying kinetics and produced similar baking quality. This study demonstrated that temperature is not the only parameter that ensures effective minimization or elimination of microbial load. Contacting efficiency plays an equally important role in this respect. Therefore, if the drying material is in the form of a bed of solids, fluidized bed, spouted bed, vibrating bed, etc., may be considered. Figure 5 shows the schematic diagram of a typical fluidized bed and a spouted bed. In a fluidized bed, gas is charged into the fluidized bed column from the bottom, the fluidizing gas stream is powerful enough to suspend all particles in the gas stream, thus making the particles always in contact with gas stream. In a spouted bed, the gas stream penetrates the bed of solids at the center region, thus producing a fountain-like particle bursting at the center region. Particles after losing its momentum fall back on the bed surface and slowly move toward the bed center for another round of thrusting. In both systems, particle–gas contacting efficiency is enhanced if compared with conventional packed bed system.

Low Temperature Drying at Subzero Condition – Sublimation Drying

Drying at temperatures below ambient, including subzero temperatures, may offer significant advantages to materials that are sensitive to high temperatures, for example, biomaterials. Low temperature drying of grain has been reported in barley, corn, wheat, and rough rice. This technique is feasible for temperate regions where seasonal temperature falls

Table 6 Effect of washing pretreatment on microbial load

Technique	*Findings*	*References*
Washing shredded cabbage with acetic acid solution (0.5, 1.0, 1.5%) at different temperatures (5, 10, 30 °C)	• *Salmonella anatum* was destroyed rapidly during the first 5 min of soaking and decreased slightly thereafter • Higher temperature resulted in a higher elimination effect on *S. anatum*	Nanuam (2005)
Washing fresh and semi-dry tomatoes with chlorinated water (200 ppm) followed by hot air drying at 60 °C	• 1.7 log reduction for 5 min washing and 3.1 log reduction for 10 min washing in terms of yeast and mold count	May and Fickak (2003)
Washing cabbage slices with acetic acid solution (0.5, 1.0, 1.5% v/v) followed by hot drying (50–60 °C)	• Initial cell numbers of *Salmonella* was reduced approximately 1.5 log10 after soaking and a reduction of 3 log10 after drying • Higher acetic acid concentration resulted in a higher degree of acid injury and hence increased the susceptibility of *Salmonella* to heat during drying	Chiewchan and Morakotjinda (2009)
Beef slices inoculated with *L. monocytogenes* were treated with marinades with addition of acetic acid followed by hot air drying (60 °C for 10 h) and aerobic storage (25 °C for 60 days)	• Bacterial populations dropped below the detection limit (-0.4 log CFU cm^{-2}) as early as 4 h during drying • Acetic acid solution was found to be effective in inactivating *L. monocytogenes*,	Calicioglu *et al.* (2002)
Peach slices inoculated with *L. monocytogenes* were treated with sodium metabisulfite or acidic solutions followed by hot air drying (60 °C for 6 h)	• Bacterial populations were reduced by 4.3–5.1 log CFU g^{-1} (on TSAP agar) and 5.3–6.2 log CFU g^{-1} (on PALCAM agar), respectively	DiPersio *et al.* (2004)
Carp fillets treated with electrolyzed NaCl solutions and essential oil compounds followed by drying at 45 °C	• Inhibited microbial growth; reduction in 4 log (CFU g^{-1}) as compared with control sample • Gave good antioxidant effects and sensory attributes	Mahmoud *et al.* (2006)

after harvest and cooling can be achieved using ambient air. It has been reported that initial stage of low temperature drying of grain at subzero condition inhibits growth of molds, coupled with rapid drying (with the assistance of higher air flowrate) could reduce mold count as the molds have shorter time to multiply.

Pretreatment

To ensure the safety of dehydrated food products by drying techniques that do not eliminate microbial activity during the process, various pretreatment methods may be applied to reduce the initial numbers of spoilage and pathogenic organisms on the surfaces of food stuff. For food products that contain high initial microbial load, conventional drying techniques such as oven, convective hot air drying at moderate temperature (e.g., 60–80 °C) may not inactivate the microbial activity completely. Instead, the microorganisms could be incubated in the dryer. Pretreatment may be applied to reduce the initial microbial load to avoid incubation of microorganism during drying at moderate temperature. In this regard, pretreatment methods such as cooking, washing, radiation, etc., may be applied.

For washing pretreatment, chemicals such as ozone, chlorine, hypochlorite, and organic acids such as lactic acid and acetic acid have been suggested to sanitize the food stuff before drying. Proper washing of food stuff during the pretreatment stage can reduce microbial load by a factor of 10–100 although it may not remove pathogens completely from the product surface. Further to this, the efficiency of these chemicals on eliminating or reducing the initial microbial load is dependent on the chemical concentration, temperature, and treatment duration. It is noteworthy that some organic acids such as acetic acid have been shown to reduce enzymatic browning activity. Table 6 shows the effect of washing pretreatment using various chemicals on the microbial inactivation and elimination of microbial activity.

Coating of Photocatalyst

A thin coating of titanium dioxide (TiO_2) can be applied on the inside walls of a drying chamber. Titanium dioxide is a photocatalyst which generates strong oxidative potential that can oxidize water to create hydroxyl radicals (OH^-) if exposed to ultraviolet radiation or sunlight. It can also oxidize oxygen or organic materials including microorganisms that exist in the air or on the drying material surface. This in turn provides a hygienic environment to a drying process. Photocatalysis has been applied to many unit operations for bactericidal, deodorizing, and antifouling purposes but this technique is not common in commercial dryers yet.

In an investigation of the drying of pineapple slices in a solar-assisted heat pump dryer, it was reported that the average total counts of potato dextrose agar (PDA) and plate count agar (PCA) were reduced from 20 CFU per plate to less than 5 CFU per plate after the dryer was coated with a layer of titanium oxide photocatalyst.

In addition, exposure to UV, irradiation during drying can be an alternative to reduce microbial load and inactivate microbiological activity.

Good Manufacturing Practice in Drying to Avoid Contamination

Microbial activity in the final product may be derived from contamination sources located in the production line even preprocessing (such as predrying) is carried out in a hygienic condition. Contamination sources may establish at any site where temperature and moisture provide conditions that are conducive for the multiplication of microorganisms. This is more prevalent when the plant is idle. Recontamination therefore mainly occurs at the initial stage of production and in processes that have frequent production shutdowns.

With reference to drying system, microbial contamination and multiplication of microorganisms can occur in nozzle if it is not cleaned properly, and if dead ends and corners where flow of drying material is uneven or obstructed. Surface of components in a dryer which makes contact with product has to meet specific design standards to prevent occurrence of any internal sources of microbial contamination. In addition, contamination risks from external sources have to be avoided by applying good prevention system and GMP.

Concluding Remarks

Design of a good drying system needs to consider various aspects which include foods safety, product quality, energy efficiency, environmental impact, drying efficiency, and engineering aspect. Food safety aspect is definitely an important aspect and in this regard, drying techniques such as superheated steam drying, pulse combustion drying, microwave drying, and their hybrid drying such as microwave convective drying, superheated steam fluidized bed drying, etc., have the potential in minimizing microbial proliferation or eliminating microbial contamination hazards. Pretreatments such as washing may be applied before drying. During drying process, irradiation and exposure to ionized environment by photocatalyst may be applied to achieve this objective. Further it is important to practice good prevention system and GMP when operating a drying process.

Fermentation

MJR Nout, Wageningen University, Wageningen, The Netherlands

Glossary

Back-slopping A method to initiate fermentation by using a small quantity of previously fermented products as a starter.

Fermentation (1) Anaerobic metabolism for energy generation and (2) any microbiological process used to achieve desirable food product properties.

Food environment A combination of intrinsic (chemical composition) and extrinsic factors (external factors, such as temperature, relative humidity, and microbial contaminations) that influence the speed of biological and chemical reactions in the food.

Natural enrichment A fermentation starter with often complex and unknown microbiological composition, obtained by repeated natural fermentation with back-slopping.

Natural fermentation Fermentation in which no starter is added, but which relies on creating a favorable food environment to allow extrinsic microorganisms to multiply and establish desirable food properties.

Operation Technical actions, including physical (mixing, separating, and size reduction) and thermal (heating and cooling) treatments.

Process An organized assembly of operations and ingredients, aimed at producing a final product from its ingredient raw materials.

Starter An additive containing high numbers of living microorganisms used to initiate fermentation; starters may contain single or mixed pure-culture microbial strains, or may be natural enrichments.

Introduction

Fermentation (from *fermentare*, causing to rise) in the strict sense, refers to the anaerobic metabolism and generation of energy. This takes place, among others, in alcoholic fermentations caused by fermenting yeasts and in lactic acid fermentations caused by lactic acid bacteria (LAB). In the wider sense, the word 'fermentation' is used to refer to biological processes resulting in desirable modifications of ingredients. It also refers to the aerobic growth and metabolic activity of acetic acid bacteria in the oxidative production ('fermentation') of acetic acid, of bacilli in alkaline fermentations, and of filamentous fungi (molds) in food processing and enzyme production; the word fermentation is even used for some processes that are enzymatic rather than microbial, for example, the fermentation of tea leaves and the fermentation of certain Oriental fish sauces. In this article, the word 'fermentation' will be used in its broader sense.

A food manufacturing process is defined as the organized use of ingredients, equipments, and operations aimed at achieving a final product. The fermentation itself is only a part of the process, starting from the ingredients to the final product.

Ingredients for fermented foods may include practically all types of primary agricultural food items ranging from plant-derived foods (cereals, pulses, starchy roots and tubers, fruits, vegetables, herbs, and spices) to animal-derived products (meats, poultry, eggs, fish, and shellfish), but they always include water in order to enable biological activity and, thus, fermentation. Essential ingredients for fermentations are the microorganisms; these will be mentioned below.

Equipments used for fermentation may be simple or more sophisticated depending on the socioeconomic context. Equipment is needed to prepare ingredients by grading, removing unwanted parts, mincing, mixing, heating, cooling, etc. In addition, containers for soaking, cooking, and the actual fermentation are required. Other equipments may be needed to finish and distribute the final products to the consumer market.

Process operations can be categorized in groups, including physical and thermal operations. Physical operations include activities such as (1) grading, for example, sorting by color or size; (2) size reduction by grinding; (3) separation of unwanted parts by sieving; and (4) mixing, for example, by stirring. Thermal operations refer to all phenomena involving heat transfer, mainly heating and cooling. Heating may be (1) dry heating by contact with hot air or with hot surfaces as in roasting or frying; heating can also be (2) in wet conditions, such as steaming, immersion in hot water, or boiling under atmospheric or higher pressure. Cooling may be important at various stages in the process, for example, to adjust the temperature of previously heated ingredients to enable the optimum activity of added microorganisms for fermentation. Cooling may also be used to arrest fermentations at a level of

 doi:10.1016/B978-0-12-378612-8.00270-5

optimum food composition reflected, for example, in the most attractive taste. Finally, cooling helps to lengthen the shelf life of foods.

Microorganisms are the driving force of fermentation. They need to be present in adequately large numbers and to be metabolically active, so as to exert their impact in changing the composition of the ingredients toward the desirable characteristics of the expected outcome (the fermented food). In principle, there are two approaches to ensure the presence of active microorganisms.

The first approach is called 'natural' or 'uncontrolled' fermentation; in principle, no microorganisms are added to the ingredients. Instead, the process conditions allow the survival and selective outgrowth of desirable microorganisms that were present in low numbers in one or more of the ingredients. This principle entails that – to allow microbial survival – ingredients are not heated before fermentation. In addition, process conditions may include the exclusion of air in sealed containers in order to favor the dominance of (facultative) anaerobic microorganisms. Also, certain ingredients, such as herbs, spices, and salt, may be used to favor desirable microbes, while restricting the development of potentially undesirable microorganisms or enzymatic activities.

The second approach is called 'starter-mediated' fermentation; in principle, a highly concentrated dose of desirable fermentation microorganisms is added to the ingredients, which may have been previously freed of potential competitive microbiota, and the fermentation is conducted under conditions that favor the added starter. Starters exist in various types, which could be categorized as (1) natural enrichments, (2) traditional multistrain starters, and (3) single or mixed pure-culture starters.

Natural enrichments are accumulations of groups of microorganisms that can be present in equipment, for instance, in porous textures of natural fermentation vessels, such as utensils, calabashes, leather bags, clay pots, etc. Accumulations may also be present at the processing site, for example, the ceiling, walls, and other surfaces of incubation rooms. It is well known that certain traditional Belgian beers can be made successfully only in specific brew houses, where the 'house flora' plays an essential role in the natural fermentation.

Traditional multistrain starters used for fermentation are concentrates of a mixed microbial flora in liquid or dry form. These starters are made with simple technologies without the use of selected pure cultures. In many oriental rice fermentations, such starters are used to initiate the enzymatic degradation of rice starch and the fermentation of the resulting sugars. The dry starters are sold as tablets in the open market; these have a shelf life of at least 6 months in ambient conditions.

Single or mixed pure-culture starters consist of laboratory-controlled pure strains of bacteria or fungi, which have been selected or created for their desirable fermentation outcomes. By combining diverse strains in one mixed culture, the objective is to enhance fermentation outcomes, such as combined acidification and flavor formation. The shelf life of pure-culture starters can be prolonged by freeze-drying (lyophilization) or by freezing. Usually, the viability of the strains needs to be supported by cryoprotectants, such as skimmed milk powder or glycerol.

Types of Food Fermentations

The worldwide diversity of fermented foods is amazing. Several authors observed similarities across national and continental borders and proposed categories of foods and beverages, according to the microorganisms that are responsible for the fermentation, and the kind of biochemical changes that take place, which are of relevance to the characteristic product qualities. In this article, five main categories of fermented foods will be discussed, namely (1) those acidified by the formation of organic acids, (2) alcoholic beverages, (3) those alkalized by the formation of ammonia from amino acids, (4) predigested food caused by the activity of filamentous fungi and their enzymes, and (5) those having undergone enzymatic processes in high-salt conditions.

Acidified by the Formation of Organic Acids

The major organic acids formed in fermented foods are lactic acid, acetic acid, and propionic acid. The most important microorganisms responsible for lactic acid production are LAB, although certain food-grade molds can also form lactic acid. Lactic acid is mainly produced from pyruvate, formed through glycolysis (degradation of monosaccharides). Although homofermentative LAB produce lactic acid as their only fermentation product, heterofermentative LAB may form acetic acid, ethanol, and CO_2 besides lactic acid. Lactic acid results in a decrease of pH and acidic taste; it can also affect the physical properties of food macromolecules, such as starch, and thereby influence food texture. The increased acidity may also have beneficial effects on nutritional aspects, for example, acidity increases the solubility of minerals, thereby facilitating their assimilation in the human gastrointestinal tract.

Thus, although the formation of acetic acid is mostly caused by acetic acid bacteria, it may also be formed by heterofermentative LAB. The major substrate for acetic acid production by acetic acid bacteria is ethanol, which is oxidized by acetic acid bacteria in a strictly aerobic, exothermic reaction. However, acetic acid is produced in a fermentative way by heterofermentative LAB. Acetic acid, like lactic acid, results in a pH decrease and acid taste. The internationally best-known acetic acid product is vinegar, which in principle is a watery solution of approximately 4% w/v of acetic acid. Vinegar is widely used as a natural food preservative and flavoring ingredient.

Propionic acid is formed as a result of the metabolism of lactic acid by propionic acid bacteria. Simultaneously with the formation of propionic acid, acetic acid and CO_2 gas are produced. This could lead to the characteristic taste and texture of certain Swiss cheeses.

Table 1 shows several examples of fermented foods in which organic acids dominate the quality of the product. Organic acids can be formed in a wide variety of food ingredients, such as cereals, vegetables, and dairy products. Combinations with animal protein are also possible, such as meat and fish products. However, in the latter cases, often an additional source of fermentable sugars is required for the LAB. This can be achieved by the incorporation of sugar or

Table 1 Fermented foods dominated by acidification

Name of food	*Origin*	*Main ingredients*	*Predominant microbiota*	*Typical metabolites*	*Typical pH values*
Pozol	Mexico	Maize	LAB (Lp, Lb, and S) and Y (C and T)	Lactic acid and vitamin B	3.8–4.0
Kenkey	Ghana	Maize	LAB (Lf) and Y (Ck and Sc)	Lactic acid, acetic acid, acetoin, and 2,3-butanediol	3.8–4.2
Sauerkraut	Europe	White cabbage and salt 1.5%	LAB (Lm, Lb, and Lp)	Lactic acid, acetic acid, and ethanol	3.8
Kimchi	Korea	Chinese cabbage, garlic, onion, ginger, chilli, and salt 3%	LAB (Lm, Wc, Ls, and Lc)	Lactic acid, acetic acid, and CO_2	3.9
Lassi	India	Cow/buffalo milk	LAB (Bb, Lec, Led, Lecr, St, La, and Pfs) and Y (Sc)	Lactic acid, acetic acid, ethyl alcohol, and CO_2	4–4.5
Yogurt	Europe	Cow milk	LAB (Lbg and St)	Lactic acid and acetaldehyde	4–4.5
Sik-hae	Korea	Fish, millet, and 6–7% salt	LAB (Lm and Lp)	Lactic acid and peptides	<5.0

Abbreviations: Bb, *Bifidobacterium bifidum*; C, *Candida* spp.; Ck, *Candida krusei*; La, *Lactobacillus acidophilus*; Lb, *Lactobacillus brevis*; Lc, *Lactobacillus curvatus*; Lf, *Lactobacillus fermentum*; Lm, *Leuconostoc mesenteroides*; Lp, *Lactobacillus plantarum*; Ls, *Lactobacillus saké*; Lbg, *Lactobacillus bulgaricus*; Lec, *Leuconostoc citrovorum*; Led, *Leuconostoc dextranicum*; Lecr, *Leuconostoc cremoris*; Pfs, *Propionibacterium freudenreichii* spp. *shermanii*; S, *Streptococcus* spp.; Sc, *Saccharomyces cerevisiae*; St, *Streptococcus thermophilus*; T, *Trichosporon* spp.; Wc, *Weissella confusa*; Y, yeast.

cereals, such as in the Korean product *sik-hae* in which millet provides the carbohydrates.

Pozol and *kenkey* are both made from whole-grain maize, which is processed by soaking in water, grinding, and cooking. The natural fermentation is uncontrolled, and the microbiota consists of mainly LAB, yeasts, and some minority organisms. LAB and yeasts can form rather stable communities, each group relying on metabolic outcomes of the other. In that sense, this kind of microbiota is similar to the 'sourdough fermentation communities' in which protocooperative growth of yeasts and LAB has been documented. When the fermentation is considered as completed – this depends on producers and on consumer demand – *pozol* balls are sold in the market, to be diluted with water or milk to make a beverage. *Kenkey* is wrapped in plant leaves and steam cooked, resulting in a compact sliceable mass, which is eaten with breakfast.

Sauerkraut and *kimchi* are occidental and oriental counterparts in the sense that both are made from cabbage and salt, and fermented predominantly by successive LAB without the use of added microbial starter. In *sauerkraut* making, the cabbage leaves are shredded, that is, cut to thin strips of approximately 1.5 mm width, which causes extensive damage to the plant cells. The addition of salt causes an osmotic gradient, which causes the expulsion of plant juice. Soon the cabbage is covered by its own juice, which helps to create anaerobic conditions, containing fermentable sugars and some allyl thiocyanates that all have a favorable effect on LAB. In *kimchi*, the cabbage is first wilted in salty water and then stuffed with a pasty mixture containing garlic, onion, chilli fermented fish, etc. The cabbage is left intact, and the stuffed cabbages are arranged in a fermentation vessel, which is hermetically closed. *Kimchi* is typically consumed in the raw (uncooked) state, in contrast to *sauerkraut*, which may be consumed raw or cooked.

Lassi and *yogurt* are also fermented dairy counterparts from India and Europe. *Lassi* is made by mesophilic LAB in milk from cows or buffaloes to which some salt may have been added. *Yogurt* is more solid and is obtained by cooking cow's milk and inoculating with thermophilic LAB.

Alcoholic Fermentation

Alcoholic fermentation refers to the production of ethanol. In foods, ethanol can be produced by several groups of microorganisms, including filamentous fungi, yeasts, and heterofermentative LAB.

Of these, yeasts are the major type of microorganisms that are used to produce alcoholic beverages and other alcohol-containing products, such as bread dough. In principle, two types of yeasts, that is, the oxidative and the fermenting yeasts, can be distinguished. Although the former group depends on aerobic metabolism to generate energy and thus does not produce ethanol, the latter group can derive energy under anaerobic conditions (the true fermentation) by reducing pyruvate that was formed from monosaccharides through the Embden–Meyerhof glycolysis pathway. Among these yeasts, the species *Saccharomyces cerevisiae* is the most important from an economic point of view. It is used in the fermentation of beers, wines, and other alcoholic beverages. Some major alcoholic fermented products are summarized in **Table 2**. *Saccharomyces cerevisiae* also plays an important role in the maturation (fermentation) of leavened bread dough. In dough, the main function of yeast is to produce CO_2 gas to extend the dough volume. As a favorable spin-off, yeast enzymes contribute to the bread dough texture by increasing its extensibility. In addition, the ethanol formed can react with acids to form esters, which contribute to the flavor of bread crumb.

As can be seen in **Table 2**, different principles of processing are in use to obtain alcoholic beverages. The simplest way is to harvest ripe fruit or palm sap, both of which contain high concentrations (10–30%) of mono- and disaccharides (glucose, fructose, and sucrose) that can be fermented directly by yeasts. The fruits are pressed, and the fresh juice is left to ferment naturally, that is, no yeast is added. The wide range of wines that are known worldwide are all made according to this simple principle. When all sugars have been assimilated, the fermentation will stop. Usually, grape wines will contain 10–14% v/v of ethanol.

Making of beer is more complicated. Because the main ingredient for beer is a cereal grain (barley, wheat, sorghum,

Table 2 Alcoholic fermentations

maize, or millet), the availability of freely available fermentable sugars is low. These will first have to be released by the degradation of starch, the bulk polysaccharide in cereal endosperm. It is interesting to note that worldwide, two fundamentally different strategies have evolved to achieve this aim.

The first strategy is to use starch-degrading enzymes, which are formed during the germination of cereal seeds. Germinated, and then dried, seed is called malt; it contains α-amylase (starch-liquefying enzyme), β-amylase (enzyme releasing maltose from starch and its dextrins), proteases, phosphatases, and other enzymes that are essential for the release of nutrients for the young growing seedling. The word 'brewing' refers to the transformation of starch into fermentable sugars, in this case mainly maltose. After brewing, the resulting sugar solution ('wort') is boiled with hops (providing desired bitter flavor) and inoculated with selected strains of brewer's yeast, usually *S. cerevisiae*. Two fermentation stages include the primary fermentation and the maturation, after which beer is bottled and pasteurized.

The second strategy to degrade cereal starch has evolved in Asia. Instead of using malt enzymes, fungal enzymes are used. In this principle, cereal grains are first soaked and steam cooked, either as whole kernels or as flour, to hydrate and gelatinize the starch. After cooling down, the cooked starch is inoculated with amylolytic starters consisting of mixed populations of starch-degrading molds and yeasts. During the first aerobic incubation stage, the growth of mycelial fungi is favored. These are producers of amyloglucosidase, an enzyme that splits single glucose molecules from starch and dextrin molecules. As a result, a strong accumulation of glucose (approximately 25% w/v) can result. As soon as fermentable sugars are available, the yeasts will start to assimilate them and grow. At the time when the starchy mass starts to exude liquid, the fermentation conditions are changed to favor anaerobic conditions in order to enhance the alcoholic yeast fermentation.

The fermented products resulting from both strategies can be distilled to obtain a variety of strong liquors, which can be matured subsequently. Worldwide, a diversity of strong liquors is known, including whisky and *bai-jiu* (see Table 2).

Alkaline Fermentation

The characteristic feature of alkaline fermentations is the increase of pH during fermentation, to values of approximately 7–8. This is usually caused by a decrease of organic acids in combination with the accumulation of NH_3, which tends to increase the pH. The kinds of products that undergo alkaline fermentation are mainly leguminous seeds with a relatively high protein content, such as soybeans, locust beans, baobab seed kernels, etc. To bring about the above-mentioned changes, the fermentation must be dominated by microorganisms that produce proteolytic and other lytic enzymes, in addition to enzymes acting on peptides and amino acids, such as various peptidases, deaminases, transaminases, etc. Although these kinds of enzymes are found in a range of microorganisms, the major microorganisms that have impact are filamentous fungi and *Bacillus* spp. Among the filamentous fungi, *Aspergillus* spp., for example, *Aspergillus oryzae*, as well as Phycomycetes such as *Rhizopus*, *Mucor*, and *Actinomucor* spp. are associated with alkaline fermentations. However, by far, the most important are the *Bacillus* spp. such as *Bacillus subtilis*, *Bacillus licheniformis*, *Bacillus pumilus*, etc. Some examples of alkaline-fermented foods are summarized in Table 3.

The main use of alkaline-fermented foods is as a flavoring agent. It is remarkable how very similar processing approaches have evolved as traditional fermentations in the Orient and in Africa. The common features are the use of plant seeds with a relatively high protein content (40–45% dm), a prolonged boiling of dehulled seeds in water, and a fermentation of 2–3 days at warm (30–35° C) temperatures. Prolonged cooking will not only kill all vegetative microbial cells, but also activate the heat-resistant *Bacillus* endospores to germinate. As a result, *Bacillus* spp. will germinate and already start growing during the cooling down phase; their high numbers and the metabolites formed restrict the growth of postprocessing contaminating microorganisms.

Fungal Fermentation

Fungi, especially filamentous fungi (molds), were mentioned already in the previous section. Although thousands of mold species are known, only a small number of species have a long history of safe use in (traditional) food fermentations. The most important are summarized in Table 4 along with examples of the foods and other products in which they are a functional part of the fermentation. There are some specific reasons for the use of molds, such as (1) they provide texture by forming a dense and edible mycelium, (2) they produce desirable color and flavor compounds, and (3) they are strong producers of enzymes that cause desirable modifications of the food ingredients. The latter aspect can have profound impact on the nutritional and health beneficial food properties.

Tou-shi is a fermented paste of black soybeans; the fermentation is dominated by *Aspergillus* and *Mucor* spp., which cause the partial degradation of soy protein. It is a type of product that could also be listed under alkaline-fermented foods, but the latter are dominated by *Bacillus* spp. The result is a typical zesty flavor, which makes *tou-shi* an appreciated ingredient in various Chinese dishes.

Angkak or *red kojic rice* is made by fermenting steamed whole-rice kernels with *Monascus* molds. These produce secondary metabolites, including pigments, which are used as bio-colorants in food, for example, *tou-fu-ru* and beverages. Recently, *angkak* has attracted much attention because it also contains antibiotic-like compounds, such as monacolin K, which have been associated with health benefits.

Oncom is a by-product of small-scale pressing of peanut oil. After pressing, the residue or press cake can be valorized by fungal fermentation, to provide texture and flavor to a meat replacer in Indonesia. Two different types of *oncom* are known. Red *oncom* is fermented with *Neurospora intermedia* and black *oncom* with *Rhizopus* spp.

Tapé ketan, known in Indonesian and Malaysian cuisine, is a delicious fermented snack made from glutinous rice. After steaming the rice, it is inoculated with ragi tape, an amylolytic starter (see section Alcoholic Fermentation), and incubated overnight. This will result in a partial liquefaction of the rice making it juicy, accumulation of glucose, and the production of traces of alcohol and lactic acid, all of which combine to give a sweet and sour taste with a tickle on the tongue.

Kochujang has some similarity with *tou-shi*. After fermentation, it is pounded into a paste. This is used as a side dish as well as an ingredient for *kimchi* (see Table 1).

Enzymatic Brine or Salty Fermentations

Brine is a solution of salt in water. The salt is usually NaCl, but other trace ions may be present, such as K^+, Mg^{2+}, SO_4^{2-}, CO_3^-, etc. The salinity or salt concentration depends on the product and processor's preferences. Probably, the historic reason for applying salt is its preservative effect. As it turned out, certain microbial species can grow (albeit slowly) and thus find a niche in brines. Such halophilic and halotolerant species may contribute to the flavor of salt-preserved foods. Another effect of salts is that they increase the ionic strength and improve the dissolution of, for example, enzymes. The latter effect plays a crucial role in many of the popular Asian fungal-fermented foods, such as soy sauce and fish sauces. Table 5 provides a summary of major brine fermentations.

Soy sauce is made in a two-stage process, starting with 3–5 days of fungal solid-state '*koji*' fermentation to favor the formation of fungal lytic enzymes. The molded mass is fermented in brine to be degraded to water-soluble components (amino acids, peptides, etc); during this '*moromi*' stage that may take several months; halophilic LAB and halotolerant yeasts grow slowly and contribute to flavor formation.

Tou-fu-ru is a flavorsome spreadable paste, which is a popular addition to the Chinese rice breakfast. It is made from soybeans by first producing soy milk, which is coagulated into *tofu*. *Tofu* is inoculated with a pure culture of *Actinomucor elegans*, which will cover pieces of *tofu* with its mycelium. The molded pieces ('*pehtze*') are matured in a vessel with brine containing salt, rice wine, and natural flavorings and pigments. Maturation may take 6 months and results in the accumulation of glutamic acid (taste enhancer) and the softening of the texture.

Salami and many other types of raw fermented sausages evolved from the need to preserve meat for the army. This was

Table 4 Fungal-fermented foods

Name of food	*Origin*	*Main ingredients*	*Predominant microbiota*	*Typical pH values*	*Remarks*

Soy sauce	East Asia	Soybeans and wheat	M (Ao and As), Y (Zr and H), and LAB (Th)	5–6	Condiment
Tou-fu-ru	China	Soybeans	M (Ae and M)	6–8	Soy paste
Salami sausage	Europe	Lean meat and fat (lard)	LAB (Lc, Lp, and Ls) and B (Sca and Sx)	5–6	Protein food
Cucumber pickles	Europe	Cucumbers and salt brine	LAB (Lp) and Y (Sc and Sr)	4	Side dish
Olives	Europe	Olives and salt brine	LAB (P, L, Lp, and Ld)	4–8	Side dish

Abbreviations: Ae, *Actinomucor elegans*; Ao, *Aspergillus oryzae*;; As, *Aspergillus sojae*; B, bacteria; H, *Hansenula* spp.; L, *Leuconostoc* spp.; Lc, *Lactobacillus curvatus*; Ld, *Lactobacillus delbrückii*; Lp, *Lactobacillus plantarum*; Ls, *Lactobacillus saké*; M, mold; P, *Pediococcus* spp.; Sca, *Staphylococcus carnosus*; Sr, *Saccharomyces rosei*; Sx, *Staphylococcus xylosus*; Th, *Tetragenococcus halophila*; Y, yeast; Zr, *Zygosaccharomyces rouxii*.

achieved by a combination of salting and drying. A good way to prepare a homogenous product that can be dried efficiently is to mince red muscle meat and lard (fat) with herbs, spices, starter microorganisms, and some salt, and stuffing the resulting 'dough' into pork intestines (natural casing). At present, China is the largest producer of natural casings. Nowadays, many meat processors use artificial casings made of edible fiber; these are more evenly shaped. The stuffed fresh sausages are first incubated in a warm brine bath or temperature-controlled ripening chamber to allow a rapid acidification (pH <5.5 within 12 h) by LAB, which is followed by a gradual drying process to achieve the required moisture content.

Cucumber pickles and fermented olives are preserved in brine for several months, during which an exchange of salt, sugars, and moisture will take place. At intervals, the brine concentration is adjusted. The combination of temperature, salt, fruit sugars, and anaerobic situation favors the dominance of LAB and some yeasts.

Antimicrobial Principles Formed During Fermentation, Contributing to Food Safety

In fermented foods, the presence of high numbers of microorganisms has a profound impact on the food environment, that is, the chemical and physical conditions that may influence the opportunities for survival and growth of minority microorganisms. The latter could include contaminants that could cause food spoilage, or that could be of pathogenic character.

Figure 1 explains the impact of fermentation on the food environment. It shows that, in principle, fermentations are dynamic and that environmental conditions keep changing. Table 6 summarizes the major microbial metabolites that restrict the growth of pathogenic contaminants. In addition to the accumulation of metabolites, a depletion of available substrates (sugars and amino acids) occurs, which causes intercellular competition. This results in a gradual termination of the fermentation and a competition with spoilage-causing microorganisms.

In acidified foods, the impact of the undissociated organic acids has been well documented. Other articles in this book deal with organic acids, bacteriocins, and reuterin, and the reader is referred to them.

The inhibitory effect of alcohols, ethanol in particular, is due to an increased permeability of the plasmalemma

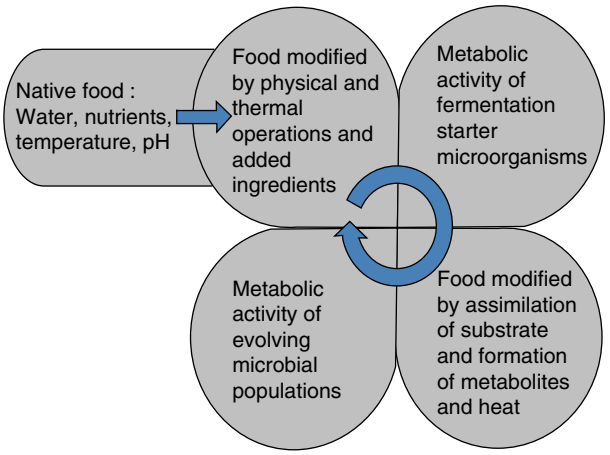

Figure 1 The impact of fermentation on the food environment.

resulting in the decrease of pH gradient and of membrane potential. Although C_2H_5OH is the most abundant alcohol, the C_6 alcohols have the highest impact on the plasmalemma.

Carbon dioxide is formed as a result of alcoholic and heterofermentative lactic acid fermentations, and decarboxylation reactions. In aqueous conditions, it is in equilibrium with HCO_3^-, which has an antimicrobial effect at pH ≤ 6 as its undissociated acid. However, at those pH ranges, the solubility of CO_2 is low, and in fermented foods, this substance has little antimicrobial impact. However, in closed packages, CO_2 in gas form has a significant antimicrobial effect when present at $>10\%$ of the gas atmosphere.

Although diacetyl has a broad antimicrobial activity, it is of little preservative importance because of its flavor, which has a low threshold value, thus making applications at higher concentrations unacceptable to the consumer.

Hydrogen peroxide is produced by microorganisms, but it is also broken down by catalase. Because of its unstable presence, there is little evidence that it has antimicrobial impact in fermented foods.

Ammonia when formed at significant levels in alkaline-fermented foods may also have an antimicrobial impact because it increases the pH to suboptimal levels. However, little evidence about the effect of ammonia has been published.

One other important effect of fermentation is the assimilation, by the functional starter microbiota, of substrates (see Figure 1), which thereby causes a competition with contaminant microorganisms. A well-documented example is

Table 6 Antimicrobial fermentation metabolites

Name	*Sensitive microbiota*	*MIC or pH levels*	*Remarks*
Lactic acid	All microorganisms	pH dependent; pK_a 5.2	Causes acidic taste
Acetic acid	All microorganisms	pH dependent; pK_a 4.75	Causes acidic taste
Ethanol	All microorganisms	At concentrations approximately $\geq$10%	Only in suitable products
CO_2	Most microorganisms	Aqueous at pH $\geq$6 Gas: at 20–50%	Can cause textural defects (bloating)
Diacetyl	Yeasts, Gram-negative bacteria Non-LAB, Gram-positive bacteria	At 200 ppm At 300 ppm	Butter flavor threshold: 2–4 ppm
Hydrogen peroxide	All microorganisms	500 ppm	Restricted use
Reuterin	Many bacteria and fungi		FDA approved
Bacteriocins, i.e., nisin	Gram-positive bacteria	50–100 ppm	Generally recognized as safe

Abbreviation: FDA, Food and Drug Administration.

Table 7 Hazardous compounds potentially encountered in fermented foods and beverages

Compounds	*Structure*	*Accepted level*	*Toxic effect*
Biogenic amines			
Histamine		100 ppm	Skin flushing, headache, abdominal cramps, and nausea
Tyramine		100–800 ppm	Tyramine pressor response (increased systolic blood pressure)
Ethyl carbamides			
Ethyl carbamate		Wines $<$15 ppb Strong liquor $<$125 ppb	Not acutely toxic, but potentially mildly carcinogenic
Alcohols			
Methyl alcohol			Highly toxic; depression, headache, and dizziness; and at 10 ml permanent blindness
Ethyl alcohol		40% strong liquor 10–15% wines to be consumed with moderation	At $>$0.1% blood alcohol content: nausea, vomiting, and intoxication; chronic: liver damage
Higher alcohols (propanol, butanol, pentanol, etc.)		Level of toxicity similar to ethyl alcohol	Headache, nausea, and hangover effect

the role of fermentative yeasts in cucumber pickle fermentation. The yeasts 'scavenge' all remaining fermentable sugars and thereby prevent growth of spoilage microorganisms.

Potential Hazardous Effects Related to Substandard Processing

Although food fermentation has a positive image because of its association with attractive sensory aspects, like all processes it also has its limitations. In this section, some of these will be shortly discussed.

Biogenic Amines

Biogenic amines (Table 7) are formed from amino acids by decarboxylation, or by amination and transamination of aldehydes and ketones. Because of the structure of their precursor amino acids, they can have either aliphatic, aromatic, or heterocyclic chemical structures. Although some play a role in

the physiology of the living cell, the formation of biogenic amines during fermentation is of most concern here. Some biogenic amines, such as histamine and tyramine, are mildly toxic. A total level of approximately 1000 ppm is associated with toxicity, and in good manufacturing practice, 100 ppm histamine, or a total of biogenic amines of 200 ppm are regarded as acceptable, no-effect levels. Prerequisites for the formation of biogenic amines include the presence of free amino acids (such as in meat, fish, cheese, and also in wine, beer, and cabbages), the ability to decarboxylate them, that is, decarboxylases (Enterobacteriaceae, Enterococci, and some heterofermentative LAB are the most relevant), and suitable conditions for the growth and metabolic activities of these bacteria (low pH and high NaCl concentrations are associated with higher levels of biogenic amines). Preventive measures include the pasteurization of cheese milk and good hygienic practice, including the use of starters selected for low decarboxylase activity.

Ethyl Carbamate

Ethyl carbamate (EC; Table 7) is formed from ethanol with urea or carbamic acid. It is found in several fermented foods, especially those in which yeasts and LAB have been active and some ethanol was formed. Urea and carbamic acid can be formed from the deamination of arginine, a pathway found in, for example, LAB. This pathway serves to generate energy and can be instrumental in the homeostasis of intracellular pH levels. The reaction leading to the formation of EC is favored by increased temperatures, and this is reflected in the higher EC levels in products such as distilled liquors (saké and whisky) and roasted products (toasted bread). Although in some countries maximum tolerated levels of EC are enforced, its toxicity is quite low compared with the health risks of the corresponding consumption of strong alcoholic liquors.

Alcohols

Methyl alcohol is highly toxic. It is formed by the enzymatic degradation of pectic polysaccharides, mainly originating from stone fruits, such as cherries, apples, plums, and pears. In pectins, the polygalacturonate backbone is methylated, and during processing, the endogenous enzymes, such as pectin methyl esterase, will release methanol from pectins. In regular fruit wines, the levels of methanol are too low to be of any concern. However, for a number of popular liquors distilled from these fermented fruits, such as kirsch, apple jack, slivovitch, and Williams, it may have safety consequences.

Although enjoyed by many, ethyl alcohol, formed by alcoholic fermentation through reduction of pyruvate, is also toxic. Excessive use leads to intoxications and if chronic, to liver cirrhosis.

Higher alcohols, such as propanols, butanols, pentanols, and their branched structures, are formed by the deamination and reduction of amino acids in yeast cells. Fermented products containing appreciable levels of free amino acids include beers from barley, maize, and other cereals in which proteins have been degraded. If such brews are used as an ingredient for distilling of, for example, whisky, their concentration may increase as a result of the distillation process. Although modest levels of higher alcohols contribute to the flavor of whiskies, in other distilled products, such as vodka, they are associated with unwanted off-flavors. In principle, the toxicity of higher alcohols is similar to that of ethyl alcohol, whereas in some reports they have been associated with the 'hangover effect.'

Hazards of Microbiological Nature and Control Measures

Inadequate processing, such as lack of pasteurization of vulnerable ingredients, poor hygienic practices, and use of low-grade ingredients, may result in fermented products that are contaminated with microbial toxins, or in which pathogenic microorganisms survive and may be the cause of foodborne infections.

Because the respective compounds and microorganisms are discussed in detail in other articles, a short summary of hazards and measures to control them will be presented here.

Raw milk, fish, and meat are known carriers of pathogenic bacteria, parasites, and viruses. Although some traditional fermented products are claimed to be of better quality when prepared from raw ingredients, experience has shown that it is wise to preheat (pasteurize) such ingredients before or after fermentation.

Poor hygiene may lead to postprocessing contamination, mostly with pathogenic and/or spoilage-causing bacteria. Although some fermented products have inherent antimicrobial properties (especially the low-pH products), many other products offer good chances for survival. In traditional fermented raw milk, the levels of Enterobacteriaceae are reduced only if pH values lower than 4.5 are obtained. Even despite this acid-sensitivity of most Enterobacteriaceae, it must be noted that some strains of *Escherichia coli*, for example, *E. coli* O157, as well as viruses are not adequately affected by acidity. Well known are the outbreaks caused by *E. coli* contaminated Brie cheese, among others. Also, several fatal cases of infections with *Listeria monocytogenes* and *E. coli* have been associated with the consumption of similar raw-milk white-mold ripened cheeses, such as Vacherin Mont d'Or. Pasteurization of cheese milk and strict hygiene are therefore control measures to minimize these hazards.

In addition to raw milk, other uncooked ingredients may cause safety problems. For instance, the custom of fermenting raw pork meat in South East Asia (e.g., Thailand and Vietnam) has caused infections with parasites, such as *Trichinella*. Such parasites are not or hardly killed by acid or salt: The only adequate way to eradicate them is heating. Therefore, the fermented meat must be cooked well before consumption. In a similar way, the consumption of raw (uncooked) fishery products may lead to foodborne infections with *Vibrio parahaemolyticus*, a typical seafood-associated pathogen.

Another hazard associated with raw (uncooked) water, shellfish, vegetables, etc. are viruses, such as norovirus and rotavirus. Cooking food before consumption is the only safe method to inactivate them.

Table 8 Major food safety hazards in fermented foods and beverages, with control measures

Hazards	*Control measures*
Chemical hazards	
Biogenic amines	Control lysine decarboxylase activity by, for example, blanching and avoidance of Enterobacteriaceae by GMP and hygiene
Ethyl carbamate	No measures
Methyl alcohol	Optimize separation of distilling units to avoid methyl alcohol collection from fermented stone fruits
Higher (fusel) alcohols	Optimize temperatures and free amino acid content in alcoholic fermentation to reduce formation, and in distilling optimize separation capacity of column
Microbiological hazards	
Botulin	Prevent outgrowth of *C. botulinum* spores
Staphylococcal enterotoxins	Prevent growth of *S. aureus*
Mycotoxins	Prevent growth of mycotoxigenic fungi and remove molded ingredients
Enterobacteriaceae (*E. coli*, *Salmonella*, *Shigella*, etc.)	Pasteurization; pH <4.4; a_w <0.95
L. monocytogenes	Pasteurization; pH <4.4; a_w <0.92
V. parahaemolyticus	Pasteurization; pH <4.8; a_w <0.94
S. aureus	Pasteurization; pH <4.0; a_w <0.83
C. botulinum	Botulinum 12D cook; pH <4.5 and/or apply sodium nitrite to avoid germination of surviving spores
Viruses	Cooking
Parasites	Freezing (not always adequate) and cooking

Abbreviations: a_w, water activity; GMP, good manufacturing practice.

In addition to the heat treatment of raw (uncooked) ingredients, some other process factors can contribute to the safety of fermented foods, such as:

- rapid (within 12 h) acidification to pH <4.5 by LAB – sometimes supported by acidulants, such as glucono-δ-lactone – supports their competition with other microbiota. In particular, the growth or survival of most Enterobacteriaceae is minimized. *Staphylococcus aureus* may still grow, although due to competition pressure from starter microbiota, it does not produce its enterotoxins;
- salt (NaCl) and nitrite used in meat curing are essential, not only for taste reasons but also to especially avoid the germination, outgrowth, and botulin formation by *Clostridium botulinum*;
- reducing the water activity (a_w) by dehydration, or by addition of sugar, salt, or other solutes; and
- hermetic sealing to prevent oxygen entry will reduce oxidative quality defects, but especially it will prevent mold growth and associated risks of mycotoxin formation in products that are cured or stored for prolonged periods of time.

Of special concern is the hazard of mycotoxins, mostly because these occur at low concentrations and lead to chronic mycotoxicoses only after long-term ingestion.

Mycotoxins may occur in fermented foods if the ingredients used were contaminated before processing. Most mycotoxins (in particular aflatoxins and ochratoxins) cannot sufficiently be degraded or detoxified during heating and fermentations to expect safe food from unsafe ingredients. However, patulin (frequently found in apple juice) has been shown to be degraded by lactic fermentation involving *Lactobacillus plantarum*.

With regard to the quality of starters used for fermentation, it has been observed that in some traditional mold-fermented products, such as sausages and country-cured hams, some strains of, for example, *Penicillium roqueforti* and *Penicillium camemberti* used as starters in the process, were actually able to produce mycotoxins when grown in the laboratory as pure cultures. Although these are very different cultivation conditions than in, for example, meat or cheese, it is an indication that much care should be taken with the selection of starter strains. Therefore, food legislation should require the use of selected starter strains selected for their inability to form mycotoxins or other toxic substances.

In Table 8, an overview is provided of the major hazards mentioned and measures to control them. Which measures will be feasible will depend on the type of food and the market preferences.

In conclusion, fermentation has much to offer as a technology that renders foods attractive, digestible, and safe. However, there remain several aspects that require research for further development, and the technology has its limitations. Research is required in order to (1) develop starter microorganisms that are both safe and beneficial for human health, (2) selection of starter microorganisms that can kill or compete with disease-causing microbes, and (3) adaptation of scientific knowledge to application in regions or situations that lack infrastructure in order to harness fermentation as a beneficial technology to public health.

FOOD TECHNOLOGIES

Food Irradiation

J Farkas, Corvinus University of Budapest, Budapest, Hungary
DAE Ehlermann, formerly Federal Research Centre for Nutrition, Karlsruhe, Germany
Cs Mohácsi-Farkas, Corvinus University of Budapest, Budapest, Hungary

Glossary

Dose (absorbed) The dose (absorbed) is the amount of energy absorbed per unit mass of irradiated ;material.
Dosimetry The measurement of radiation quantities, specifically absorbed dose, and absorbed dose rate.
D_{10}-value Amount of radiation required to reduce the population of specific (micro)organisms by 90% (one $\log_{10}$ cycle) under stated conditions.
Electron accelerator A device for imparting high kinetic energy to electrons.
Electron volt (eV) A unit of energy. One electron volt is the kinetic energy acquired by an electron in passing through a potential difference of one volt in a vacuum.
Ionizing radiation Such forms of radiation which have sufficiently high energy to cause ionization (in food processing: sgamma-rays, X-rays, and accelerated electrons). Ionization is the creation of ions by expulsion of orbital electrons from atoms.
Unit of absorbed dose The unit of absorbed dose is the Gray (Gy). (1 Gy is equal to 1 Joule kg^{-1} absorbed energy.)

Background

What is Food Irradiation?

Food irradiation is a process that exposes food to a prescribed amount of ionizing radiation. Three different kinds of ionizing radiation are applicable for food irradiation processes:

- gamma rays from the radionuclides cobalt-60 (^{60}Co) or, less commonly, cesium-137 (^{137}Cs),
- X-rays ('bremsstrahlung') generated from machine sources (electron accelerators with converters) operated at or below an energy level of 5 MeV (US 7.5 MeV), and
- electron beams produced by electron accelerators operated at or below an energy level of 10 MeV.

Even if these ionizing radiations are different, they have the same chemical and biological effects. None of these radiations has sufficient energy to induce radioactivity.

Whether every mass element of a food requires irradiation will depend on the purpose of the treatment. In some cases, irradiation of the surface will suffice. In other cases, the entire food must receive at least the minimum dose.

Because irradiation causes practically no temperature rise in the food processed, it is in effect a nonthermal technology that may even inactivate microorganisms in frozen food without thawing it. An effective radiation dose can be delivered through most standard food-packaging materials, including those that cannot withstand heat. This means that irradiation can be applied to hermetically sealed products without the risk of recontamination or reinfestation of properly packaged foods. Some food products may have to be irradiated under special conditions, for example, at low temperature or in an oxygen-free atmosphere. Others may undergo a combination treatment, using, for example, both radiation and heat.

Processing by irradiation, either alone or in combination with other treatments, offers some advantages over conventional methods of food processing. They are:

- Reduction of the need for some chemical treatments.
- Reducing contamination of foodborne pathogens or spoilage organisms in such a way and efficiency that may be difficult to achieve with other techniques.
- Preservation of food in the fresh state for extended periods in a quality-friendly way.
- Use of less energy for processing and storage when compared with other food-processing methods.
- Treatment without changing the identity of a food.

Main Biological Effects of Ionizing Radiation

One of the main reasons for the use of ionizing radiation is to inactivate living organisms that cause spoilage and other forms of quality deterioration or are a hazard to the health of the consumer. The application potential of ionizing radiation for food products is based mainly on the fact that ionizing radiation damages DNA and very effectively inhibits DNA synthesis and further cell division. Damage to the genetic material can also occur indirectly because the interaction of radiation with water molecules results in the production of reactive molecules such as hydroxyl radicals, hydrogen peroxide, and hydrogen atoms, which induce on the adjacent

 doi:10.1016/B978-0-12-378612-8.00259-6

genetic material similar effects to those resulting directly by radiation. Therefore, not only microorganisms but also insect gametes and plant meristems can be prevented from reproducing, thus securing safety and quality attributes (e.g., stability) of foods. The amount of radiation energy used to bring about the control of these organisms varies according to the radiation resistance of the particular organism, which is often specific to the species level, and to the numbers or load of organisms present.

Applications of Food Irradiation

Typical Dose Requirements

The actual dose of radiation employed in any food-processing application represents a balance between the amount of radiation needed to produce a desired result and the amount of radiation the food can tolerate without suffering unwanted changes of sensorial or technological properties. Therefore, detailed requirements must be considered as specific for a given food. The main purposes of food irradiation and examples of recommended dose ranges are given in Table 1.

To facilitate regulation of food irradiation, it has been proposed to implement advisory technological dose limits.

After the concept of 'overall average dose' has been abolished, it would be prudent to provide a frame work for regulatory dose setting, collecting from practical experiences the minimum dose values (Figure 1) needed to achieve an effective treatment and the maximum dose values below which any deterioration of the food quality can be avoided. The regulatory authorities accepting such a table could be sure that any radiation processing of food within those advisory dose limits would be safe and wholesome for the consumer. Also in international trade, the adoption of such table could facilitate export and import of irradiated products.

Inhibition of Sprouting

Radiation treatment at low doses inhibits the sprouting of potatoes and yam tubers, onions, garlic, and ginger, because cell division, elongation of growing points, and thereby bud growth are inhibited. The dose required to inhibit sprouting of potatoes and yams is 0.08–0.14 kGy; for ginger is 0.04–0.10 kGy; and for onions, shallots, and garlic, 0.03–0.12 kGy. The appropriate dose within these ranges depends on the variety and other properties of the product.

For potatoes, mechanical damage occurred during harvest and other handlings may lead to increased rotting of potatoes, due to microbial invasion of the tissue at points of injury. Thus, careful sorting and a 2–3 weeks time delay after harvesting before application of radiation treatment is required to allow for healing of such mechanical damage. However, with some varieties, cooking darkens irradiated potatoes more as opposed to nonirradiated ones; these unwanted effects can again be largely prevented by careful handling of the product before and after radiation treatment, including careful sorting, curing, and proper storage temperature. It has also been shown that in some situations increased after-cooking darkening may be related to the use of certain fertilizers on the field and agricultural practices need to be adapted to avoid such effect.

Irradiation of onions is most effective as a sprout inhibitor when the treatment is carried out in the dormancy period, preferably within 1 month of harvest and no later than 2 months postharvest. When inner buds of bulbs have already started to grow before radiation treatment, their browning may still occur due to radiation damage.

Delay of Ripening and Aging of Fruits and Vegetables

Exposure to a low dose of radiation delays the ripening or senescence of some fruits and vegetables, thereby extending their shelf life. Such positive effects were discovered in the course of studies on the role of radiation in controlling microorganisms. A delay in postharvest ripening can occur only in climacteric fruit. Senescence, or physiological breakdown, may be delayed by irradiation in both climacteric and nonclimacteric fruit during postharvest storage. The magnitude and even the direction of such changes depend on the radiation dose and the state of ripeness at the time of treatment. A measurable extension of shelf life may be obtained with doses of 0.3–1.0 kGy. This level of exposure will increase the shelf life of mangoes by

Table 1 Main purposes of food irradiation and examples of recommended dose ranges

Purpose and effects	*Dose range (kGy)*
Inhibition of sprouting stored tubers, roots, and bulbs	0.05–0.15
Prevention of postharvest losses by destruction of insects in stored cereals, fresh and dried fruits, nuts, oilseeds, and pulses, or phytosanitary (quarantine) treatment for insect pests infesting fresh fruits and vegetables	0.15–1
Delay of afterripening and senescence of certain fruits and vegetables	0.2–1
Shelf-life extension of fruits and vegetables, meat, poultry, fish, and ready meals by reduction of microorganisms that cause spoilage	0.5–3
Inactivation/destruction of various foodborne parasites	0.3–6
Prevention of foodborne illness by destruction of nonsporeforming pathogenic bacteria (e.g., *Salmonella*, *Campylobacter*, *Listeria*) in fresh or frozen foods	3–7
Reduction in viable counts of microorganisms in spices and other dry ingredients to minimize contamination of food to which the ingredients are added	5–10
Production of microbiologically shelf-stable vacuum-packaged meat, poultry, and ready-to-eat meals by heat-inactivating of their tissue enzymes and destruction of microorganisms, including bacterial spores, by irradiation in deep-frozen state.	up to 50

approximately 1 week and that of bananas by up to 2 weeks. Maturation of mushrooms and asparagus after harvesting can be retarded with doses in the range of 1.0–1.5 kGy. Irradiation of (field) mushroom had been the first commercial application in the Netherlands; later on this treatment was no longer used, as irradiation essentially retarded the cap-opening but did not significantly preserve the overall quality. Likewise, irradiation of asparagus did not become commercial as the consumers preferred to buy it immediately after harvest.

Insect Disinfestation and Phytosanitary/Quarantine Treatment

Radiation at relatively low doses (up to 0.5 kGy) inactivates or sterilizes all of the developmental stages of common insect pests of grain, including insect eggs deposited inside grains. The effective radiation dose must be determined for a specific insect species, food product, and set of conditions.

Fresh and dried fruits, vegetables, and nuts are also liable to insect attack, and some of these products, especially dried fruits, cannot be effectively disinfested by either chemical treatments or physical means other than irradiation. Application of 0.2–0.7 kGy to products that have been suitably packaged to prevent reinfestation eliminates the insect problem in dried fruits and vegetables and in nuts. Cocoa beans, which are traded in bulk quantities, can also be disinfested without impairing the technological or sensory quality. The same technique could drastically reduce losses of dried fish, an important source of protein in many developing countries.

Radiation disinfestation can contribute significantly to improving trade in certain tropical and subtropical fruits, such as citrus fruit, mangoes, and papayas. Irradiation could be used in place of chemical fumigation, and it affords a residue-free means of preventing the introduction of harmful insects. As such, radiation treatment may offer a viable alternative to fumigation to satisfy the quarantine regulations in a number of countries. Fruit flies, for example, and even the weevil that lodges deep inside the seed of mango can be controlled by irradiation. (Note: the mango weevil cannot be reached by chemical or heat treatment, there is no alternative to irradiation.) Irradiation is different from all other quarantine treatments that have been used commercially in one key aspect: irradiation does not provide significant acute mortality (within 48 h) at doses tolerated by fresh agricultural commodities. However, irradiation is the fastest quarantine treatment available. The measure of efficacy of irradiation quarantine treatments for fruit flies is prevention of emergence of adult flies.

Controlling Foodborne Parasites

Irradiation inactivates foodborne parasitic organisms that are responsible for both human and animal diseases. Such precautionary treatment would, in particular, be beneficial where such food is traditionally eaten raw. The parasitic roundworm, *Trichinella spiralis*, which causes trichinosis and may be found in pork, is inactivated by radiation at minimum dose of 0.15 kGy. Other parasites, including tapeworms in pork and beef, as well as the protozoon responsible for toxoplasmosis and various

flukes that infest fish are rendered noninfective by low-dose radiation treatment. The doses used to treat food to reduce microbial load is sufficiently high to control many types of parasite as well. However, the larvae of *Anisakis* spp. are exceptionally resistant to irradiation. For example, *Anisakis simplex* larvae require doses as much as 6–10 kGy for inactivation.

Control of Foodborne Microorganisms

Important uses of food irradiation are for inactivating microorganisms that cause spoilage or other aspects of quality deterioration of the food and to destroy foodborne nonsporeforming pathogenic bacteria, such as *Salmonella* spp., *Campylobacter* spp., *Listeria* spp., *Escherichia coli* O157:H7, and *Yersinia* spp.

The amount of radiation needed to inactivate these microorganisms depends on the radiation tolerance or resistance of the target microorganism, and their number in the particular volume or mass of food to be treated. Relatively low or medium doses are needed in this application as the target is to reduce the microbial load below the infective level. The effect of ionizing radiation on microorganisms is also affected by the environmental conditions under which they are irradiated. Such factors include among others: temperature, water activity, pH, chemical composition of food, and gaseous environment.

Irradiation, for instance, is beneficial in reducing the microbial contamination of food characterized by a low water activity such as dry food ingredients. For such ingredients radiation treatment may improve the safety and storage properties of foods prepared with them. Spices, dry vegetable seasonings, herbs, protein concentrates, and commercial enzyme preparations used in the food industry are very often heavily contaminated with spoilage and pathogenic microorganisms, and can be decontaminated with radiation doses of 3–10 kGy without adverse effect on their flavor, texture, or other properties. Dried commodities are more resistant than fresh foods to the organoleptic effects of ionizing radiation because their low water content suppresses most of the indirect effects of irradiation. Therefore, from the omnifold possibilities of food irradiation, radiation decontamination of dried food ingredients, particularly spices, herbs, and vegetable seasonings, has the most immediate application potential, and it has been commercially implemented in numerous countries. Notably, microorganisms that survive this treatment become more susceptible to subsequent processing.

Food irradiation may successfully be used for control of foodborne diseases by radiation decontamination of specific foods. Radicidation is the term for the reduction in the number of specific viable nonsporeforming pathogenic microorganisms (other than viruses), thereby improving the hygienic quality and reducing the microbiological risk of foods. Thus, radiation could play an equally important role in the processing of critically important solid foods as does heat treatment (pasteurization) in the processing of fluid milk and fruit juices.

Extensive experience has demonstrated that radiation treatment under normal industrial conditions, at a dose that does not produce unacceptable changes in the food product, will destroy pathogenic nonsporing bacteria in red meat, poultry, and fish. A dose of 2–7 kGy is sufficient to control such foodborne pathogens, for example, in frozen meats, poultry, egg pulp, shrimp, and frog legs.

Irradiation as a Critical Control Point in Risk Management

On the basis of the facts above, food irradiation could and should play a role as an effective critical control point in the framework of application of the hazard analysis critical control point (HACCP) risk management system. This HAACP-based approach of food safety is of particular importance in the production of foods which are to be marketed raw or minimally processed, such as poultry, meat, meat products, fish, seafood, and fruits and vegetables. In these products, pathogens must be eliminated or reduced to acceptable (i.e., below the infective) levels, at the primary processing and, therefore, not be allowed to reach the home or institutional kitchen. When integrated into an overall food safety management program that includes good agricultural, manufacturing, and hygienic practices and HACCP, depending on the dose applied, food irradiation can contribute to improved consumer safety.

Extension of Shelf Life of Foods by Reduction of Populations of Spoilage Microorganisms

Radurization is the term for substantial reduction in the number of spoilage microorganisms, thereby extending the shelf life of a food. Most food-spoilage microorganisms are killed at doses of less than 5 kGy. Thus, the shelf life of many fruits and vegetables, meat, poultry, and fish and other fishery products can be considerably prolonged – certainly doubled – by treatment with relatively low doses of radiation that do not alter flavor or texture combined with storage under refrigeration conditions.

With higher doses, approaching 5 kGy, the normal spoilage organisms are often eliminated, whereas some more resistant but metabolically less active species, for example, *Moraxella* spp., lactic acid bacteria, and yeasts, may remain. During chilled storage, this surviving microbiota grows less rapidly than the normal spoilage biota. As with unirradiated foods, the nature and behavior of the spoilage biota is strongly influenced by the nature of the packaging. In anaerobic packages, lactic acid bacteria and yeasts may predominate.

Radiation Resistance Parameters

Table 2 shows ranges of decimal reduction doses (D_{10} values) of the most important nonsporeforming pathogenic bacteria determined in various atmospheres and solid foods. The data have been summarized from a large amount of publications.

Bacterial spores are more resistant to irradiation than vegetative bacteria. *Clostridium botulinum* type A and B spores are particularly resistant. Owing to their usually nonlinear survival curve, estimating a lethality parameter such as the minimum required dose (MRD) to achieve n log cycles reduction can be more meaningfully calculated. This approach has been used to calculate the dose required to achieve a 10^{12} reduction in certain foods under specific conditions (see the section on Radiation Sterilization of Enzyme-Inactivated High-Moisture Foods).

Table 2 D_{10} values (kGy) of some foodborne nonsporeforming pathogenic bacteria[a]

Bacteria	*Nonfrozen food*	*Frozen food*
Vibrio spp.	0.02–0.14	0.04–0.44
Yersinia enterocolitica	0.04–0.0.21	0.20–0.39
Campylobacter jejuni	0.08–0.20	0.18–0.32
Aeromonas hydrophila	0.11–0.19	0.21–0.34
Shigella spp.	0.22–0.40	0.22–0.41
Escherichia coli (iactncl. O157:H7)	0.24–0.43	0.30–0.98
Staphylococcus aureus	0.26–0.57	0.29–0.45
Salmonella spp.	0.18–0.92	0.37–1.28
Listeria monocytogenes	0.20–1.0	0.52–1.4

[a]Courtesy of Wageningen Academic Publishers, The Netherlands.

Similarly, nonlinear survival curves with an initial shoulder may often be found when plotting $\log_{10}$ numbers of survivors of fungal propagulae against dose. For this reason, the radiation sensitivity of microscopic fungi may also be expressed as the minimum required or effective dose rather than as a D_{10} value. The effective dose is then related to the size of the initial population of these microorganisms.

D_{10} values for viruses generally tend to be high, typically 2–7 kGy. Thus, irradiation doses below 10 kGy often will not give an adequate reduction in their numbers depending on the numbers present in the food to be treated. However, viruses can be well inactivated by heat so the combination of heating with irradiation can possibly be used successfully (see the section on Combination Processes Involving Food Irradiation).

Preformed bacterial and fungal toxins are not affected at the doses normally used in food irradiation.

Combination Processes Involving Food Irradiation

The benefit of treating food with a combination of irradiation and heat, low temperature storage, modified-atmosphere packaging, or conventional preservatives is recognized. Rational combinations of ionizing radiation and other antimicrobial factors may allow the use of lower radiation doses. The overall effectiveness of combination treatments will depend on the target organisms present in the product and the specific sequence of the individual treatments. A combination of mild heat treatment (immersion in hot water), low-dose irradiation, and proper packaging may be successfully applied to those fruits that are sensitive to higher radiation doses. Particularly, irradiation can be involved in apparently synergistic combinations with other preservative factors to further increase antimicrobial treatment efficiency, as such improving microbiological safety and keeping quality of foods.

Radiation treatment offers a great potential for improving microbiological safety of minimally processed foods. 'Minimally processed' is an equivocal term that is applied to such different types of products as precut, prepackaged fresh produce, or fresh meat for short refrigerated shelf life, and mildly cooked or pasteurized foods (meals or meal components) that can be stored under refrigeration for more than a week. Many food processors also take advantage of using modified atmosphere packaging (MAP). It is frequently used, for example, for precooked chilled food for catering and retail sale. Such foods aimed for refrigerated storage may enhance its microbiological safety by using a quality-friendly, nonthermal microbicide treatment such as irradiation. Special versions of cook–chill items are the 'sous-vide' foods. These foods are cooked in vacuum packaging and usually receive only a mild heat treatment, and rely heavily on vacuum packaging and refrigeration for preservation. The combined effect of irradiation and sous-vide cooking was investigated with promising results with respect to improvement of the microbiological safety and keeping quality. Postprocess recontamination, for instance, of heat treated ready-to-eat (RTE) products before packaging, is a serious safety concern, especially for pathogens whose infective doses are low (e.g., *Salmonella* spp., *Shigella* spp., or *E. coli* O157) and where there is a potential for growth. Low-dose irradiation could play a role in elimination of such postprocessing contaminants.

Radiation Sterilization of Enzyme-Inactivated High-Moisture Foods

Radappertization is the term used to describe a specific combination process that involves application of ionizing radiation to prepackaged, enzyme-inactivated, deeply frozen foods at radiation doses sufficient to reduce the number and activity of viable microorganisms to such an extent that in the absence of postprocessing contamination no microbiological spoilage or toxicity of microbial origin occurs, no matter how long and under what conditions the food is stored (radiation sterilization). A mild heat treatment is sufficient for enzyme inactivation. The dose requirement for radappertization is determined by the most radiation-resistant microorganisms that may be associated with the enzyme-inactivated food. For nonacid, low-salt foods this is *Clostridium botulinum* type A spore. By analogy with thermal processing (canning), the microbiological safety of the radappertized foods is based on a 12-D reduction in the viability of botulinal spores. For such foods the required dose is approximately 45–50 kGy. The irradiation of the product is performed in deep-frozen condition to prevent sensory changes and significant vitamin losses when applying the high radiation dose. Radiation sterilization has been successfully applied, for instance, for meals for army personnel and astronauts as well as for meals prepared for hospitalized patients whose immune systems have been suppressed by disease or therapy. The safety, palatability, and nutritional quality of meals for such patients can be improved if radiation sterilization is used instead of thermal sterilization. It seems reasonable that this application may prove useful among other population groups, such as air travelers, and the young and old residents of nursing facilities.

Quality Matters

The Necessity of Good Manufacturing and Hygienic Practices

One should keep in mind that the quality of irradiated foods, as is the case for any other preserved food, is dependent on the quality of the original material. To obtain good results,

therefore, good hygienic practices and good manufacturing practices are essential. The longest shelf life may be obtained if the quality of the raw material is good and proper hygienic conditions are maintained. In certain cases, the use of more thorough inspection and sorting to remove substandard quality materials before treatment (or treatments such as washing or blanching) can be used to reduce the radiation dose required and to produce a high-quality product. The benefits of irradiation should never be considered as a substitute for product quality or as compensation for poor handling and storage conditions.

Dose Limitations, Unwanted Changes of Sensorial or Technological Quality

Depending on the absorbed dose level, irradiation can cause sensory changes (e.g., off-flavors, especially in foods of animal origin, such as dairy products). In fresh fruits and vegetables, radiation may cause softening and increase in the permeability of tissue. These effects may limit the permissible dose because they are often accompanied by accelerated spoilage if the product becomes contaminated by microorganisms after the irradiation treatment. However, because irradiation slows the rate of ripening of fresh fruits and vegetables, properly stored and packaged products remain in a usable condition considerably longer than they would be without radiation processing. The extent of radiation-induced organoleptic changes in foods is dose related and there seems to be a threshold dose below which these changes are not detectable. For this reason, the selection of dosage, and, often, the decision to employ supplementary processing to contribute to the intended result are critical factors. Environmental conditions prevailing during the growing phase may also strongly affect the dose–response of the product from both textural and organoleptic points of view.

Technical Aspects

Irradiation Facilities

Food irradiation is carried out in specific containment areas applying the necessary shielding to prevent the escape of ionizing radiation and to avoid exposure of personnel. In automated irradiation facilities, conveyors or other carrier systems move the products to be irradiated at a predetermined speed or rate to deliver the necessary dosage. With the exception of Florida and Hawaii, USA, there are no irradiation facilities devoted exclusively to the processing of food; in general, food irradiation is conducted in commercial irradiation facilities treating a wide variety of other nonfood products.

Gamma rays emitted by radioactive sources (^{60}Co or ^{137}Cs) are highly penetrative and their energy levels are constant. Electron beams produced by electron accelerators are much less penetrative. Photons of high-energy X-rays produced when an electron beam hits specific heavy metal targets (the X-ray converter) are also able to treat large packages of food (e.g., pallet boxes). However, unlike photons emitted by the above radionuclides, X-rays have a photon energy spectrum. Both electron beams and X-rays are produced by machine sources which can be switched off if they are not in use.

Irradiation facilities can be operated as a part of the food-processing operation such as a processing line or of handling lines in storehouses. They can, alternatively, be operated as service facilities on a fee basis. Examples of a high-capacity commercial cobalt-60 irradiation facility and an electron-beam machine facility are illustrated by Figures 2 and 3, respectively.

The International Atomic Energy Agency (IAEA) maintains a Food Irradiation Facilities Database, containing the facilities' location, contact details, type of irradiators, etc.

Food Irradiation Process Control and Detection of Irradiated Foods

Process control of food irradiation involves monitoring absorbed radiation dose, radiation dose distribution, machine parameters such as voltage and beam current as well as speed of the conveyor or carrier system.

Chemical and physical changes in foods induced by irradiation are very small and mostly nonspecific to this treatment. Therefore, food irradiation results in a product that is virtually indistinguishable from unprocessed food by the consumer. However, a number of ingenious chemical, physical, and biological methods were developed and adopted, for example, by the European Committee for Standardization (CEN) to assist regulating authorities in determination whether a particular food sample has been irradiated or not. Several such methods have also been adopted by the Codex Alimentarius.

Detection of irradiated food products on the marketplace also serves the enforcement of labeling regulations; most countries require clear information to inform the consumer. Mostly, labeling phrases as 'irradiated' or 'treated by ionizing radiation' are required; France has chosen 'ionized.' Codex Alimentarius proposes the use of the Radura logo (Figure 4) some countries require different design and varied color, however, the EU directives exclude the use of the logo. The logo is considered to give the consumer an easily recognized symbol for the information about the treatment by ionizing radiation.

Figure 4 The Radura logo.

Irradiation Costs/Economic Feasibility

Economics of food irradiation are one of the key factors for utilization just like in other technologies, and the costs

involved in the process must be less than the benefits that can be derived from it. Economic feasibility is greatly affected by local circumstances. In general, however, one can state that the unit cost of irradiation would be in the range of a few percent of the value of food treated, and in many cases they are in the same order of magnitude as those of other preservation or decontamination methods. As with any food process, many items of costs make up the total costs and many variables exist that affect the actual cost for a practical application, for example, capital cost (building and radiation source), source efficiency, plant utilization, cost of labor, overheads, rate of depreciation, and interest. Irradiation has relatively low labor cost. The input requirement for conventional energy is low. The capital cost, however, is relatively high, especially when an economically effective scale of operation is involved. Evidently, there must be a product volume sufficient to support the capital cost, and the unit cost of irradiation decreases rapidly with increasing plant utilization.

There are several arguments about the costs of radiation processing. As it relates to microbiological safety and the protection against food-mediated infections, estimates of authorities see such extra costs much lower than the costs of illnesses and even death from the unirradiated product; however, such advantages in costs would mainly be counted in relation to public budgets for health issues. Practical experience in the marketplace proves that the irradiated product (e.g., hamburgers or exotic fruit) has an insignificant increase in the price.

Legislation of Food Irradiation

Wholesomeness (radiological safety, toxicological innocuity, nutritional adequacy, and microbiological safety) of irradiated food has been carefully evaluated by an unprecedented width of research and testing. Specific research programs and international projects by specialized agencies of the UN, such as the Food and Agriculture Organization (FAO), the IAEA and the World Health Organization (WHO) have been important partners in assisting progress. The scientifically acceptable evidence described in detail in a separate article in this Encyclopedia supports the safety of irradiated food for consumption. Considering the potential role of food irradiation in the safety of food supply, the WHO formed a positive attitude toward the utilization of food irradiation. For example, in collaboration with the FAO, the WHO published in 1988 a booklet entitled 'Food Irradiation – a technique for preserving and improving the safety of food'. In its 'WHO Golden Rules for Safe Food Preparation,' the rule No.1 ('Choose foods processed for safety') states "…always buy pasteurized milk as opposed to raw milk, and if you have the choice, select fresh or frozen poultry treated with ionizing radiation…." The WHO set up a Consultation on Food Irradiation in 1992, and published its detailed report in 1994, with the endorsement that "food irradiation is a thoroughly tested technique, that it has not been shown to have any deleterious effects when performed in accordance with good manufacturing practices, and that it can keep to ensure a safer and more plentiful food supply by extending shelf life, eradicating pests and inactivating pathogens". These efforts assisted a worldwide development of clearances on food irradiation.

Food irradiation is approved for use in an increasing number of countries worldwide for various application and purposes in a wide variety of foodstuffs. The IAEA is also updating and maintaining a Food Irradiation Clearance Database. At the EU level, there are two main pieces of legislation regulating the irradiation of food: Directive 1999/2/EC and Directive 1999/3/EC. The Joint FAO/WHO Codex Alimentarius Commission adopted a Codex General Standard for Irradiated Foods as well as a Recommended International Code of Practice for Radiation Processing of Food. These Codex documents were revised in 2003, and are publicly available on the websites indicated below.

Legislative authorities require that irradiated food products be labeled. In general, the international food irradiation symbol, the so-called Radura logo is required with a statement that the product has been intentionally subjected to ionizing radiation.

FOOD TECHNOLOGIES

Freezing

SJ James and C James, The Grimsby Institute of Further & Higher Education (GIFHE), Grimsby, UK

Glossary

Conduction, thermal Mechanism for heat transfer. The process of heat transfer through a solid material/medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

Convection, thermal Mechanism for heat transfer. The process of heat transfer through a liquid or gas by means of circulating currents caused by changes in density.

Drip Exudative liquid from meats and fish containing water and proteins. Produced by protein denaturation/structural breakdown during chilling/freezing and storage, particularly freezing and thawing. Also referred to as exudate, purge fluid, press fluid, etc.

Heat transfer coefficient Coefficient used in thermodynamics to calculate heat transfer, typically by convection or phase change, between a fluid and a solid.

Latent heat of fusion The amount of thermal energy required to change the state of a substance without a change in temperature. The thermal energy absorbed or rejected by a substance during its conversion, respectively, from a solid to a liquid, as from ice to water, or from a liquid to a solid, as from water to ice.

Radiation, thermal Mechanism for heat transfer. Electromagnetic radiation generated by the thermal motion of charged particles in matter. All matter with a temperature greater than absolute zero emit thermal radiation.

Refrigeration May be defined as the process of removing heat from any substance to: (1) render colder – reduce temperature, (2) change its state – for example, water to ice, and (3) maintain its state – preserving foods, storing ice.

Water activity (a_w) A measure of the available water in a substance. 'High a_w' foods support bacterial growth, 'low a_w' do not. This is not the same as water content. Some foods with a high water content have a relatively low a_w because the water is bound up with dissolved salts or sugar, for example, jam.

Introduction

Freezing, i.e., holding a food in a refrigerated environment with the majority of the water in the food turned into ice, is a major preservation method for foods. In foods, containing free water, ice can form at any temperature below the initial freezing point of that food. In addition once ice has been formed it will remain present unless, or until, the temperature of the food is raised above the initial freezing point (more properly described in such case as the final melting point). Whereas water has a single freezing point, foodstuffs (as they are a mixture of different constituents, between 10% and 30% of substances other than water) have a freezing range. The 'freezing point' of a food is usually considered as the initial freezing point, the temperature at which ice formation starts following supercooling. In foods with low water contents and high sugar or salt contents the initial freezing point may be as low as -4 to $-10\,^{\circ}C$, or even lower. International Institute of refrigeration (IIR) Recommendations for the Processing and Handling of Frozen Foods state that "a food product is regarded as a frozen food product when the product temperature is $-10\,^{\circ}C$ or colder, or when a high proportion of the freezable water in the product is converted into ice (usually more than 80% of water content)."

The freezing of a food can be divided into five distinct periods (Figure 1):

1. An initial cooling period, where cooling takes place without a phase change.
2. A supercooling period, where the product temperature falls below the freezing point without there being a phase change, due to the requirement of high activation energy for starting nucleation (of the crystallization).
3. A phase change period, which starts when nucleation occurs and ice begins to form in the surface layer. Although the water is initially changing to ice there is little change in temperature due to the heat required for the change in state (the latent heat of fusion). The freezing front gradually advances into the product, until it reaches the thermal center and there is ice throughout the food.
4. A completion of freezing period, during which the required amount of heat is extracted to create the desired ice content throughout the food.
5. An equalization period, as the food temperature tends to the temperature of the heat transfer medium.

In general, the term freezing refers to the initial process in which the temperature of the food is reduced to a temperature below its freezing point, whereas the term frozen is used to

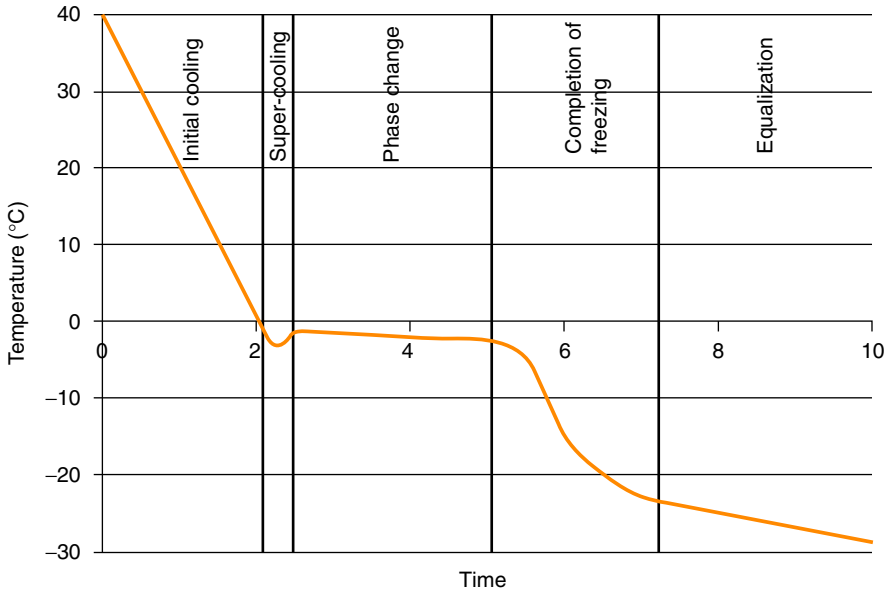

Figure 1 Typical representative freezing curve showing periods of freezing.

describe the subsequent state the food is kept in, i.e., the maintenance of the food below that temperature during the rest of the cold-chain.

A frozen food has a 'safe' storage and distribution life that can be measured in years when compared to the days or months of a chilled product; the storage life being controlled by chemical changes that affect the taste of the food not microbiological safety. A reliable frozen cold-chain initially reduces the temperature of the food below a temperature (−12 °C) that prevents the growth of any pathogenic or spoilage microorganisms and stops it rising during the rest of the cold-chain, i.e., storage, distribution, retail display, and domestic handling.

With many foods, freezing is the best long-term food preservation method because it produces no significant changes in the texture, taste, smell, or appearance of the food at the point of consumption. Changes to the structure and loss of water-holding capacity are noticeable after thawing and are important if the food, i.e., soft fruit, is to be consumed uncooked. In addition nutrients such as vitamins are better preserved in freezing than traditional preservation methods, including chilling. It is therefore preferable to traditional alternatives such as smoking, drying, salting, or canning.

The removal of heat from a material diminishes the kinetic energy of that material, thus decreasing the temperature (temperature being a measure of the rate of motion of molecules, or atoms, within a body). The rate at which molecules and atoms move within a material determines the rate at which they react with one another. In food products many important reactions and processes are, among others, controlled by temperature:

- the growth of microorganisms;
- chemical and enzymatic reactions, such as browning reactions, lipid oxidation, cold-shortening, vitamin degradation, and pigment degradation; and
- physical processes, such as moisture loss.

In almost all cases, reducing the temperature reduces the rate of these changes in foods and thus extends their preservation. Provided the food is of a safe quality before freezing, as long as the temperature remains below −12 °C during storage there will be no growth of microorganisms so the food will remain safe. Frozen storage life will ultimately be limited by enzymic reactions, which will in time affect the taste of the frozen product. The rates of these reactions are a function of temperature, so the storage life will generally be longer at lower temperatures. Once thawed, however, any microbes present can again become active, and under the right conditions will multiply to levels that can lead to foodborne illness.

Freezing Process

Freezing is a process of removing heat and can only be achieved by four basic mechanisms: radiation, conduction, convection, or evaporation. Conduction requires a good physical contact between the food to be frozen and the cooling medium, and this is generally achieved only with foods that can be shaped into regular shapes, such as blocks of meat and fish or in the freezing liquids, i.e., ice cream, fruit juices, etc. Radiation does not require any physical contact but a large temperature difference is required between the surface of the food being cooled and that of surrounding surfaces to achieve significant heat flow. In primary freezing, radiation is only important in the initial stages of the process in a system where the food is not surrounded by other products. Again, in the initial stages of the freezing of cooked food products (e.g., pies, pastries, joints), radiant heat loss can be substantial if the products are surrounded by cold surfaces. Evaporation from a food surface reduces yield and is not desirable in most food refrigeration operations but can be useful again in the initial cooling of cooked food products. However, as soon as the surface of the food is frozen then any heat loss due to

evaporation is minimal. Convection is by far the most important heat transfer mechanism employed in the majority of food freezing systems. In most cases, refrigerated air is the transfer medium; however, in some cases brine or a cryogenic gas can be used. The rate of heat removal depends on the following:

1. Surface area available for heat flow.
2. Temperature difference between the surface and the medium.
3. Surface heat transfer coefficient.

Each combination of product and cooling system can be characterized by a specific surface heat transfer coefficient whose value depends principally on the thermophysical properties and velocity of the medium. Typical values range from 5 $W\,m^{-2}\,K^{-1}$ for slow moving air to 500 $W\,m^{-2}\,K^{-1}$ for immersion in an agitated refrigerant. Heat must also be conducted from within the food to its surface before it can be removed. Most foodstuffs are poor conductors of heat and this imposes a severe limitation on attainable freezing times for either large individual items or small items cooled in bulk. However, because the thermal conductivity of ice is approximately three times that of water, as freezing proceeds it becomes easier to extract heat from the deeper regions.

Effect of Freezing on Food Safety

Microorganisms vary in their ability to tolerate freezing and frozen storage. Survival is affected by the type and age of microorganism. In general, Gram-negative bacteria (which include pathogens such as *Escherichia* and *Salmonella* spp.) are more susceptible to freezing and frozen storage than Gram-positives, with bacilli being more susceptible than cocci. Yeasts and molds are more resistant than bacteria, in part due to their tolerance to reduced water activity (a_w). Psychrophilic and psychrotrophic microorganisms are generally more tolerant to freezing and frozen storage due to their ability to synthesize larger amounts of enzymes to compensate for reduced enzymic activity at low temperatures, and their reduced susceptibility to cold shock in comparison to thermopiles and mesophiles.

Spoilage microorganisms do not grow below *ca.* -10 to $-12\,^{\circ}C$ and pathogens below $-1\,^{\circ}C$, thus the growth of pathogenic microorganisms is only normally relevant to handling before freezing or during thawing. In these contexts, frozen foods behave like their unfrozen counterparts, if surface temperatures are reduced rapidly during freezing this allows less time for any microorganisms to grow, although growth rates may be faster after thawing due to increased drip. Also, thawing may take a long time and on large objects subjected to long uncontrolled thawing cycles, surface spoilage can occur before the center regions have fully thawed.

Although salmonella, staphylococci, and other potential pathogens can survive freezing and frozen storage, the saprophytic flora (spoilage bacteria) tend to inhibit their growth. During freezing and thawing of food, the temperature favors the growth of psychrophilic organisms, most of which are spoilage organisms. Hence, in nearly all cases, if a frozen product is mishandled, spoilage is apparent before the food becomes a health hazard.

Repeated freeze-thaw cycles have been shown to disrupt and destroy bacteria; however, the effects of cyclic freezing on most microbial pathogens are not well documented. As bacteria generally grow more rapidly than fungi, mold spoilage of foods is thought to develop only when competing bacteria are inhibited. Temperature is usually assumed to be the critical factor, mold spoilage being classically associated with frozen meat. It has been generally accepted that molds can develop on meat at temperatures as low as -10 or $-12\,^{\circ}C$. However, there is some evidence that this is an exaggeration and that for practical purposes the minimum temperature for mold growth on meat should be taken to be approximately $-5\,^{\circ}C$, and that surface desiccation rather than temperature is the factor that inhibits bacterial growth. In the past, carcass meats were imported at temperatures of -5 to $-10\,^{\circ}C$. At these temperatures there were problems with the growth of psychrotrophic molds such as strains of Cladosporium, Geotrichum, Mucor, Penicillium, Rhizopus, and Thamnidium, causing 'whiskers' or 'spots' of various colors depending on the species. Because little meat is now stored at these temperatures, mold spoilage is largely of historic importance and thus any reports of mold growth on frozen meats should be taken as indicative of particularly poor temperature control. Despite this, many meat microbiology textbooks continue to discuss this subject in great detail.

Freezing and crust-freezing has been suggested as a means to reduce numbers of campylobacter organisms on poultry carcasses, and is one of a number of measures taken to reduce the incidence of campylobacteriosis in Iceland, although the exact impact of this measure is unclear. This work in Iceland has been very influential and many risk assessment models have incorporated freezing as an import factor due to this work. Freezing to approximately $-20\,^{\circ}C$ has been reported by a number of studies to result in an initial fall in numbers of campylobacter organisms, followed by a slower decline during storage. Freezing has been recommended as a control measure for reducing campylobacter by the European Food Safety Authority. The mechanism of damage during freezing has been attributed to mechanical damage caused by ice crystals, desiccation due to the reduced water activity, and oxidative damage.

Freezing has little effect on viruses, or on histamine and microbially produced toxins. Inadequate freezing and thawing procedures have been identified as factors in cases of scombroid poisoning associated with the consumption of spoiled fish flesh that is high in histamine (from pelagic species such as mackerel, sardines, pilchards, and certain tuna species).

Nematode parasites are very susceptible to freezing and freezing is a control measure for inactivating trichinae in pork and nematode parasites in seafood (particularly for lightly processed seafoods that will receive no cooking before consumption). The United States Department of Agriculture recommended holding times for pork to inactivate *Trichinella spiralis* range from 106 h at $-18\,^{\circ}C$ to 0.5 h at $-37\,^{\circ}C$. Freezing is also used as a control measure for inactivating tape worms (*Taenia saginata*) in beef carcasses with localized infections in the EU by holding at $-10\,^{\circ}C$ or less for 14 days or more.

Many of the chemical changes that limit the storage life of frozen foods are enzymic. Although freezing inhibits some enzymes, a considerable number, such as invertases, lipases, lipoxidases, catalases, peroxidases, etc., remain active. Because frozen foods are stored for relatively long periods, these enzymic reactions although slow (reactions that take 45 min at 37 °C will take over a week at −29 °C) can cause significant problems. In time this can lead to off-flavor development and color and texture deterioration. It has been demonstrated that food deterioration due to enzymes of microbial origin can occur at temperatures too low for the activity of the microorganisms that generated them. For vegetables, and to a lesser degree fruits, where enzymic deterioration during frozen storage is a problem, blanching, a mild heat treatment, is required to deactivate the enzymes. Typically, blanching is done by treating the product with steam or hot water for 1–10 min at 75–95 °C, the time/temperature combination depending on the specific product. Such treatment times and temperatures are also capable of reducing, to varying extents, the numbers of viable microorganisms on the food.

Whether 'rapid' freezing offers any clear advantages to product safety will depend on what biological hazards (pathogens, etc.) are present, at what numbers they are present, and whether they are on, or in, the food in question, and how 'rapid' the rate is in comparison to other rates. There is no definition of 'rapid' and 'slow' rates. Size of product will also have a big effect on relative rates of freezing, because conduction through the product will be the rate limiting factor.

Effect of Refreezing on Food Safety

General advice to consumers is that once thawed previously frozen food should not be refrozen. The rational for such advice is that microbial growth may have occurred during thawing and that further microbial growth may occur during subsequent thawing of the refrozen product. However, commercially many foods, particularly fish and shellfish, are repeatedly frozen and thawed during production and supply. Provided conditions are controlled to prevent any growth of pathogens during the period the food is no longer frozen, foods can be repeatedly frozen and thawed safely. In general it is recommended that product temperatures should be kept below 10 °C during thawing. Ideally two-stage thawing procedures should be used, in which the thawing medium temperatures are initially high (15–20 °C) but are reduced to $\leq$5 °C as the product surface temperature rises. There is evidence that in some cases repeated freeze-thaw cycles can disrupt and destroy bacteria. Concerns have been expressed that thawed food may represent an increased safety hazard due to the release of nutrients caused by ice crystal damage, however, there is little evidence that thawed foods represent any more of a hazard than foods that have not been frozen, although exudate from thawed products such as meat may contain pathogens and be a source of contamination. The use of carbon dioxide has been suggested during thawing and post thawing to mitigate any increased hazard. There is some evidence that refreezing may cause additional quality damage to some products (such as gaping in fish, further drip in meat, etc.), although this is not always detectable in a final cooked product.

Freezing Operations

Freezing systems for foodstuffs will contain many, if not all, of the following unit operations:

- Preparatory treatment; conditioning, waxing, cooking, pasteurizing, blanching, etc.
- Freezing.
- Storage.
- Transportation.
- Retail display.
- Domestic storage.
- Thawing/tempering.

During the preparatory treatment there can be a range of temperature responses, from a large gain to a small decrease in the temperature of the product. During freezing there is a substantial decrease in the mean temperature of the product. During thawing/tempering there is a substantial increase in the mean temperature of the product. Within a correctly designed frozen chain there should be no significant change in mean product temperature during storage, transport, retail display, or domestic storage.

Freezing Equipment

From a hygiene/hazard analysis and critical control points (HACCP)-based approach, prepacking the food before freezing may lower the risk of contamination/cross-contamination during the freezing process, however, it will significantly affect the rate of freezing (particularly in systems with low surface heat transfer rates such as low-velocity air), and this in turn may allow the growth of any microorganisms present during the initial cooling stage. Provided the cooling media (air, refrigerant, etc.) and refrigeration equipment used is kept sufficiently clean, no one freezing method can be said to be intrinsically more hygienic than any other.

Blast Air Freezers

Air is by far the most widely used method of freezing food as it is economical, hygienic, and relatively noncorrosive to equipment. Systems range from the most basic in which a fan draws air through a refrigerated coil and blows the cooled air around an insulated room, to purpose-built conveyorized blast freezing tunnels or spirals. Relatively low rates of heat transfer are attained from product surfaces in air cooled systems. The big advantage of air systems are their versatility, especially when there is a requirement to freeze a variety of products particularly of irregular shapes.

Batch Air Freezers

Placing food in large refrigerated rooms is a common method of freezing. With few exceptions the product is always wrapped and packaged before freezing.

In simple batch air freezing systems air distribution is a major problem that is often overlooked by the system designer and the operator. The freezing time of the product is reduced as the air speed is increased. An optimum value exists between the decrease in freezing time and the increasing power required to drive the fans to produce higher air speeds. Up to 30% of the total energy consumed in a blast freezer may be consumed by the fans and the extra refrigeration required to extract the heat generated by the fans. This optimum air velocity can be as low as 1.0 m s^{-1} when freezing pallets or large cartons to greater than 15 m s^{-1} plus for thin products. In addition even when a system has been designed to distribute the air through the product, poor management and/or poor understanding of the requirement of the plant commonly leads to uneven cooling. Products stacked or racked irregularly will leave channels around the stacks that are larger in cross sectional area than those within the stacks and channels of differing area through the stacks. Air leaving and returning to the refrigeration coil will take the path of least resistance through the largest gaps, instead of passing evenly through or over the product.

Continuous Air Freezers

Conveying the product through the freezing system overcomes the problem of uneven air distribution because each item is subjected to the same velocity/time profile. In the simplest continuous air freezing systems the food is suspended from an overhead conveyer and moved through a refrigerated room.

In more sophisticated plants the product is conveyed through a freezing tunnel. The main advantage of this method is that the refrigeration capacity and air conditions can be varied throughout the length of the tunnel. Large capacity evaporators can be installed in the initial stage to cater for the high rates of heat release encountered at the start of the freezing process.

Some small cooked products are continuously frozen on racks of trays (8 to 16 high) that are pulled or pushed through a freezing tunnel using a simple mechanical system. In larger operations it is more satisfactory to convey the cooked products through a linear tunnel or spiral freezer. Linear tunnels are far simpler constructions than spirals but their use is often ruled out due to constraints on floor area. In spirals, advantages are claimed for either horizontal or vertical systems of air distribution. In horizontal systems a lower pressure drop and smaller temperature difference across the products and coil result in less weight loss from unwrapped products. In systems utilizing a vertical air distribution, there is increased turbulence and higher, and more uniform, heat transfer coefficients, which lead to reduced freezing times.

The use of impingement technology to increase the surface heat transfer in freezing systems is now common practice. Impingement is the process of directing a jet or jets of fluid at a solid surface to effect a change. The very high velocity (20–30 m s^{-1}) impingement gas jets 'breakup' the static surface boundary layer of gas that surrounds a food. The resulting medium around the product is more turbulent and the heat exchange through this zone becomes much more effective. Impingement freezing is best suited for products with high surface area to weight ratios, i.e., hamburger patties or products with one small dimension. Testing has shown that products with a thickness less than 20 mm freeze most effectively in an impingement heat transfer environment. When freezing products thicker than 20 mm, the benefits of impingement freezing can still be achieved, however, the surface heat transfer coefficients later in the freezing process should be reduced to balance the overall process efficiency. The process is also very attractive for products that require very rapid surface freezing.

Fluidized bed freezing is a modification of air-blast freezing. The principal behind fluidization is that fairly uniform particles are subjected to an upward air stream. At a certain velocity the particles will float in the air stream, each separated from the other, surrounded by air and free to move. In this state the particles act in a similar fashion to a fluid, thus the term 'fluidized.' Products are fed into the higher end of a sloping tunnel, where they are simultaneously conveyed and frozen by the same air. Fluidized bed freezers can also be combined with a conveyorized system. Additional agitation, in the form of a movable base, may be required for some irregular products such as French fries. Fluidized bed freezers are used to produce free-flowing products, most notably vegetables (such as peas, sliced carrots, green beans, etc.) and fruit, but can also be used for peeled cooked shrimps, diced meats, etc. Products frozen by this method, as well as in other in-line blast freezers, are commonly referred to as individually quick frozen (IQF). Fluidization achieves a very efficient air-to-product contact, thus giving much higher heat transfer rates than for conventional air-blast freezing tunnels or belt freezers and subsequently shorter freezing times.

Plate Freezers

Modern plate freezers differ little in principle from the first contact freezer patented in 1929 by Clarence Birdseye. Essentially product is pressed between hollow metal plates containing a circulating refrigerant. A hydraulic cylinder is used to bring the refrigerated plates into pressure contact with the product. These plates can be either horizontal or vertical. They tend to be expensive, especially if automatic loading and unloading is required, but have low running costs. Good heat transfer is dependent on product thickness, good contact, and the conductivity of the product. Plate freezers are often limited to a maximum thickness of 50–70 mm. Air spaces in packaging and fouling of the plates can have a significant effect on freezing time. With thin materials a plate freezing system has the potential to halve the time required in an air-blast system.

Belt Freezers

Belt freezers employ a contact method of freezing similar to plate freezers. Simple belt freezers consist of an endless steel belt (approximately 1 mm in thickness), the underside of which is cooled either directly with brine, glycol, or cryogenic sprays, or by sliding over a stationary cold surface. Because only one side of the product is in contact with the cooling surface relatively thin products are required, such as

hamburgers, fish fillets, or liquid and semiliquid products such as purées and sauces.

In double-band systems the product is frozen between two endless belts of which the top is flat and the lower belt corrugated. The product is spread into the corrugations, the top belt enclosing the exposed surface thus freezing the product as IQF pellets. Liquids and semiliquids are often frozen into pellets using this method.

Scraped Surface Freezers

Scraped surface, or cylindrical, freezers are designed for freezing liquid products either on the inner or the outer surface of a cooled cylinder. The layer of frozen product formed on the surface of the cylinder is continuously scraped from the cylinder surface, thus achieving high heat transfer and a rapid freezing rate. Scraped surface freezers are used for manufacturing ice creams and similar products.

Immersion/Spray Freezers

Immersion/spray freezing systems involve dipping product into a cold liquid, or spraying a cold liquid onto the food. Because heat transfer medium temperatures of $<0\,^{\circ}C$ are required this necessitates the use of nontoxic salt, sugar, or alcohol solutions in water, or the use of cryogens or other refrigerants. The type of salt depends on the required temperatures, calcium chloride solutions are capable of temperatures as low as $-55\,^{\circ}C$. This produces high rates of heat transfer due to the intimate contact between product and cooling medium. For example, bulk freezing times of less than 1 min can be obtained for peas, diced carrots, snow peas, and cut green beans using a 23% sodium chloride solution.

Clearly if the food is unwrapped the liquid has to be 'food safe.' Any uptake of the cooling medium, whether 'food safe' or not, by the product may present problems both in terms of flavor changes and the requirement for periodic replacement of the medium. This transfer can be minimized by packaging, although this will hinder heat transfer.

Cryogenic Freezers

The term cryogenic simply means very low temperature. Cryogenic cooling uses refrigerants, such as liquid nitrogen or solid carbon dioxide, directly. Cryogenic freezing is often treated as a specific type of freezing method on its own, however, it is essentially an immersion/spray system, depending on how the cryogen is utilized.

Although it is common in laboratory studies to freeze samples with liquid nitrogen by direct immersion, few commercial liquid nitrogen freezers employ this technique. One reason for this is that many foods will shatter and split if frozen in this way; due to rapid ice expansion, it is also inefficient. Cryogens are typically employed as sprays in tunnel, spiral, or batch cabinet systems.

Cryogenic freezing is often cited as the fastest method of freezing a food. Rapid freezing in comparison with other methods is principally due to very low operating temperatures. In general, commercial cryogenic freezers do not provide substantially higher surface heat transfer coefficients between the product and medium than other refrigeration systems, unless the cryogen comes in direct contact with the product. Cryogenic systems are best suited to freezing thin products with a high surface area to weight ratios in which heat conduction within the product is not rate limiting. Although running costs of cryogenic systems can be expensive, capital investment is low, with cryogenic suppliers often renting the equipment to users. Also installation and maintenance costs are lower than mechanical refrigeration systems.

Frozen Storage

Publications such as those in the IIR provide data on the storage life of many foods at different temperatures. Storage lives for food can be as short as 3–4 months for IQF, polybag-packed shrimps at $-18\,^{\circ}C$. However, lamb stored at $-25\,^{\circ}C$ can be kept for over 2.5 years.

Traditionally the frozen food industry was interested in two problems that were detrimental to the appearance of the frozen food; 'freezer burn' and 'in-package frosting,' both of which may occur during storage. Freezer burn is caused by water loss from the surface of the frozen food due to sublimation. The resulting desiccation produces a dry fibrous layer at the surface that has the appearance of a burn. It is irreversible. It only occurs in unwrapped, or poorly wrapped, foods and its development is fastest at high storage temperatures and high air movements. It occurs during storage and not during the freezing process (unless the freezing process is excessively long); it is not caused by fast freezing. In-package frosting results from a combination of water loss from the surface, lose packaging, and temperature fluctuations during storage. The water lost from the surface is deposited and frozen on the inner surface of the packaging. The use of suitable packaging and good temperature control should eliminate both problems. Neither has an effect on food safety.

Thawing and Tempering Systems

Frozen raw material as supplied to the industry ranges in size and shape, although much of it is in blocks packed in boxes. Thawing is usually regarded as complete when the center of the block has reached $0\,^{\circ}C$, the minimum temperature at which meat or fish can be filleted or cut by hand and fruits and vegetables hand sorted. Lower temperatures (e.g., -5 to $-2\,^{\circ}C$) are acceptable for produce that is destined for mechanical chopping, but such meat is 'tempered' rather than thawed. The two processes should not be confused because tempering only constitutes the initial phase of a complete thawing process.

Thawing is often considered as simply the reversal of the freezing process. However, inherent in thawing is a major problem that does not occur in the freezing operation. The majority of the microorganisms that cause spoilage or food poisoning are found on the surfaces of foods. During the freezing operation, surface temperatures are reduced rapidly

and bacterial multiplication is severely limited, with microorganisms becoming completely dormant below $-12\,^{\circ}C$. In the thawing operation these same surface areas are the first to rise in temperature and microbial multiplication can recommence. On large objects subjected to long uncontrolled thawing cycles, surface spoilage can occur before the center regions have fully thawed.

Most thawing systems supply heat to the surface and then rely on conduction to transfer that heat into the center of the food. A few use electromagnetic radiation to generate heat within the food. In selecting a thawing system for industrial use a balance must be struck between thawing time, appearance and bacteriological condition of product, processing problems such as effluent disposal, and the capital and operating costs of the respective systems.

Transportation

Frozen foods are transported around the world and locally via a range of transportation systems. All these transportation systems are expected to maintain the temperature of the food within close limits to ensure its optimum safety and high quality shelf-life. As with chilled food it is important that the food is at the correct temperature before loading because the refrigeration systems used in most transport containers are not designed to extract heat from the load but to maintain the temperature of the load.

Overland Transport

Overland transportation systems range from 12 m refrigerated containers for long distance road or rail movement of frozen products to small uninsulated vans supplying food to local retail outlets or even directly to the consumer. The rise in supermarket home delivery services where there are requirements for mixed loads of products that may each require different storage temperatures is introducing a new complexity to local overland delivery.

The majority of current road transport vehicles for frozen foods are refrigerated using either mechanical, eutectic plates, or liquid nitrogen cooling systems. Irrespective of the type of refrigeration equipment used the product will not be maintained at its desired temperature during transportation unless it is surrounded by air or surfaces at or below the maximum transportation temperature. This is usually achieved by a system that circulates moving air, either forced or by gravity, around the load. Inadequate air distribution is probably the principal cause of product deterioration and loss of shelf-life during transportation. Conventional forced air units usually discharge air over the stacked or suspended products either directly from the evaporator or through ducts toward the rear cargo doors.

Sea Transport

Most International Standard Organization (ISO) containers for food transport are either 6 or 12 m long, hold up to 26 t of product and can be 'insulated' or 'refrigerated.' The refrigerated containers incorporate insulation and have refrigeration units built into their structure. The units operate electrically, either from an external power supply on board the ship or dock or from a generator on a road vehicle. Insulated containers either utilize the plug-type refrigeration units already described or may be connected directly to an air-handling system in a ship's hold or at the docks. Close temperature control is most easily achieved in containers that are placed in insulated holds and connected to the ship's refrigeration system. However, suitable refrigeration facilities must be available for any overland sections of the journey. When the containers are fully loaded and the cooled air is forced uniformly through the spaces between cartons, the maximum difference between delivery and return air can be less than $0.8\,^{\circ}C$. The entire product in a container can be maintained to within $\pm 1.0\,^{\circ}C$ of the set point. Refrigerated containers are easier to transport overland than the insulated types, but have to be carried on deck when shipped because of problems in operating the refrigeration units within closed holds. On board ship they are therefore subjected to too much higher ambient temperatures and consequently larger heat gains, which make it far more difficult to control product temperatures.

Retail Display

No frozen food, with the possible exception of ice cream, should be unwrapped when in a retail display cabinet. Traditionally frozen food was displayed in a 'well-type' cabinet with only the top faces of food packs being exposed. In many cases the cabinets were fitted with a see-through insulated lid to further reduce heat infiltration.

Increasingly there is marketing pressure to display an increasing amount of frozen food in open multideck display cabinets. Maintaining the temperature of products below set limits while they are on open display in a heated store will always be a difficult task. Radiant heat gain on the surfaces of exposed packs can result in the food thawing in extreme cases. During display, temperature, temperature fluctuations, and packaging are the main display parameters that control quality.

Temperature fluctuations can increase the rate of weight loss from wrapped meat. Higher rates of dehydration have been measured in a retail cabinet operating at $-15\,^{\circ}C$ than another cabinet operating at $-8\,^{\circ}C$. Fluctuations in air temperature in the $-15\,^{\circ}C$ cabinet ranged from -5 to $-21\,^{\circ}C$ compared with $\pm 1.5\,^{\circ}C$ in the $-8\,^{\circ}C$ cabinet. Successive evaporation and condensation (as frost) caused by such a wide temperature differential resulted in exaggerated in-package dehydration.

The extent of temperature fluctuations will be dependent on the air temperature over the product, the product packaging, and the level of radiant heat. Retail display packs have a relatively small thermal mass and respond relatively quickly to external temperature changes. These can be from store and display lighting, defrost cycles, and heat infiltration from the store environment. In products where air gaps exist between the packaging and the meat, sublimation of ice within the product leads to condensation on the inside of the packaging,

resulting in a build-up of frost. This dehydration causes small fissures in the surface of the food, allowing the ingress of any packaging gases into the food. This can aid the acceleration of oxidative rancidity within the product. Minor product temperature fluctuations are generally considered to be unimportant, especially if the product is stored below $-18\,^{\circ}C$ and fluctuations do not exceed $2\,^{\circ}C$.

Domestic Handling

After a frozen product has reached the operating temperature of a domestic freezer it is very unlikely that its temperature will rise above $-12\,^{\circ}C$ during domestic storage, unless there is electricity cut. However, safety can be compromised during handling before and after the product reaches the storage temperature.

When removed from display cabinets the temperature of frozen foods can rise rapidly if exposed to ambient conditions. Surveys have shown that the majority of consumers do not use insulated bags or boxes to transport frozen food to their homes. Once the food has warmed during transportation it can take many hours in a domestic freezer for the food temperature to fall below a safe temperature of $-12\,^{\circ}C$.

It is common for consumers to purchase chilled products and freeze them at home. Studies have shown that it can take over 6 h for the temperature of a chicken portion to cool from 0 to $-5\,^{\circ}C$ in a domestic freezer.

There have been relatively few published surveys of temperatures in domestic freezers. In a survey of domestic freezers in New Zealand, mean temperatures ranged from -11.5 to $-23.3\,^{\circ}C$ with an overall mean value of $-16.6\,^{\circ}C$. Only 28% of freezers operated at $-18\,^{\circ}C$ or lower, with 68% operating between -13 and $-18\,^{\circ}C$. The type of freezer did not influence the mean air temperature values recorded. These ranged from -16.3 to $-16.6\,^{\circ}C$, irrespective of other considerations such as data logger location and freezer loading. The warmest freezer temperature encountered was in a top-loading fridge-freezer, whereas the coldest was in a vertical freezer. Temperature control in freezers does not appear to have improved over 20 years. Freezers ≤ 10 years old and freezers ≥ 21 years old had similar mean temperature values. Freezers of 11–15 and 16–20 years of age had respective mean air temperatures approximately $3\,^{\circ}C$ lower and $2\,^{\circ}C$ higher than the other freezer age groups but came from small sample sizes. The mean air temperature recorded in the top sections of surveyed freezers was on average 2–2.5 $^{\circ}C$ warmer than the middle and bottom sections, respectively, which suggests that freezing could be slightly slower in the upper areas of the freezer compartment.

It is usually recommended that large individual frozen items, i.e., meat joints, whole poultry carcasses, are thawed to above $0\,^{\circ}C$ before cooking. If carried out in a domestic refrigerator this process may take many days but the food will not reach a temperature that will support pathogenic growth. Thawing product in ambient air or water is far quicker but the process should be controlled so that the food is only above $5\,^{\circ}C$ for a minimum time before cooking.

Conclusions

Frozen foods generally have an excellent overall safety record. However, the production of safe frozen foods requires the same attention to good manufacturing practices and HACCP principles as the chilled or fresh counterpart.

Provided the food is of a 'safe' condition before freezing, freezing is a very safe method of preserving food. During the time the food remains below $-12\,^{\circ}C$ there will be no growth in food poisoning or food spoilage microorganisms. Freezing has little effect on viruses or on histamine but will inactivate nematode parasites in pork and seafood. As long as the temperature of the food is reduced to below $-12\,^{\circ}C$ in a reasonable time (hours rather than days) during the initial freezing operation and not allowed to rise above $7\,^{\circ}C$ during thawing, it will generally be as safe to consume after thawing as it was before freezing. Once thawed, however, any microorganisms present can again become active, and under the right conditions will multiply to levels that can lead to foodborne illness. Overall it is therefore very important from a food safety point of view that control measures are put in place to ensure that processing before freezing results in safe food when frozen and that the thawing process does not result in any growth of food poisoning organisms.

High Pressure Processing

MF Patterson, Agri-Food and Biosciences Institute, Belfast, UK

Glossary

Adiabatic heating or adiabatic heat of compression The work of compression during the high-pressure treatment will increase the temperature of foods through a process known as adiabatic heating. The extent of the temperature increase varies with the compression fluid and composition of the food. In water-based systems, the temperature is approximately 2 °C/100 MPa.

Megapascals (MPa) The SI unit of pressure is the pascal (Pa). 1 Pa is equivalent to 1 N m^{-2}. This is a very small unit of pressure and most food applications require pressures in the megapascal range (MPa), where 1 MPa is equivalent to 1×10^6 Pa. Other units of pressure have been, and still are used and a conversion table is given below.

MPa	*kbar*	*kgf mm^{-2}*	*atmospheres*	*lbf in^{-2}*	*tonf in^{-2}*
100	1	10.20	986.9	14 504	6.475
600	6	61.20	5921.40	87 024	38.85

Introduction

High pressure processing (HPP) is being used around the world to treat a wide variety of foods. The rapid increase in commercial use of the technology in the last decade is largely due to the increase in availability of equipment that can routinely and reliably operate at up to 600 megapascals (MPa) at 5–35 °C (~90 000 pounds per square inch or 6000 atmospheres). This is sufficient to destroy many microorganisms in foods, leading to improved safety and shelf-life without adversely affecting sensory characteristics or nutritional quality. However, these conditions are not sufficient to inactivate bacterial spores, so the treatment has been referred to as a 'cold pasteurization' process. It cannot, currently, be used commercially to sterilize foods. The pressure treatment is normally carried out on prepackaged foods so as to minimize the risk of recontamination, post-treatment.

High pressure is generally a batch process for solid foods, although it can be a semicontinuous bulk process for liquid foods. A typical high-pressure system consists of a pressure vessel and a pressure generator (Figure 1). Food packages are loaded into the vessel and the top closed. The pressure transmission fluid, usually water, is pumped into the vessel from the bottom. Once the desired pressure is reached, the pumping is stopped, valves are closed, and the pressure is held without the need for further energy input. Processing costs are claimed to be £0.04–0.20 per liter or per kilogram depending on factors such as the pressure applied, process time, and throughput. Pressure vessels, up to 600 l capacity, capable of processing foods are now available and >150 commercial facilities are in operation around the world, treating a wide range of products with a relatively high throughput, compared to early machines. For example, a 350 l machine can process two tons of poultry products per hour.

A detailed description of how the technology works in practice and the type of equipment involved can be found in articles in the Further Reading section of this article.

Effects of High Pressure on Microbial Cells

There has been much research into the effects that pressure treatment has on microbial cells, which include alterations to the cell membrane, effects on proteins (including enzymes), and effects on the genetic mechanisms of microorganisms. Most authors agree that the lethal effect of high pressure on

 doi:10.1016/B978-0-12-378612-8.00262-6

bacteria is due to a number of different processes taking place simultaneously. In particular, damage to the cell membrane and inactivation of key enzymes, including those involved in DNA replication and transcription, are thought to be primary sites of pressure damage in microorganisms. Stationary-phase cells are normally more pressure-resistant than exponential-phase cells and this may be due to differences in the composition of the cytoplasmic membranes. The complex tertiary and quaternary structure of proteins can be affected depending on the level of pressure applied and this protein denaturation can lead to physical damage to cell membranes. This causes alterations to membrane permeability and has been demonstrated as leakage of adenosine triphosphate (ATP) or ultraviolet (UV)-absorbing material from bacterial cells after pressure treatment or increased uptake of fluorescent dyes such as propidium iodide that do not normally penetrate the membranes of healthy cells. Changes in protein structure can lead to enzyme activity being enhanced or decreased by pressure, either due to changes in the structure of the enzyme itself or to changes in the substrate. In contrast, covalent bonds are generally not affected by pressure, so many compounds associated with the nutritional and sensory quality of foods, such as vitamins, flavor, and color components, are not destroyed.

Factors Affecting the Microbiological Safety of Pressure-Treated Foods

Many factors can affect the response of microorganisms to high pressure. Treatment conditions in terms of the level of pressure applied, the hold time, and process temperature are parameters that need to be optimized. There are significant variations in pressure resistance between different species and even between strains of the same species and the composition of the substrate can also influence the level of inactivation achieved. The response of a variety of foodborne pathogens to pressure treatments in different foods is given in Table 1.

In general terms, applying higher pressures normally results in greater levels of kill in vegetative cells. However, in many cases the inactivation curves do not follow first-order kinetics, and a plot of hold time versus $\log_{10}$ survivors does not give a straight line. Tailing effects are common, with plots showing an initial decrease in numbers, followed by a leveling of the curve, where there is little further inactivation as treatment time increases. Tailing effects have also been reported in thermal processing studies but seem to be more common and more pronounced with pressure treatment.

Table 1 Response of selected foodborne pathogens to high hydrostatic pressure

Pathogen	*Foodstuff*	*Processing conditions – pressure (MPa)/initial temperature (°C)/hold time*	*Level of inactivation*
Aeromonas hydrophila[a]	Ground pork	253/25/15 min	7 $\log_{10}$ inactivation
Campylobacter jejuni[b]	Whole milk	400/25/10 min	>8 $\log_{10}$ reduction
Campylobacter jejuni[b]	Chicken pureé	400/25/10 min	>8 $\log_{10}$ reduction
Campylobacter jejuni[c]	Pork slurry	300/25/10 min	5 $\log_{10}$ reduction
Chronobacter (Enterobacter) sakazakii[d]	Reconstituted infant formula	500/25/26.3 min or 500/40/7.9 min	90% probability of obtaining a 5-log reduction
C. botulinum type A spores[e]	Crab meat	827/75/15 min	3.2 $\log_{10}$ reduction
Clostridium sporogenes spores[f]	Meat emulsion	621/98/5 min	>5 $\log_{10}$ reduction
C. parvum[g]	Apple juice	530/20/1 min	>4 log reduction of oocysts
Eimeria acervulina[h]	DMEM containing 5.8 $\log_{10}$ oocysts	550/40/2 min	No pathogenicity detected in chickens and no fecal shedding of oocysts
Escherichia coli O157:H7 NCTC 12079[i]	UHT milk	600/20/15 min	<2 $\log_{10}$ reduction
E. coli O157:H7 NCTC 12079[j]	Raw poultry mince	600/20/15 min	3 $\log_{10}$ reduction
E. coli O157:H7 (cocktail of 3 strains)[j]	Grapefruit juice pH 3.2	615/15/2 min	>8 $\log_{10}$ reduction
E. coli O157:H7 (cocktail of 3 strains)[j]	Carrot juice pH 6.2	615/15/2 min	>6 $\log_{10}$ reduction
Hepatitis A virus[k]	Experimentally contaminated Pacific oyster (*Crassostrea gigas*)	400/9/1 min	Reduction of >3 $\log_{10}$ plaque forming units
Hepatitis A virus[l]	Green onions	375/21/5 min	Reduction of $\log_{10}$ 4.75 plaque forming unit g^{-1}
L. monocytogenes[m]	Cold-smoked salmon	450/12/5 min	~ 2 $\log_{10}$ reduction
L. monocytogenes[n]	Human milk	400/21/2 min	8 $\log_{10}$ reduction
Murine norovirus[o]	Experimentally contaminated oyster tissue	400/5/5 min	Reduction of $\log_{10}$ 4.05 plaque forming unit g^{-1}
Salmonella spp. (5 individual serovars)[j]	Grapefruit juice pH 3.2	615/15/2 min	>8 log 10 reduction

(*Continued*)

Table 1 Continued

Pathogen	*Foodstuff*	*Processing conditions – pressure (MPa)/initial temperature (°C)/hold time*	*Level of inactivation*
Salmonella spp. (5 individual serovars)[j]	Carrot juice pH 6.2	615/15/2 min	5.31–7.81 $\log_{10}$ reduction, depending on strain
Salmonella spp. (cocktail of 5 serovars)[p]	Orange juice (pH 4.3 and pH 3.7)	600/18/5 s	5 $\log_{10}$ predicted from mathematical modeling of inactivation data
Salmonella enteritidis[q]	Raw chicken breast fillets	400/8/20 min	>5 $\log_{10}$ reduction
S. aureus[n]	Human milk	400/21/30 min	8 $\log_{10}$ reduction
S. aureus[j]	Raw poultry mince	600/20/30 min	<4 $\log_{10}$ inactivation
Vibrio parahaemolyticus[r]	Oysters	300/10/3 min	5 $\log_{10}$ reduction
Yersinia pseudotuberculosis 197 (surrogate for *Y. pestis*)[s]	Orange juice	500/10/2 min	>5 $\log_{10}$ reduction

These tailing phenomena cannot be ignored, for several reasons. First, the effectiveness of any high-pressure treatment must be known in order to produce pressure-treated foods that are safe to consume. Accurate information on inactivation kinetics is therefore essential and a number of models, including Weibull and log-logistic models, have been used successfully to describe nonlinear inactivation data. Second, from a commercial viewpoint, the optimum treatment time needs to be established. HPP is a batch process, so it is important not to have hold times that are longer than necessary, in order to maximize throughput.

Treatment temperature can be another important factor in the level of inactivation achieved. Currently, most commercial treatments are carried out when the initial temperature is in the range of 5–25 °C. There is normally an increase in temperature during processing, due to adiabatic heating. In water-based systems, this equates to approximately a 2 °C rise in temperature per 100 MPa, and the heat quickly dissipates once the pressure is released. Operating at these temperatures means that the fresh appearance and flavor of many foods can be maintained – which is an important advantage of HPP over other technologies. For many commercial applications, the exact initial temperature is not critical, provided it is in the 5–25 °C range. However, in some cases, treatment temperature can have a significant effect. For example, studies with murine norovirus in oyster tissue found that the inactivation achieved was significantly greater at 5 °C than at 20 or 30 °C.

Bacterial spores, including *Clostridium botulinum*, can withstand exposure to very high pressures (>1000 MPa) for long periods of time (>60 min) at room temperature. Therefore, currently, HPP cannot be used commercially to sterilize foodss. However, recent research as shown that the

combination of high pressure and high temperature can be effective in inactivating spores. The process, also known as pressure-assisted thermal sterilization (PATS), requires the food to be preheated to approximately 90 °C, followed by pressurization to approximately 600 MPa for a few minutes and then a rapid decompression. The temperature increase during pressurization, due to adiabatic heating, means that the final product temperature can reach 121 °C, whereas the product can cool rapidly once the pressure is released. Overall, the processing times are shorter and there should be less damage to the quality attributes than when foods are subjected to conventional heat sterilization.

The first PATS product was approved by the US Food and Drug Administration (FDA) in 2009. This was mashed potato, which had the quality expected of the traditional pasteurized product but with the ambient shelf-life capability of a sterilized product. This is a positive development but a number of technical challenges still need to be addressed before PATS will be suitable for widespread commercial use. From a food safety perspective, there is a need to demonstrate control of temperature variation within the processing vessel so as to ensure that products receive a consistent minimum process regardless of spatial position within the vessel.

Vegetative bacteria, including those associated with foodborne disease, are much more sensitive to pressure than spores. Cells in the stationary growth phase tend to be more resistant than cells in the exponential phase, and Gram-negative rods such as *Vibrio* spp. and *Campylobacter* spp. tend to be more sensitive than Gram-positive cocci such as *Staphylococcus aureus.* Significant variation between different strains of the same species has been noted in, for example, *Escherichia coli* O157:H7, *Listeria monocytogenes*, *S. aureus*, and *Salmonella* spp. All of these factors need to be taken into account when preparing suitable cocktails of strains for use in inactivation studies.

There is relatively little information on the effects of pressure on parasites. However, *Cryptosporidium parvum* does appear to have a sensitivity similar to those of vegetative bacterial cells. Treatment of 530 MPa at 20 °C for 1 min gave >4 $\log_{10}$ inactivation of oocysts in apple juice, whereas all treatments between 305 and 550 MPa for 1–3 min gave a significant reduction in oocysts recovered from experimentally contaminated oysters.

The chemical composition and nature of the food can affect the response of microbial cells to pressure. Bacteria are usually most pressure-resistant at a neutral pH and become more sensitive as the pH reduces. This is useful in acid products, such as fruit juices, where the combined effect of pressure and low pH results in a greater level of inactivation than in more pH neutral products such as cooked meats. Water activity (a_w) also affects pressure resistance and a number of studies have demonstrated that reducing a_w from 0.98–1.00 (typical of foods such as fresh meat, fish, and fruits) down to 0.94–0.96 (typical of some cheeses as well as mayonnaise and other sauces) increases pressure resistance. However, these effects may vary, depending on the processing conditions. For example, increasing the processing temperature may counteract the protective effect of a reduced a_w. The baroprotective effect can also vary, depending on the type of solute even at the same a_w. For example, in a model gel system with an a_w of 0.95 and treated between 400 and 600 MPa, sodium chloride appeared to confer less protection than glycerol or fructose, whereas sorbitol had the most protective effect on the inactivation of *E. coli* K12.

The complex composition of foods can make it difficult to predict the response of pathogens to pressure. There are numerous reports that show that the inactivation obtained in buffer systems is generally greater than in real foods. For example, *E. coli* O157:H7 and *L. monocytogenes* appeared to be more resistant when treated in UHT milk than in poultry meat, which was, in turn, more protective than phosphate-buffered saline (PBS) buffer. Cations such as Ca^{2+} can be baroprotective and this may partly explain why many microorganisms appear more pressure resistant when treated in certain foods, such as milk.

As discussed earlier in this section, there are many interacting factors that must be taken into consideration when designing the optimum pressure-processing conditions for the production of safe, high quality foods. These conditions are likely to vary, depending on the product.

Commercial Applications of HPP

In 2008 there were over 150 commercial HPP facilities in use around the world, processing approximately 130 different products. This compares to just 9 commercial facilities worldwide in 1998. For an application to be successful, HPP has to give a unique or significant commercial advantage over existing technologies. These advantages include the fact that vegetative bacteria can be killed without affecting the fresh qualities of the product. This is important for some products such as fruit juices and sauces, where the fresh taste, color, and odor, along with retention of vitamins and antioxidants are unique selling points and can command a premium price. Another important application of HPP is the fact that it can be used to easily and cleanly remove (shuck) meat from shellfish, including oysters, lobster, and crab without affecting the raw, fresh characteristics of the product. The level of pressure required is lower than for many other applications, but will still be sufficient to give some reduction in microbial numbers, including viruses. In addition, this method of shucking significantly improves meat yield, and in the case of lobster, is the only method whereby raw meat can be cleanly removed from the shell and gives the possibility of new products such as lobster sashimi.

HPP can also reduce, or replace, the use of chemical preservatives in certain products such as cooked and cured meats, thus leading to 'clean labels,' which consumers perceive to be more natural and healthy. Other advantages of using HPP include a reduction in waste from spoiled food, as it can extend shelf-life and it is relatively energy efficient, compared to thermal processing, as normally heat is not required.

The main commercial applications are discussed in more detail in the following five sections.

HPP Applications for Cooked and Ready-to-Eat (RTE) Meats

This is one of the most common HPP food applications, in terms of commercial throughput. One of the main drivers

for this use of the technology has been the need to improve the safety of RTE meats. This is particularly true in North America, where there have been a number of product recalls due to contamination with pathogens, particularly *L. monocytogenes*. Within the USA, the USDA Food Safety and Inspection Service (FSIS) published its interim rule in 2003 for the control of *L. monocytogenes* in RTE meat and poultry products (9 CFR 430.). This required meat processors to implement and declare the food safety protocols they use to control *L. monocytogenes*, based on one of three risk-based alternatives (1–3). One obvious way of controlling the problem is to use a suitable postpackaging preservation treatment. An application was made to FSIS, and they have subsequently issued a letter-of-no-objection (LNO) for the use of HPP as an effective postpackaged intervention method in controlling *L. monocytogenes* in RTE meat and poultry products. Within Canada, Health Canada also issued a similar LNO for the control of *L. monocytogenes* in cured and uncured RTE pork products. HPP is now commonly used by many US and Canadian processors to meet the FSIS Alternative 1 category.

Typically pressures up to 600 MPa are applied for several minutes with an initial temperature of less than 10 °C. This is sufficient to give a 5 $\log_{10}$ reduction in *L. monocytogenes*. The treatment has the added advantage of extending shelf-life without affecting product quality.

HPP Applications for Fish and Seafood

One of the main reasons for pressure-treating shellfish is the fact that it allows meat to be easily shucked from the shell without adversely affecting eating quality. The pressure conditions required (typically 400 MPa or less for a few minutes) can also give useful reductions of typically approximately 4 $\log_{10}$ for pathogens such as Hepatitis A virus and *Vibrio* spp. Other viruses, such as murine norovirus-1 (MNV) and Feline Calicivirus, which have been used as surrogates for human noroviruses, are also relatively sensitive to high pressure. For example, with experimentally contaminated oysters, a 5 min treatment at 400 MPa at 5 °C was sufficient to give a 4.05 $\log_{10}$ reduction in plaque forming units.

Overall, these reductions in pathogen loads are particularly useful for oysters and other bivalve shellfish which are often eaten raw or lightly cooked.

Cold-smoked salmon is commonly prepared as an RTE food. The current manufacturing trend is have a less dry product which has lower levels of salt and smoke than in the past. Thus, the antimicrobial hurdles have been reduced, favoring the development of pathogens such as *L. monocytogenes*. HPP has been investigated as one way of improving the microbiological safety of the product. *L. monocytogenes* is relatively resistant to pressure and a treatment of >450 MPa for 5 min would be necessary to achieve a 2 $\log_{10}$ reduction in numbers. However, this treatment has adverse effects on the color and texture of the product. Therefore it is more likely that HPP will be useful in the development of other salmon products where consumers do not expect the specific traditional characteristics of cold-smoked salmon.

HPP Applications for Fruit and Vegetable Products

Fruit purees and sauces became the first HPP foods to be available commercially when they were launched on the Japanese market in the early 1990s. These products generally have a pH <4.5 and the primary reason for using high pressure was to extend shelf-life through the inactivation of yeasts and molds, rather than for reasons of microbial food safety. In the more recent years pressure-treated fruit juices and smoothies have become increasingly popular due to the fact that the treatment better retains quality attributes such as color, flavor, and vitamins, compared to conventional heat pasteurization. Typically pressures of 500 MPa are applied at room temperature or below for 1–2 min and the juices have a shelf-life of 3 weeks with a storage temperature of 4 °C. There have been a number of foodborne disease outbreaks attributed to the presence of pathogens such as *E. coli* O157:H7 and *Salmonella* spp. in high-acid foods, including nonpasteurized apple cider and orange juice. The pathogens generally cannot multiply at low pH, but some strains are acid tolerant and can survive storage in acidic fruit juices. High pressure combined with low pH results in increased inactivation and sublethally injured cells are less able to repair and so die more rapidly during subsequent storage of the juice. Thus, HPP can be incorporated into hazard analysis and critical control points (HACCP) programs to achieve the FDA requirement of 5 log reduction of pathogens in fresh juice.

Vegetable products generally have a higher pH and can potentially support the survival and growth of a wide range of pathogens. However, one of the most successful pressure-treated foods in the USA is guacamole. Its market share continues to grow and is reportedly based on the consumer preference for the 'fresher' taste of guacamole processed in this manner compared to heat-treated or frozen products. Treatment of approximately 500 MPa for 2 min is sufficient to extend shelf-life from 7 to 30 days at refrigeration temperatures. Challenge studies with a variety of pathogens have shown that this treatment is sufficient to give a 5-$\log_{10}$ reduction in numbers.

Other HPP vegetable products available commercially include wheatgrass, broccoli, and carrot juices. In these cases the products are acidified to pH <4.5 to ensure microbiological safety.

HPP Applications for Dairy Products

Currently there are relatively few HPP applications for milk and dairy products, probably because of the widespread acceptance and acceptability of heat treatments.

Patents have been filed for the use of HPP to treat extended shelf-life probiotic dairy-based foods such as yoghurt. Pressure-resistant and acid-resistant strains of lactic acid bacteria are used that can survive the processing conditions and subsequent storage. The use of HPP in the manufacture of cheese has also been the subject of much research. In some cases, the milk was treated with pressure instead of heat as a way of removing pathogens, leading to the possibility of microbiologically safe, high quality cheese with 'raw milk' characteristics. In other cases, mature cheese was treated with pressure in order to stop the ripening process.

There have been a few studies on the use of HPP as a method for inactivating *Cronobacter sakazakii* in liquid infant formula, before spray drying. The organism seems to be relatively pressure-resistant, compared to other pathogens. In one study, a modeling approach was used to determine treatment conditions required to achieve a 90% probability of achieving a 5-$\log_{10}$ reduction in numbers. The pressure-holding times required at 500 MPa were 26.3 and 7.9 min at 25 and 40 °C, respectively.

HPP Applications for Raw Meats, Fish, and Poultry

Research investigations have shown that HPP can be used successfully to inactivate vegetative pathogens in raw meat, fish, and poultry, thus giving safer products with a longer shelf-life. However, until recently, this has not been applied commercially as the pressures required (generally >500 MPa) generally cause changes in the appearance of the raw muscle, which leads to a cooked appearance. However, this problem can be overcome by covering the meat in a suitable sauce. This will also add value to the product as well as improving the microbiological quality. The products can be sold at a premium and there are now some of these in the marketplace.

Future Prospects for HPP

High-pressure-treated foods represent only a small share of the market, compared to foods processed by heat. However, the use of the technology is increasing, especially where it can give unique advantages over existing methods. To date, where pressure is used commercially to improve the safety of foods, this has been applied for the purpose of 'cold pasteurization' rather than sterilization. The next major development in the technology may be the ability to produce shelf-stable foods through the combined use of moderate heat and high pressure. Small experimental facilities are now available, which are capable of operating at temperatures of approximately 100 °C and pressures up to 600 MPa. These systems have been used to produce a limited range of shelf-stable products. Further research is required before this will be commercially feasible. This includes the need for sufficient experimental data to validate the microbiological safety of the foods produced in this way.

One major drawback of using HPP is the fact that it is a batch process. Modern commercial vessels can have a capacity of up to 600 l and such systems can produce 2 or more tons of product per hour per system, depending upon the vessel utilization and packaging configuration. This production rate can be increased further if multiple systems are used in parallel. However, this will still not give the same throughput that can be achieved with other methods, such as heat pasteurization, and this can add to the unit cost of pressure-treated foods. It is likely, therefore, that for the foreseeable future, HPP will mainly be used commercially for high value products, where it gives a unique advantage over other technologies, and where any additional processing cost can be justified.

Microwave Heating

M Regier, Trier University of Applied Sciences, Trier, Germany

Glossary

Athermal- or nonthermal effects Reactions that do not require the transfer of electromagnetic energy into thermal energy thus enhancing the temperature. Instead, the electromagnetic energy itself directly couples to energy to the molecule or lattice.

Electromagnetism Is one of the four fundamental interactions of nature and causes the interaction between electrically charged particles or magnetic dipoles; the areas in which this happens are called electromagnetic fields. Electromagnetism manifests as both electric and magnetic fields. Both fields are different aspects of electromagnetism and are intrinsically related. The classical interactions are governed by Maxwell's equations.

Emission The emission is the emitted (microwave) radiation power of an equipment.

Exposure The exposure is the quantity of absorbed (microwave) radiation energy by a human body or body part.

Pasteurization A heat-treatment process the aim of which is to inactivate or remove most microorganisms but definitely all pathogenic microorganisms from the product with a predefined probability.

Sterilization A heat-treatment process the aim of which is to inactivate or remove all viable forms of microorganisms from the product with a predefined probability.

Introduction

Starting in the 1960s–70s thermal continuous short-time processing operations of food (often combined with high temperatures) became more and more necessary. This is due to the increasing trend to produce foods industrially with high throughputs as well as the trend to produce food with minimum loss of sensorial and nutritional valuable ingredients or even increased nutritional quality, keeping its safety untouched (minimum processed food). The pasteurization of milk in the high-temperature short-time process (ultra-high temperature (UHT) or extremely high temperature (EHT) process) at 140 °C ensuring a safe product needs only a few seconds, during which the product suffers only slight quality deterioration is just one well known example.

For such short-time thermal processes, the heating rate period cannot be neglected compared with the holding times. Short heating times depend on rapid heat transfer mechanisms, which cannot be achieved by conventional heat conduction especially for solid foods, giving a technological push to alternative heating techniques as microwave heating. Although the heating capacity of microwaves was already found in the 1950s, its use in food processing is still relatively limited to niche applications – apart from the domestic use.

Physical Principles

Microwave heating is based, as most other alternative heating techniques, on electromagnetism. The main difference between ohmic heating, microwave heating and infrared heating is in the frequency of the electromagnetic field used. The coupling of the electromagnetic field (mainly the electric component) with the matter is responsible for the energy conversion into heat. Waves of frequencies between 300 MHz and up to 300 GHz are called microwaves (the corresponding wavelength in vacuum or air range from 1 m down to 1 mm).

Electromagnetic waves with frequencies smaller than ultraviolet rays and thus also microwaves can be summarized as nonionizing radiation, which means that the wave photon does not have enough energy to directly produce ions from neutral atoms or molecules. The latter is important for the chemical/physical impact of the radiation.

Generally, electromagnetism waves may be basically described using Maxwell's equations. The interaction of electromagnetism with matter is included in constitutive relations (1–3), where the permittivity or dielectric constant ε, interaction of nonconducting matter with an electric field, the electrical conductivity σ and permeability μ, interaction with a magnetic field, describe their behavior. The zero indexed values belong to vacuum values:

$$\vec{D} = \varepsilon_0 \varepsilon \cdot \vec{E} \quad [1]$$

$$\vec{B} = \mu_0 \mu \cdot \vec{H} \quad [2]$$

$$\vec{j} = \sigma \cdot \vec{E} \quad [3]$$

 doi:10.1016/B978-0-12-378612-8.00410-8

Equation [3] is equivalent to Ohm's law, when the definitions of the current density j and of the electric field (within a homogeneously filled plate capacitor with plate distance l and plate area A) are taken into account.

In general, the material parameters do show a directional-dependent behavior. For most food substances, for practical use this directional dependency is neglected and the relative permeability can be set to $\mu = 1$. Thus, the permittivity tensor can be reduced to a complex constant with real (ε') and imaginary part (ε''), which may include the conductivity σ when an isotropic material is assumed.

Starting from Maxwell's equations the corresponding wave equations (for the electric eqn [4] or magnetic field) or the more general Telegrapher's eqn [5] can be easily derived:

$$\Delta\vec{E} - \mu_0\mu\varepsilon_0\varepsilon\frac{\partial^2\vec{E}}{\partial t^2} = 0 \qquad [4]$$

$$\Delta\vec{E} - \mu_0\mu\sigma\frac{\partial\vec{E}}{\partial t} - \mu_0\mu\varepsilon_0\varepsilon\frac{\partial^2\vec{E}}{\partial t^2} = 0 \qquad [5]$$

showing the wave velocity as defined by eqn [6]:

$$c = \frac{1}{\sqrt{\mu_0\varepsilon_0\mu\varepsilon}} = \frac{c_0}{\sqrt{\mu\varepsilon}} \qquad [6]$$

Furthermore, the conductivity is an additional term to the imaginary part of the dielectric constant (eqn [7]):

$$\varepsilon''_{\text{total}} = \varepsilon'' + \frac{\sigma}{\varepsilon_0\omega} \qquad [7]$$

as the exponentially damped waves are a solution of the above differential equations.

The corresponding electric field penetration depth, the distance in which the electric field is reduced to the fraction $1/e$ can be calculated by eqn [8]

$$\delta_E = \frac{1}{\omega}\cdot\sqrt{\frac{2}{\mu_0\mu\varepsilon_0\varepsilon'\cdot\left(\sqrt{\sqrt{1+\frac{\varepsilon''^2}{\varepsilon'^2}}-1}\right)}} \qquad [8]$$

An important consequence of the frequency dependency of δ_e is that microwaves of 915 MHz do have an approximately 2.5 times larger penetration depth than waves of 2450 MHz, when similar permittivities at both the frequencies are assumed. This larger penetration depth helps to heat larger (industrial) pieces more homogeneously.

With the assumption of the excitation and the propagation of a plane wave, first estimations of the field configurations within applicators and food are possible. For example, the laws of the geometric optics can be inferred, which are also valid for microwaves when the object size is much larger than the wavelength.

So the particular center heating of objects of cm-dimensions with convex surfaces (like eggs) can be easily understood, as at the convex surface the microwave 'rays' are refracted and focused to the center.

For objects that are of the same size as the wavelength or smaller, as well as complex food and applicator geometries direct field modeling by numerical solutions of Maxwell's equations becomes more and more important.

To calculate temperature changes within an object by microwave heating, the power density starting from the electromagnetic field configuration is necessary. Mostly, the electric field is essential to calculate the power dissipation into heat. This power dissipation (per unit volume) p_V is determined by ohmic losses which are calculable by

$$p_V = \frac{1}{2}\sigma_{\text{total}}\cdot\left|\vec{E}\right|^2 = \frac{1}{2}\omega\varepsilon_0\varepsilon_{\text{total}}\cdot\left|\vec{E}\right|^2 \qquad [9]$$

The increase of the power dissipation with increased microwave frequency is obvious (when the permittivity is constant). The power dissipation penetration depth δ_p is reduced by a factor of 2 compared with the electric field penetration depth δ_E (eqn [10]):

$$\delta_p = \frac{1}{\omega}\cdot\sqrt{\frac{1}{2\cdot\mu_0\mu\varepsilon_0\varepsilon'\cdot\left(\sqrt{\sqrt{1+\frac{\varepsilon''^2}{\varepsilon'^2}}-1}\right)}} \qquad [10]$$

Typical values for the penetration depth are listed in Table 1.

Table 1 Penetration depth of microwaves in food materials

Material	*Temperature* $\theta/°C$	*Penetration depth* δ_p*/mm at 915 MHz*	*Penetration depth* δ_p*/mm at 2450 MHz*
Water			
Distilled/deionized	20	122.4	16.8
0.5% Salt	23	22.2	10.9
Ice	−12	–	11 615
Corn oil	25	467	220

Microwave Heating Equipment

Safety Regulations

The frequency range of microwaves is used for telecommunication purposes like mobile phones, radar, or in modern times bluetooth connections, too. To prevent interference problems special frequency bands have been assigned for industrial, scientific, and medical (the so-called ISM) applications, where a certain radiation level has to be tolerated by other applications like bluetooth communication devices. The microwave ISM bands are located at 433, 915, and 2450 MHz whereby the first frequency is not often used, the second is not generally permitted all over the world.

For microwave ovens at home the only used frequency is 2450 MHz, whereas 915 MHz (as well as combinations) has some considerable advantages for industrial applications. Apart from the interference regulations, two types of safety regulations exist:

1. the regulation concerning the maximum exposure or absorption of a human, working in a microwave environment, and
2. the regulation concerning the maximum emission or leakage of the microwave equipment.

Concerning the food safety for microwave equipments no special regulations exist, but microwave-specific safety concerns are addressed in the next article.

1. *Exposure*: The exposure limits for humans is based on the estimation of thermal effects that microwaves can cause in the human body. Thus, the limit for human exposure that is generally considered to be safe is at a level of 1 mW cm^{-2} body surface in most countries. Furthermore as common in the case of ionizing radiation, there is also a trend to express the exposure or absorption by humans by the value of the specific absorption rate (SAR), which is defined as the quotient between the incident power and the body weight. For microwaves the International Commission on Non-ionizing Radiation Protection (INIRC, 1998 as confirmed in a statement of 2009) recommends a value for the SAR to be set to 0.4 W kg^{-1}.
2. *Emission*: The maximum emission of a microwave equipment is limited to a value of 5 mW cm^{-2} measured at a distance of 5 cm from the point where the leakage has the maximum level. Thus, the permissible leakage level is higher than the maximum exposure limit. However, the power density of nonfocused radiation, what is normally the case for leakage, decreases proportional to the inversed square of the distance from the source. So a leakage which just manages to stay in the limits of 5 mW cm^{-2} at 5-cm distance is already below the maximum exposure limit of 1 mW cm^{-2} at a distance of 11.2 cm.

Setup

Three basic parts are generally necessary in a microwave heating device: a microwave source, a waveguide, and an applicator.

The generally used microwave sources for industrial and domestic applications are magnetron tubes with a maximum power of 1.5 and 25 kW for air- or water-cooled systems, respectively, and efficiencies of approximately 70%.

Transmission lines (e.g., coaxial lines) and waveguides are used for guiding the microwaves with minimum losses to the applicator.

Already the waveguide itself can be used as applicator for microwave heating when the material to be heated is introduced by wall slots and the waveguide is terminated by a matched load (the so-called traveling wave device). More common in the food industrial and domestic field are standing wave devices where the microwaves irradiate by slot arrays or horn antennas.

Tuners are waveguide components used to match the load impedance to the impedance of the waveguide, so that tuners minimize the amount of reflected power, which results in the most efficient coupling of power to the load. Furthermore, circulators – directional-dependent microwave traveling devices – are used that let the incident wave pass and guide the reflected wave into an additional load.

Common applicators can be classified into three types based on the type of field configurations:

1. *Near-field applicators*: In the case of near-field applicators the incident microwaves are completely absorbed by the product to be heated.
2. *Single-mode applicators*: To heat substances with low dielectric losses efficiently by microwaves, applicators with resonant modes that enhance the electric field at certain positions (where the material to be heated is located) are used. The applicator has a relatively small dimension to avoid standing wave modes that differ from the desired mode.
3. *Multimode applicators*: By increasing the dimensions of the cavity a fast transition from the single mode to the multimode applicator occurs due to the strongly increasing mode density with applicator size. In industrial as well as in domestic applications the multimode applicators play by far the most important role although a nonhomogeneous field distribution is often dominant. In opposition to the case of the single-mode application, usually this inhomogeneous field distribution which would result in an inhomogeneous heating pattern is not desired as it is hard to control. An undesired inhomogeneous heating pattern can be prevented by changing the field configuration by varying cavity geometries (e.g., mode stirrer) or by moving of the product (conveyor belt and turn table), which also influences the field distribution.

Regulations require the avoidance of leakage radiation through the product flow cavity through the inlet and the outlet. For fluids or granular products with small dimensions (cm range), this can be guaranteed by the small in- and outlet sizes together with the absorption of the entering product sometimes coupled with additional dielectric loads just in front of the openings.

Especially in the case of larger product pieces, inlet and outlet gates that completely close the microwave application device have to be used.

Microwave-Specific Safety and Quality Aspects for Foods

Effect on Microorganisms and Chemical Compounds

Some literature in the past as well as today report on the experimental results that cannot be explained solely due to the thermal effect of microwaves on chemical structures and microorganisms. Thus, frequently assumptions have been made if and how a possible athermal effect of microwaves on cells, spores or chemical compounds could be explained.

However, it is generally believed that inactivation due to dielectric heating in the range of microwave frequency is solely caused by thermal effects. This is also supported by the ICINRP statement on the electric, magnetic and electromagnetic fields (EMF) guidelines from 2009, where only thermal effects are taken into account.

The most impressive theoretical reason for the no-existence of athermal effects is that electromagnetic energy can only be absorbed in quantums. For any athermal effect of microwaves their quantum energy has to exceed the bond energy of chemical bonds but in reality lay 4–5 orders of magnitude below.

Elevated but also reduced inactivation levels that are sometimes observed in microwave applications could be explained in the way that before a temperature equilibration can take place temperatures in hot or cold spots falsify integrated measured values. An elevation of the temperature of a few degrees in the critical temperature range can potentiate the success of inactivation, whereas lower temperatures may serve as 'life-boats' for microorganisms.

Whereas improbable athermal inactivation effects would even support the microbial food safety, a reduced inactivation by microwave heat compared with 'conventional' heat would be much more problematic but in the literature there is no evidence for an elevated heat resistance of pathogenic bacteria exposed to microwaves.

Thus, the United States Food and Drug Administration recommends to act on the assumption that solely thermal effects exist, the more so as all proposed athermal effects increase the inactivation rate. So the ignorance of athermal effects in pasteurization and sterilization processes improves food safety.

n general, it is to be stated that – as opposed to the cell phone and communication sector – in the food sector possible athermal effects do not endanger the consumer. If athermal effects had an influence on food safety, it would increase. This is due to that no chemical changes that can be induced by microwaves that do not occur in conventionally heated foodstuffs.

IActually, the possible risk for food safety in microwave processes stems from another microwave specificity: The temperature distribution in microwave-treated foodstuffs develops completely different compared with conventional processes. So unexpected changes in quality – positive or negative – can occur due to uncommon heating patterns. In principle, it can be stated that where microwaves increase heating uniformity an enhancement in quality can be expected; meanwhile, in processes where extreme uneven heating patterns occur, quality levels fall below the ones of conventional processes.

Inhomogeneous Heating

Depending on the compounds, the geometry of a food sample as well as the used microwave input uneven heating can occur in microwave processing. Several effects that even interact with, amplify and cancel each other, may contribute to inhomogeneous temperature distributions.

On one hand the electric field independent of the load does often not develop homogeneously in the applicator. Especially in geometrically simple structures as, for example, cuboids used in household standing wave patterns will cause the load to be heated more intensely in some parts of the oven than in others.

On the other hand, the dielectric properties of the heated body are temperature dependent and vary in space caused by an inhomogeneous composition of the sample. Sometimes, 'runaway heating'-effects can occur if the absorbed energy by far exceeds the energy that can be transported by heat conduction and when the dielectric loss factor increases with temperature. This happens, for example, if small areas of food melt, meanwhile, most of the sample stays frozen.

Furthermore, the electric field is influenced by the load due to the change in dielectric constant and dielectric loss. In a simple approximation, the electric field is damped exponentially by traveling in a lossy load. The higher the frequency, the more will be the electric field strength already damped in the outer regions of the load.

In addition to that, the geometry of the heated sample plays an important role. Edges and corners often overheat faster than round surfaces. Small bodies with a diameter below some millimeters barely heat, bodies with a diameter below some centimeters tend to overheat in the center due to microwave refraction, superposition of different waves, and focusing effects.

Different from conventional heating processes, on the surface of microwave-heated foodstuffs the effect of evaporative cooling may be pronounced even in drier products, when surface moisture is driven to the surface due to internal vapor pressure buildup.

Nutritional Value of Microwave-Heated Food

A broad literature overview on the nutritional value of microwave-processed food is given by Cross 1982 stating that no significant nutritional differences exist between foods prepared by conventional and microwave methods and any differences reported in the literature are minimal. Again it should be emphasized that differences stem from thermal effects (different temperature distributions) supported by following heat and mass transfers. Nevertheless, for consumer products the worst case scenario for temperature distributions in a household microwave oven has to be taken into account, thus the minimum time and power to reach the necessary temperature has to be labeled on the packaging as well as additional explanations to ensure a homogeneous heating pattern (if wanted). For example, stirring or equilibration times should be stated.

Use of Microwaves in the Industry

Microwave processes often compete with well known and well established standard processes. Of course, only when strong

quality or financial reasons support the use of microwaves these standard processes may be overcome, as the implementation of 'new' techniques also expose some risk.

A possible problem is the right choice of the packaging material. As of high-temperature peaks that can occur in microwave applicators it must have a sufficiently high melting point. Generally, it should be transparent to microwaves, but some metal may on one hand be used as shielding to avoid the overheating of edges and corners. On the other hand, the so-called susceptors allow for additional heat dissipation at selected parts of the product. Thus, for example, browning of surfaces, what cannot be achieved by ordinary microwave processes, is possible. Nevertheless, due to extreme temperatures that can develop in these processes it cannot be generally excluded that chemical compounds migrate from the susceptor material to the food.

Pasteurization and Sterilization

As mentioned in Section Introduction, a shift toward elevated temperatures and shorter process times for microbial inactivation while avoiding intense loss of quality is necessary. This effect is caused by the stronger dependency of inactivation kinetics of microorganisms from temperature than the corresponding degradation kinetics of quality attributes as vitamins and texture. Owing to the limited heat conductivity this advantage cannot be used for the processing of solid and highly viscous foods, where surface regions degrade much faster than central ones. Here lies one chance for the use of microwaves as they overcome the slow heat conduction by heat generation within the product.

A process for microwave based-microbial inactivation consists of four phases: heating, temperature equilibration, holding, and cooling. The special relevance of the second phase due to inhomogeneous heating patterns in microwave fields may exist.

Thus, the most critical point in microwave pasteurization and sterilization processes is to assure that any point in the treated body has reached the working temperature for a selected time. As temperature distributions cannot be easily measured three dimensionally alternative approaches are necessary for the validation of the sterile criteria. One approach is the use of time-temperature integrators.

Often, the effect of evaporative cooling on the surface gives rise to smallest temperatures at the surface in microwave heating of moist foods. This cannot be overcome by simply prolonging the times for equilibration and holding, but by humid atmospheres, waterproof packaging or by using external heating sources.

Tempering and Thawing

Possible benefits of microwave thawing are shorter thawing time, smaller processing space, reduced drip loss, less microbial problems, and chemical deterioration (both due to shorter times). However, the difference of the dielectric loss between frozen water and liquid water of three orders of magnitude is the cause for the so-called runaway heating as soon as a part of the product is completely thawed.

To overcome this problem, instead of fully thawing the food, it is tempered by microwaves to just some degrees below the melting point. Furthermore, surface cooling at temperatures just below the freezing point bewares the surface from melting and minimizes drip loss and quality deterioration.

To achieve a more uniform heating especially for larger products usually a frequency of 915 MHz is used due to its larger penetration depth.

Drying

Microwave-assisted drying has possible advantages: The correlation between dielectric loss and moisture content, the so-called leveling effect, makes the electromagnetic energy rather dissipate in wet regions than in regions of the product that have already been dried. Furthermore, a preferred volumetric heating (even of the product center) that cannot be as easily reached by heat conduction from the surface is possible. Besides, microwave drying processes show often a high efficient drying in the falling rate period that is even delayed observing an extended constant rate period. So, as soon as the evaporation temperature has been reached, the drying rate is proportional to the applied microwave power that makes controlling relatively easy. The volumetric heating and evaporation also reduces the migration of water-soluble constituents to the surface and may increase the internal porosity, which facilitates rehydration.

Nevertheless, some problems may also occur, which also influence the food quality and safety. If at the end of drying, regions of high water content are still existent (due to inhomogenities in heating and evaporation) they may give rise to microbial spoilage. Another critical point may be the occurrence of plasma due to a dielectric breakdown of the atmosphere. Even when the process starts at an uncritical power level where all the power is delivered directly to the load the fall of lossy (moist) material may give rise to an increasing maximal field strength in the applicator (especially at metallic corners). Thus, unadjusted microwave power can allow for a glow discharge (or plasma) that may scorch or burn the product when it appears close to it. Of course, the quality of the product is reduced or even toxic combustion products may develop.

Nanotechnology and Food Safety

VJ Morris, Institute of Food Research, Norwich, UK.

Glossary

Material A single or closely bound ensemble of substances at least one of which is in a condensed phase, where the constituents of substances are considered to be atoms or molecules.
Nanoparticles At present generally accepted as particles with one or more external dimensions in the range 1–100 nm.
Nanoscience The study of materials at the atomic or molecular level.
Nanotechnology The manipulation or materials at the atomic or molecular level.
Particle A minute piece of matter with defined physical boundaries.
Particulate nanomaterial It is currently considered to be a material in the form of particles with one or more external dimensions in the size range 1–100 nm.

Introduction

There are several aspects of nanotechnology that relate to food safety. These include the use of the products of nanotechnology in protecting the authenticity and ensuring the traceability of foods, and the use of nanotechnology in the design of coatings, surfaces, and other food contact materials that will inhibit microbial contamination and detect microbial spoilage. On the other hand, there is considerable debate over the issues and processes of the regulation of nanotechnology, because of concerns about the safety issues related to the ingestion of certain particulate nanomaterials that may persist and accumulate in the body.

Authenticity and Traceability of Foods

Perhaps the most successful use of nanotechnology is in the miniaturization of electronic circuits that has led to vast improvements in computing, communication, and data accumulation and processing. These aspects of nanotechnology offer considerable promise for enhancing food safety. The use of labels or packaging materials, capable of monitoring and reporting on changes in environmental conditions, in combination with radio frequency identification and satellite tracking, provides a basis for tracking food products and their quality throughout distribution and storage. There is considerable interest in the development of a range of sensors that can be incorporated into labels or packaging materials. The particulate nanomaterial components of these sensors, surfaces, labels or coatings will be enclosed within larger solid matrices and are unlikely to lead to migration of nanostructures into food: Migration of particulate nanomaterials into food structure on contact will be an important aspect of the evaluation, regulation, and approval of these products. The use of hand held electronic devices during shopping and to interrogate labels, electronic remote shopping, and the data bases collected by major retailers on consumer purchasing are all benefits of nanotechnology that are regarded as safe and acceptable.

Food Contact Materials

In Europe and in many countries worldwide there is currently debate on the definitions and regulatory procedures needed to evaluate the use of nanotechnology in the development of food contact materials. Recent guidelines from bodies such as World Health Organisation/Food and Agricultural Organisation have stressed the need for universally accepted definitions and regulatory procedures. While this debate continues a perusal of the internet reveals the advertisement and availability of a growing number of food related products claimed to be 'nanoproducts'. A large proportion of these products are food contact materials, and most of these products are claimed to reduce microbial contamination and improve the shelf life of food produce. Although individual manufacturers may have evidence to support their health claims and the safety aspects of the use of these products, there is generally no independent verification of these claims or approval for use in the countries in which these products can be purchased through the internet. The labeling of these products as nanoproducts is used as a branding tool and does not necessarily confirm that they contain nanostructures, or are really produced through the use of nanotechnology. Examples of such products include packaging materials, containers, kitchen utensils, cutting boards, eating utensils, pots, pans, cloths, kettles, and larger objects such as refrigerators. Many of these products use silver

 doi:10.1016/B978-0-12-378612-8.00277-8

nanoparticles as antimicrobial agents (although nanoparticles of other materials such as magnesium oxide and zinc oxide have also been reported to have antimicrobial activity). For these applications the (silver) nanoparticles are enclosed in a solid matrix at the surface of the products. Given that manufacturers of food and food contact materials have a requirement to ensure that their products are safe, and that any approval for use will require studies to establish lack of migration of the silver nanoparticles into foods, it is likely that these products will be safe for use. If they reduce microbial contamination and improve shelf like then they will be of benefit to the food industry. However, there may be ecological or social arguments for restricting the use of such products, particularly if such nanoparticles were incorporated into biodegradable or edible coatings.

An alternative to the use of nanoparticles as antimicrobial agents is the use of nanotechnology to coat surfaces to inhibit the adsorption of microorganisms and the growth of biofilms. This may include the deposition of single layers or multilayers to reduce the roughness of the surface, or to change the physical properties, in order to repel bacteria and ease cleaning and reuse of the materials.

There are suggestions that sensors could be designed to detect the presence of microorganisms and then trigger release of antimicrobial agents. There is also research on the development of sensors that can detect products of microbial spoilage that could be used to signal that a food product is no longer safe to eat – the sensor could for example trigger a color change on a label.

There are already commercial examples of the incorporation of nanoparticles into packing to enhance shelf life on storage: Incorporation of clay nanoparticles into plastics has been used to control the flow of gases into and out of plastic bottles by introducing lengthened diffusion paths for the gases within the plastic composites.

Ingestion of Nanoparticles

There is considerable interest in the use of nanoencapsulation as a tool for the delivery of a variety of components such as vitamins, lycopene, beta-carotene, lutein, phytosterols, coenzymes such as Q10, natural colors, and unsaturated fatty acids. The components themselves can be fabricated as nanoparticles that can be amorphous or crystalline, which often require surface modification to enhance dispersion and prevent irreversible aggregation on dispersion. Examples of nanocrystals include starch, lycopene, and certain fatty acids. Delivery vehicles include nanomicelles, nanoemulsions, molecular cages that can be organic or inorganic and certain biopolymer latex nanoparticles. There are benefits common to nanoencapsulation and microencapsulation. Both techniques can be used to reduce transport and storage costs through the production of powders, to protect components from deterioration on storage, to partially protect or target delivery during digestion, to disguise unpleasant tastes and odors, and to improve the dispersion of fat soluble materials in aqueous medium and enhance their bioavailability. Nanoencapsulation is considered to enhance availability through improved uptake at cellular surfaces. The smaller size of nanoparticles means that they will remain in suspension longer, and scatter less light than larger colloidal particles, allowing use in a wider range of transparent aqueous food and drinks.

The nanoparticles used in nanoencapsulation will be novel food additives or ingredients and the foods they are incorporated into will be novel foods. As such they will require approval for use. At present there is debate as to whether the current regulatory systems are capable of adequately assessing these new types of products. Where the encapsulated components and the capsules themselves are completely broken down and metabolized during digestion the products are probably covered by current regulatory procedures. However, if the components themselves, or the carriers used in nanoencapsulation, are not metabolized or excreted then there is need for more detailed evaluation procedures. Because of their size these materials may enter and accumulate in areas of the body that larger colloidal particles cannot enter: In this case there is a lack of information and methods for assessing the consequences of this persistence and bioaccumulation.

Definitions, Regulation, and Labeling

It is widely accepted that there is a need for worldwide acceptance of definitions of engineered nanomaterials and a procedure for the evaluation and approval of uses of nanoscience and nanotechnology in foods, food additives and ingredients, and in food contact materials. Such definitions need to be enforceable and for this reason it is suggested that they are based on size alone. There is a wide range of definitions of nanostructures and most are summarized in the EU Joint Research Center Reference report EUR 24403 EN. This report suggested particulate nanomaterials as a class of materials that could be identified and that represented those nanostructures that raised concern over their ingestion. The growing consensus is that the evaluation procedure should involve a tiered approach that looks at whether a particular 'nano' product is covered by current regulatory procedures and, if not, identifies classes of products requiring additional information, or new types of methodology for their evaluation. In this context the definitions of nanostructures adopted for regulatory purposes may be important. The term nanomaterials does by definition exclude natural food macromolecules, such as polysaccharides, proteins, and certain lipids, which by most definitions would be called nanoparticles: Materials are by definition structures composed of atoms and molecules. The term particulate nanomaterials would exclude most naturally occurring self-assembled nanostructures present in plant and animal food products, and those nanostructures introduced during processing to generate food gels, foams, and emulsions. Finally, there is growing awareness of the fact that there are essentially two classes of particulate nanomaterials: nonpersistent and persistent particulate nanomaterials. The former, which are completely broken down during digestion are probably covered by current regulatory procedures but will require additional information related to how size affects the site and level of adsorption. For the latter class new information and methodologies will in general be required to evaluate the safety of these products as, on ingestion they can penetrate into regions of the body where larger colloidal particles cannot reach.

Any definitions of nanostructures used for regulatory purposes need to be enforceable. Hence it is likely that they will be based on size alone. The size range chosen is usually between 1–100 nm, although the upper limit is open to debate. This size range is currently chosen such that it will include all particulate nanomaterials where reduction in size leads to significant changes in physical and chemical properties. Given that most of the concern is with the ingestion of persistent particulate nanomaterials that accumulate in the body, and which because of their reduced size penetrate into regions that colloidal particles cannot reach, it may be that this aspect offers an alternative basis for defining the upper size limit.

Environmental Concerns

The incorporation of nanoparticles into solid matrices that limit or prevent migration of the nanoparticles into food or drinks will result in nanoproducts that are safe for use as food contact materials. The products may provide benefits to the food industry, primarily through preventing or detecting spoilage or microbial contamination, thus enhancing shelf life, reducing food wastes and improving food safety. However, there must remain some concern, and some need to consider as part of any approval process, the 'whole life' aspects of these new food contact materials, particularly if persistent particulate nanomaterials are incorporated into biodegradable food contact materials. Approval for food use should consider whether the disposal of these products may ultimately lead to release and accumulation of nanoparticles in the environment and entry into the food chain: There is growing evidence that particulate nanomaterials can be passed up the food chain once they are released into the environment. Thus there may be a need for specific recycling of these products to prevent contamination and/or labeling to enable consumers' choice in the purchase, use, and disposal of these products. The nanoparticles when incorporated into these food contact materials have antimicrobial properties this will need special consideration in terms of the environmental effects. The widespread use of particulate nanomaterials as antimicrobial agents in food contact materials or as food supplements raises concerns that their ingestion or release into the environment may lead to low-level exposure and acquired bacterial resistance to these materials. This may preclude their future medical use as antimicrobials. Where there are ecological concerns this may warrant selective labeling in order to enable consumer choice and to identify any need for special recycling of the products.

Glossary

Good manufacturing practices All practices regarding the conditions and measures necessary to ensure the safety and suitability of food at all stages of the food chain.
Hazard A biological, chemical, or physical agent in food or the condition of food itself with the potential to cause an adverse health effect.
Package A metal can, glass bottle, plastic bag, or pouch suitable for its function of containing the food product, besides providing protection, convenience, and communication for the product.
Permeability The transport of a gas, vapor, or liquid through a barrier without affecting it physically or chemically.
Shelf life Consumer acceptability of product under specified conditions of storage.

Food Packaging

Food packaging is of paramount significance to preserve the quality of fresh and processed foods. It would be practically impossible for the food processors to distribute food without packaging. The several packaging functions include prevention of spoilage and contamination, preservation of food quality, physical protection and product information, bring convenience, and facilitate transportation as well as distribution. Therefore, food packaging may be defined as, 'the enclosure of food products in a wrapped pouch, bag, box, tray, can, bottle or any other packaging material with the functions of containment, protection, preservation, communication, utility and performance.' Packaging may be performed before processing (canning, retort pouch, dairy fermentations, etc.) or can be followed after major processing steps (pasteurization, ultra high temperature (UHT) processing, baking, frying, etc.).

Packaging Functions

The primary function of packaging is to protect the food quality and to prevent the spoilage and pathogenicity during its entire period from production to consumption (Figure 1). The basic packaging functions are elaborated as follows:

Protection

The deterioration of food is either caused by external factors like oxygen, moisture, off flavors, toxins, microorganisms, mass transfer, physical and mechanical damage, or by internal factors like inherent microorganisms. Therefore, the primary function of the package is to protect the food from adverse effects of environment, retain the beneficial effects of processing, extend the shelf life and maintain the quality and safety of fresh or processed foods. Moreover, the diversity in composition, structure, and physiology of fresh and processed foods demands varying levels of protection throughout the supply chain. Therefore, the packaging should be aimed to protect the food from physical, chemical, and biological hazards.

Physical protection shields the food from mechanical damage due to shock and vibration during transportation and distribution. Packaging materials like paperboard, corrugated materials, etc. resist impact, abrasion, and crushing damage caused to fruits, eggs, cakes, etc., during transportation. The replacement of glass bottles with plastic packaging material is another example for increasing the physical protection levels to liquid foods. Chemical protection is aimed to reduce the compositional changes caused due to, for example, oxidation, light, and the resulting degradation of color, vitamins, and nutrients. Glass packaging materials, for example, are inert with absolute barrier to substances, but lack protection against light, whereas metal packaging materials act as an absolute barrier but with some migration issues. Plastic packaging materials as commonly used in food packaging show a wide range of different levels of barrier properties. The third role is to protect the food from biological deterioration caused by spoilage and pathogenic microorganisms (bacteria, yeasts, fungi, and viruses), and animals like insects or rodents.

Containment

The other basic packaging function is to contain food products in specific containers (packages) to facilitate transportation and distribution throughout the supply chain. Without packaging, there would be a huge product loss due to several environmental factors. Moreover, it would be impossible to move liquid products without packages; furthermore, mixing

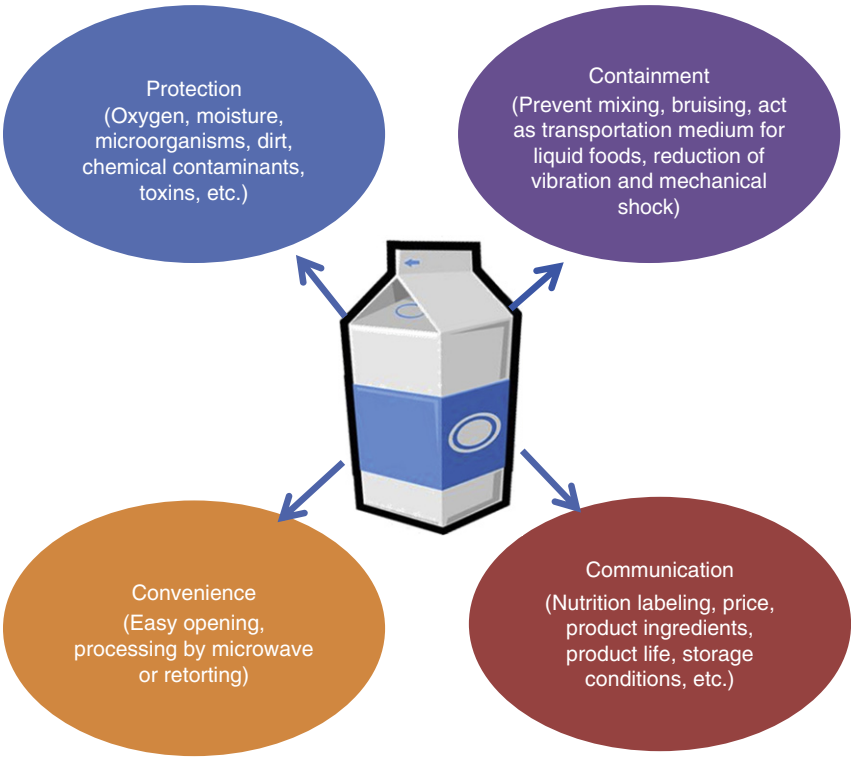

Figure 1 Major functions of food packaging.

of different solid foods is possible due to shock and vibration during transportation. The other associated problems include mixing of graded food stuffs, bruising of soft fruits, physical damage due to friction of loose materials, contamination with air suspended particles, etc. Therefore, packaging reduces the huge loss of food products in the entire product chain.

Convenience

Industrialization and busy work schedules demand the food and packaging industry to bring convenience to food through innovative packaging solutions. The packaging industry has brought convenience by incorporating features such as easy opening, reclosability and processing in the package via, for example, microwavable packaging, oven safe trays or boil in bags. This has enabled the consumers to prepare food in shorter time, which in turn has increased the global demand for packed food.

Communication

Each package is labeled to inform the consumers about the product contents, brand, shelf life, and storage conditions. This communication is important to consumers in order to know the product quality, characteristics, and handling, besides assistance in marketing strategies. Several packaging designs are used to accommodate the product information (nutrients, weight, brand labels, certification, ingredient labeling, barcodes, etc.) in order to satisfy the legal requirements and to promote the product branding. Moreover, the package conveys important information on product storage, cooking instructions, price, and life cycle.

Developments in Packaging

The developments in packaging have moved beyond these basic packaging functions. The introduction of modified atmosphere packaging, active packaging (oxygen scavenging, antimicrobial activity), and intelligent technologies have performed beyond basic functions and increased the product quality, safety, and shelf life beyond consumer expectations. Such innovative technologies need further experimentation to optimize them for cost effectiveness.

Packaging Materials

A number of packaging materials are currently in use for food applications, which are accepted by regulatory bodies like the United States Food and Drug Administration (FDA), European Union (EU), etc. The packaging design and material properties determine the package end use and shelf life of packaged foods. Glass, paper, metal, and plastics are the most important groups of materials used for food packaging.

Glass

It is an inert packaging material with absolute barrier to gases and moisture making it versatile packaging material to retain the flavor and freshness of delicate food products like beer and wine. The other advantages of using glass are that it can withstand high thermal processing conditions, provides good insulation, can be formed into different shapes, and can be supplied in different colors with an optical transmission

between nearly opaque and nearly transparent. Additional oxide coatings help to improve the mechanical properties and give a barrier against chemical attack. Heavy weight, and fragility to internal pressure, impact and thermal shock are some of the limitations for their extensive use in food industry.

Paper

Paper is another commonly used material in the packaging of several food products. Plain paper is hardly ever used for food packaging alone. It has to be modified with several additives (lacquers, waxes, resins, etc.) or extrusion coated with other polymers to improve the barrier properties. Paper and paper boards are used in several forms such as corrugated boxes, cartons, bags, sacks, and wrapping paper. Selected forms of paper used for packaging are given in the following:

1. Kraft paper – Available as natural brown, unbleached, and bleached white. It is the strongest type of paper and is used for bags and wrappings.
2. Sulfite paper – It is usually glazed to improve the appearance, wet strength, and oil resistance. Sulfite paper is relatively lighter and weaker than kraft paper, but has high print quality. It is often used in plastic or foil laminates.
3. Densified and greaseproof papers of different types, e.g. glassine or parchment. They offer fat resistance but give a high permeability to moisture and are used for packaging of biscuits, confectionery and fats.
4. Paperboard – Available in several forms (white board, solid board, chip board, fiber board, and paper laminates), mainly used as secondary packages to improve the handling and distribution of food products.

Metal

The basic metals used for food packaging are steel and aluminum. Steel has to be plated against corrosion by tin, thus giving tinplate or chromium. They offer excellent barrier properties, physical protection, printability, consumer acceptance, and recyclability. Tinplate is produced from low carbon steel, which is coated on both sides with a thin layer of tin. In most applications, they are further lacquered with epoxy or polyester resins to provide an additional barrier to the food materials against corrosion. Containers from tinplate or aluminum are commonly used in retort processing of fruit and vegetables, meat, fish, pulses, cans for drinks, containers for baby foods or powders, confectionery, etc.

Aluminum is further used to produce flexible packaging materials like foil, laminated paper/plastic films, and metalized films. It has several advantages over other metals such as light weight, corrosion resistance and good recycling properties.

Plastics

Plastics can be classified into thermosets and thermoplastic polymers, the latter constituting the major packaging material in form of films, bottles, cups, jugs, etc. for food industries. Although polymers from petrochemical sources are mainly used for food packaging (see Table 1 for details), a tendency has emerged to replace them with bioplastics for reasons of sustainability and environmental issues. The other specific aspect of plastics in food packaging includes the impact of the migration of monomers, oligomers and additives into food, thereby affecting the food quality and, in the worst case, human health. These concerns shall be discussed in more detail in the latter section of the article. However, the use of plastics in food packaging has continuously increased due to the low cost and other functional advantages such as optical properties, thermoselability, microwavability, optical properties, etc. The details of the most important plastics in food use are listed in Table 1.

Special Packaging Technologies

Vacuum Packaging

This is based on the principle of excluding oxygen to prevent the oxidation in oxygen sensitive foods, for example, nuts, beer, chocolates, fats and oils, fried products, etc.

Modified Atmosphere Packaging

This technology makes use of an internal gas composition in the headspace of the package that differs from the composition of the surrounding atmosphere to preserve the food quality for both fresh (fruits and vegetables, meat, etc.) and processed foods (cakes, pastries, etc.) for a longer time. Whereas fresh foods often create a different internal atmosphere due to their own respiration, processed foods need the admission of specific gas mixtures into the headspace of the package.

Active and Intelligent Packaging

Active packaging uses active principles that are generated by or originate from the package and exert a specific effect on the packed food product like antimicrobial agents, oxygen absorbers, ethylene scavengers, etc. The purpose of its use is to preserve and maintain the food quality throughout the supply chain and the storage period at the consumer. Intelligent packaging uses different principles to monitor the status of the packed product and to communicate it.

Aseptic Packaging

This technology creates a package that is virtually free from fertile microorganisms via separate treatment of the product and the package. Thus, a sterile product and a sterile package are combined in the filling step and directly closed afterwards to avoid recontamination. Aseptic packaging gives less thermal loads to the filled product than conventional retorting and allows for a shelf life in the range of several months.

Product-Specific Packaging Materials and Technologies – Shelf Life and Food Safety Aspects

Owing to an array of responsible factors, food quality tends to deteriorate following the produce harvest, processing steps, or

Table 1 Some properties of the commonly used plastic packaging materials for food products

Type	*Physical properties*	*Mechanical, chemical, and miscellaneous properties*	*Barrier properties*	*Food use*
Polyolefins				
PE-LD	Density (910–925 kg m^{-3}); transparency (poor–fair); low crystallinity, temperature range (– 50 to 80 °C)	Tough, flexible, resistant to grease and chemicals, and good sealing properties	High moisture barrier, very low gas barrier	Bread and frozen food bags, flexible lids, squeezable food bottles, etc.
PE-LLD	Density (910–940 kg m^{-3}); transparency (poor–fair); high crystallinity, temperature range (– 30 to 100 °C)	Tough, extensible, good resistance to grease, and good sealing properties	High moisture barrier, very low gas barrier	Stretch/cling wrap, heat sealant coating, etc.
PE-HD	Density (945–967 kg m^{-3}); transparency (poor); high crystallinity, temperature range (– 40 to 120 °C)	Tough, stiff, strong, resistant to grease and chemicals, good sealing properties, and easy to process and form	Very high moisture barrier, very low gas barrier	Used for bottles of milk, juice and water, cereal box liners, margarine tubs, trash and retail bags
PP	Density (900–915 kg m^{-3}); transparency (fair); low crystallinity, temperature range (– 40 to 120 °C), high meting point of 160 °C	Moderately stiff, strong, and good resistance to grease and chemicals	High moisture and low gas barrier	Used for bottles of milk, juice and water, cereal box liners, margarine tubs, hot filled and microwavable packaging, trash and retail bags
PET	Density (1380–1410 kg m^{-3}); High transparency (good); low crystallinity, temperature range (– 60 to 200 °C)	Stiff, strong, and good resistance to grease and chemicals	Good barrier to gases and moisture, very good barrier to flavors and contaminants	As containers (bottles, jars, and tubs), semirigid sheets as (trays and blisters), and thin oriented films (bags and snack food wrappers)
PEN	Density (1.36 g cm^{-3}); transparency (good); applicable at both high and low temperatures	Stiff, chemical and hydrolytic resistance, and thermal & thermo-oxidative resistance	Good gas and moisture barrier properties, UV light barrier	Suitable for hot refills, rewashing, and recyclable Suitable for beer and wine bottles to preserve the flavor
PC				
PVC-U	Density (1350–1450 kg m^{-3}); transparency (good); temperature range (– 2 to 80 °C)	Strong, stiff ductile, resistant to chemicals, and stable electrical properties	Good moisture barrier, moderate oxygen barrier, good resistance to grease and oil	Used in bottles and packaging films Limited use in food applications
PVdC	Density (1600–1700 kg m^{-3}); transparency (good); temperature range (– 20 to 130 °C)	Strong, stiff ductile, resistant to chemicals, and stable electrical properties	Excellent oxygen and moisture barrier properties, very good grease and oil resistance	Suitable for poultry, cured meats, cheese, tea coffee, snack foods, and confectionary. May be used in hot filling, low temperature storage, and modified atmosphere storage conditions
Polystyrene	Density (1030–1100 kg m^{-3}); transparency (very good); temperature range (– 20 to 90 °C)	Hard and brittle with low meting point	Low moisture and gas barrier, fair to good resistance to oil and grease	Used as protective packaging for eggs, disposable plastic ware, cups, plates, bottles, and trays. Expanded form may be used as cushioning material
EVOH	Density (1140–1210 kg m^{-3}); transparency (good); applicable temperatures (– 20 to 150 °C)	Stiff, strong, and very strong oil & grease resistance	Excellent gas barrier, high moisture barrier, very good resistance to grease and oil	Used in coextruded films to avoid its contact with water
PA 6	Density (1130–1160 kg m^{-3}); transparency (good); applicable temperatures (– 2 to 120 °C)	Stiff, strong, and good resistance to grease and chemicals	High gas barrier, low moisture barrier, good resistance to grease and oil	Used for boil-in-bag packaging

Abbreviations: EVOH, ethyl vinyl alcohol copolymer; PA 6, polyamide 6 UV, ultraviolet; PE-HD, high-density polyethylene; PE-LD, low-density polyethylene; PE-LLD, linear low-density polyethylene; PEN, polyethylene naphthalate; PET, polyethylene glycol terephthalate; PP, polypropylene; PVC-U (not plasticized), polyvinyl chloride; PVdC, polyvinylidene chloride.

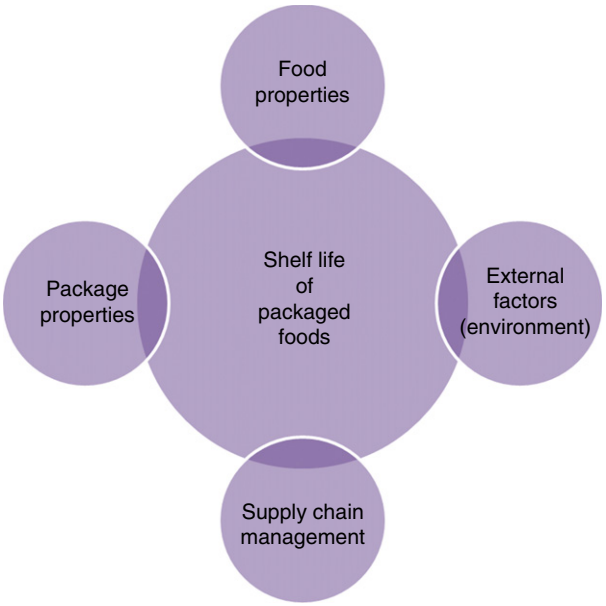

Figure 2 Responsible factors for shelf life of packaged foods.

during storage and handling (Figure 2). The influencing factors may be intrinsic (pH, water activity, enzymes, microorganisms, sensitive food ingredients like poly unsaturated fatty acids, etc.) or extrinsic (temperature, relative humidity, light, storage, and handling). The latter can be controlled to preserve the food quality. The expected shelf life of food products can also be used to group them into product categories from the shelf life perspective, for example, highly perishable, perishable and nonperishable foods. The other aspects of food deterioration have been discussed in detail in other sections of this encyclopedia. Good manufacturing practices in the processing & packaging play a significant role in preventing the food safety hazards. The product-specific packaging considerations may be classified as follows:

Meat, Fish, and Poultry Products

Meat and meat products are one of the most demanded food categories throughout the world. The consumer-related quality indicators for fresh red meat are color, juiciness, and microbial safety. Once the animal is slaughtered, the red meat color pigment (myoglobin) tends to oxidize to either to an unwanted grey-brownish color (metmyoglobin) upon exposure to low levels of oxygen or to the red oxymyoglobin at high oxygen levels. The color change towards grey in meat is an undesirable quality, which is determined by consumers during the meat purchase. Other changes after slaughter include the exudation of fluid from meat muscles that besides resulting in shrinkage of myofibrils, allows a pool of spoilage and pathogenic microorganisms to grow on a nutrient-rich substrate. To preserve the meat quality, packaging plays a vital role in maintaining the shelf life and safety of meat and meat products. Several packaging methods are used by the meat industry for marketing the fresh meat. Vacuum packaging has been widely used to pack meat either for retail or bulk storage. Vacuum packaging may be performed either as shrink packaging, nonshrink packaging, or as thermoformed trays. This method is effective for the prevention of oxidative greying, oxidative rancidity and aerobic microbial spoilage. Some of the limitations to vacuum packaging include proliferation of anaerobic pathogenic bacteria, release of muscle water due to pressure on muscle filaments, and residual oxygen resulting in surface color changes due to oxidation of surface meat pigments. Vacuum packaging is suitable for refrigerated bulk storage with an estimated shelf life of 10–12 weeks at 0 °C. Oxygen permeable trays for meat are in use for a limited shelf life of 2–3 days. The advantage of these packaging systems is the rapid oxidation of the myoglobin to oxymyoglobin, giving the bright red meat color, generally preferred by consumers. However, discoloration proceeds rapidly due to aerobic microbial growth. In the recent years, modified atmosphere packaging (MAP) has emerged as an innovative approach to pack fresh red meats. Modified atmosphere packaging has several advantages over vacuum packaging as it prevents the drip loss, restricts the growth of microorganisms, and retains the meat color. Several gas combinations are in practice and use depending on the type of the meat, for example, high-oxygen MAP, low-oxygen MAP, and ultra low-oxygen MAP. Further details on the MAP of fresh meat and the food safety aspects have been discussed in detail by Robertson (2006) and McMillin (2008). For red meats, a gas composition of 60–80% N_2 and 20–40% CO_2 is reported to be optimal for both the preservation of meat color, avoidance of oxidative processes and prevention of microbial hazards. Industrial practice, however, is to use gas compositions with excess oxygen up to 80%, thus allowing for a very fast formation of oxymyoglobin, but also at the risk of faster oxidative degradation of fats and proteins. Meat is also stored under frozen conditions for long-term storage or during long distance transportation for retail marketing. This is mainly done to arrest the microbial growth. Generally, shrink vacuum packaging is used for frozen meats and restructured meat products. Fresh meat is often processed into different meat products such as cured meats, smoked meat, sausages, minced meat, etc. They require attention against high spoilage risks due to restructuring of meat and exposure to contaminants during processing and handling. Extrinsic factors like proper temperature control is one of the main factors to restrict microbial spoilage and pathogenicity. For processed meat, the packaging requirements include oxygen and light barrier films to prevent especially light-mediated oxidation.

Poultry meat is also prone to spoilage due to favorable pH that supports the growth of a number of microorganisms during storage and distribution. Although the color degradation is not a major concern for poultry, spoilage and pathogenic microorganisms have been the limiting factor. Vacuum packaging of poultry meat is limited to strict refrigerated storage conditions. However, commercially MAP may be suitable at 25–50% CO_2 and 50–75% N_2 levels. The microbial safety of MAP packed poultry has often raised safety concerns. However, MAP with strict temperature management has been successful in preventing spoilage and foodborne outbreaks. Fish is another source of white meat that is highly prone to microbial and enzymatic spoilage. In the natural habitat, the microorganisms are generally attached to the fins

and skin of the fish besides their intestines. Often, these microorganisms are adapted to lower temperatures. Once the fish is caught, postmortem changes follow a series of enzymatic reactions, leading to putrification and spoilage. The spoilage is further aggravated by rapid bacterial growth due to suitable muscle pH. Traditionally, fresh fish is packed in plastic containers directly on ice. Vacuum packaging of fish is limited due to the possible growth of anaerobes. However, the appropriate MAP conditions combined with super chilling have proved efficient for the packaging of seafood. The gas combinations for nonfatty fish and shellfish vary from 25% to 35% O_2, 35% to 45% CO_2, and 25% to 35% N_2, whereas for fatty and smoked fish, the gas combinations vary from 35% to 45% CO_2 and 55% to 65% N_2. However, high CO_2 levels may increase drip loss, pack collapse, clouding of eyes, and acid flavor, all being the negative attributes of fish quality. MAP has been successful in extending the shelf life from a few days to a week's time depending on the fish type, temperature abuse, and other intrinsic and extrinsic factors.

Dairy and Dairy Products

Milk and milk products are highly prone to spoilage and need special packaging requirements to protect them from adverse conditions. A discrimination has to be made between shorter shelf life products like pasteurized milk or yoghurt and longer shelf life products like UHT milk treated at very high temperature. For the latter group, the package should be impermeable to light, oxygen, and moisture. Owing to high water activity, suitable pH and sufficient nutrients, bacteria rapidly grow in milk, thereby spoiling milk and milk products. Fresh pasteurized milk is generally packaged in opaque materials of glass, plastic (PE-HD or PET) or liquid packaging board laminates. If glass containers are used, the headspace is sometimes flushed with inert gas to avoid light-induced flavor changes. In developing countries, pasteurized milk is still packed in PE-LD pouches without a light barrier, which results in loss of Vitamin C and light mediated oxidation. On the other hand, UHT milk is often packed under aseptic conditions in sterile packaging materials to avoid any further contamination. UHT milk is generally packaged in sterile paper-based laminates with an anticipated shelf life of 90–150 days at ambient temperature. Butter is packaged in greaseproof paper laminated with aluminum foil for retail marketing to avoid the contact of any moisture, light, and oxygen. For bulk marketing, butter is also packaged in plastic tubs that are fabricated from PVC. Being sensitive to oxygen and moisture, dry milk products require packaging materials with specifically selected barrier properties. To prevent oxidation, they are often packed in tin cans and flushed with nitrogen gas or vacuum packaged. Aluminum foil/plastic laminates with gas flushing are also used as flexible packaging material for the packaging of milk powders. The class of fermented milk products constitutes cheese and products like yoghurt, kefir, etc. The packaging requirements depend on the product type. Moisture and light barrier properties are required for most types of fermented milk products. However, some cheeses like mold ripened cheese (Camembert) require oxygen for mold growth, and oxygen-permeable films are used to facilitate the fermentation. Modified atmosphere packaging is quite often used nowadays for retail marketing (CO_2 and N_2 in the ratio of 80:20 or 70:30) to avoid undesirable quality changes. Sliced MAP packaged cheese in reclosable tray packages has acquired high consumer acceptance as a convenience product.

Fruits and Vegetables

Packaging requirements largely vary for fresh, fresh cut, and processed fruits and vegetables. They also depend on the respiratory pattern (climacteric and nonclimacteric) of the fresh produce. Temperature, gas conditions in storage, relative humidity, released ethylene, and fruit type are the major factors affecting the postharvest life of fresh fruits. Therefore, packaging materials with shock and vibration resistance as well as different permeation properties are the primary considerations for packaging materials for fruits and vegetables. One has to differentiate between consumer packages used for storage under normal atmosphere and those intended for storage in larger rooms equipped with controlled atmosphere. The latter type has to be highly permeable like corrugated paper board boxes with cushion pad or fruit trays with larger openings to allow a fast exchange of gases with the surrounding. Sometimes, the fresh produce itself is coated with wax or edible emulsions to prevent moisture loss during storage or transportation. The use of MAP for fresh produce and fresh cut fruits and vegetables has gained paramount significance due to retention of flavors, texture and color during marketing. Due to the respiration of the products, the oxygen level in the package is maintained at lower values in relation to the surrounding atmosphere whereas carbon dioxide is enriched. Thus, the fresh produce creates its own modified atmosphere with a composition specific to respiration rate and permeability of the package. Therefore, oxygen barrier films should not be used as it would result in off flavor development during storage. The safety for MAP packed fresh cut fruits has been a challenge in developing countries, especially due to the temperature abuse during marketing of these products. Several microbes of concern include *Clostridium botulinum*, *Pseudomonas* spp., *Erwinia herbicola*, *Flavobacterium*, *Xanthomonas*, *Enterobacter agglomerans*, lactic acid bacteria such as *Leuconostic mesenteroides* and *Lactobacillus* spp., molds, and yeasts. Moreover, the growth of pathogenic microorganisms (*Aeromonas hydrophila*, *L. monocytogenes*, *Yersinia enterocolitica*, etc.) under refrigerated conditions has raised safety concerns. Multiple hurdles can be incorporated in the processing steps and supply chain to inhibit survival, growth, and toxin formation of microorganisms during the shelf life of fresh produce. Laurile and Ahvenainen have suggested the below mentioned hurdles for the minimal preservation in order to extend the shelf life of fresh cut fruits and vegetables:

- Short-time heat treatment
- Lowering the pH (≤ 5)
- Reduction in aw (≤ 0.97)
- Addition of NaCl (3.5%)

Packaging materials used in MAP are usually highly permeable, such as PE-LD, PE-LLD, often coextruded with EVA copolymer, or BOPP, often microperforated to adapt the gas

exchange rate to the requirements of the produce. For cut products with their lower respiration rates and higher sensitivity, an initial gas atmosphere has to be provided. Common gas mixtures for cut fresh salads are 1–5% O_2 and 5–20% CO_2 with N_2 as balance. Sometimes, Argon is added in levels up to 17%. Fruits and vegetables are also thermally processed in metal cans for long-term storage. Defects in cans may be observed when the food leads to corrosion of the metal via pinholes in the interior lacquer coating. In some cases, the cans may bulge on both ends, mostly due to inadequate heat processing, which allows the survival of spoilage or pathogenic microorganisms. *Clostridium botulinum* is of serious concern in the bulged cans as it produces heat stable neurotoxin, which can prove fatal. Glass jars also find their way in the packaging of high moisture fruit products, pickles, chutneys, jams, jellies and soups. Some dehydrated fruits and vegetables are also marketed and they need protection against moisture and oxygen. They can be easily packaged either under vacuum or inert gas atmospheres in extruded flexible plastic pouches, with aluminum lining in order to prevent the oxidation of pigments or color loss.

Cereal and Cereal-Based Products

This group constitutes a diverse range of food products from cereal grains, breakfast foods, to bakery products. Therefore, the packaging requirements considerably vary with the product type. After drying, cereal grains are quite stable due to low moisture content, which does not support any microbial growth. An increase in moisture during storage may be detrimental for e.g. the quality of flour due to the action of amylases. To prevent the permeation of moisture cereal grains are generally packed in kraft paper bags, solid board boxes or even jute bags, all with polyethylene lining. Breakfast cereals are commonly packaged in flexible pouches, sometimes from simple PE-HD, for hot and humid environment also coextruded films of PVdC–PP or PVdC–LDPE in order to prevent permeation. Often, the pouches are further packed in paper cartons to prevent them from light mediated oxidation and mechanical damage. Except for dried baked products like biscuits, crackers and cookies, standard bakery products like bread, buns, pizza, cakes, and doughnuts are prone to microbial spoilage. Antimicrobial agents in use have raised health concerns and research for alternate preservation methods is needed. MAP has attained attention and is currently used in the packaging of several cereal-based baked food products.

Beverages

One of the largest and vital groups of food products (water, tea, coffee, juices, carbonated soft drinks, beer, and wine) requires special packaging requirements to preserve their essence and quality. The consumption of packaged bottled water has increased significantly in the past decade due to the concerns over the safety of municipal water supplies. Bottled water is processed through a series of steps and finally packaged into glass bottles now largely replaced by PET, PP, PVC, or HDPE. The major concern in the packaged bottled water is to avoid microbial growth and the formation of off-flavour. Microbial growth may either be caused by inappropriate UV or ozone treatment or due to microbial contamination from the packaging materials. An associated problem is the development of off-flavors in ozone treated water packed in PE-HD containers. This is due to the migration of butylated hydroxytoluene (BHT) in water. For fruit juice and carbonated soft drinks, packages should have strong barrier for microorganisms, oxygen, and light. Fruit juices are usually packed in glass bottles, metal cans, paper–aluminum–plastic laminates or plastic packaging materials. Glass is mainly used for high quality fruit/vegetable juices, beer, and wine. It has the advantage of being an absolute barrier, which shifts the weakest point of the package to the closure. It allows both for hot filling as well as for thermal treatment of the filled and closed container. to avoid further contamination risks. The cleaning of glass bottles for reuse needs proper attention as they may act as a source of contamination. Metal cans give the same options for filling as glass containers. As many beverages have a low pH value, stable lacqer formulations for interior coating have to be selected to avoid corrosion. Board laminates with plastic and aluminum foil are used for aseptic packaging of juices, whereas plastic film laminates with aluminum foil allow for an easier thermal treatment after filling. The major consideration for the use of plastic packaging materials for beverages is to achieve low oxygen permeability in order to prevent the oxidation of valuable ingredients, like vitamins, and of other constituents, to avoid phenomena like color changes or the formation of off-flavors. For carbonated soft drinks with their added flavors, the barrier against permeation of carbon dioxide and flavor substances becomes another important issue. Although glass and metal containers are frequently used as packaging medium for premium beverages, the gas barrier properties of plastic packaging materials have improved considerably over the last decades with the introduction of new multi-layer materials, including oxygen-absorbing layers, and new barrier coating techniques. This has created a large market segment of plastic containers, mainly on the base of PET for all types of beverages.

Snack Foods and Confectionary

Snack foods are valued for their crisp and crunchy texture, which is lost with moisture admission. The other major cause of deterioration is off flavor development due to the oxidation of fatty constituents like vegetable oil. This group primarily constitutes fried snack foods (potato chips, banana chips, French fries, etc.), extruded puffed snacks, and fruit-based snacks. Their common property is the porous structure which allows the fast access of moisture and oxygen. The second group, confectionary, has a closer structure and is, therefore, much less sensitive. Examples are, sugar boiled confectionary (hard boiled candies, toffees, chewing gum, etc.), and chocolates. The packaging materials for snack foods, have to meet high requirements for oxygen and moisture barrier properties in order to protect them from the above deteriorations. Vacuum packing or inert gas flushing is often used. For confectionary, the influence of elevated temperature is of highest importance. In such instances, strict temperature control as well as optimal

product formulation and design should be taken into account while marketing such products, and the package should be labeled with a temperature storage warning.

Migration Aspects of Packaging Materials

Migration, i.e. the transport of potentially harmful substances from the different packaging materials into the packed food products has been a serious concern for the consumers. Many factors influence this transfer: The composition of the packaging material, the conditions of material conversion and processing and the properties of the food itself determine the amount of substance being transferred into the food. Most of these phenomena are known for plastics packaging which is the reason that this packaging sector has been regulated worldwide to the largest extent. Examples of the migration of monomers or additives from polymeric packaging materials are vinyl chloride, acrylonitrile, styrene (as monomers), diethyl hexyl phthalate, acetyltributyl citrate (as plasticizers), among many other additives. For the single substances, maximum admissible values have been recommended by the relevant regulatory bodies on the basis of toxicological considerations, for example in the form of specific migration limits (SML) in the EU.

Package Opening

The package opening has been a serious issue in the past and has undergone many innovations, leading to the development of easy-to-open packages. True consumer risk with package opening mainly existed with glass bottles and metal cans. Today, opening of a package has to be consumer friendly, which depends on the gender and target group. Females generally exert 75% of the forces that males exert while opening a specific package. Fraunhofer IVV has laid force guidelines for designing easy-to-open packages for different age groups (children, adults, and seniors). The package intended for children (3–4 years old), children (8–10 years old), adults (20–60 years old), and older adults (61–80 years) should open with a force capacity of 4, 10, 17, and 11 N respectively. The opening process, opening principle, removal of the products, consumer safety and behavior, and resealing wherever applicable are major considerations while designing the package opening system.

Conclusion

In summary, the critical factors for food quality and safety considerations of packaging materials are:

Mechanical stability – The material should have sufficient mechanical stability strength to maintain the package integrity during storage and distribution of its entire life cycle.
Permeability – The material should have adapted and sufficiently low permeability for gases, moisture, and flavors as per the product requirements to preserve the quality of fresh and preserved food. Moreover, the package design should prevent changes in water activity during transportation mainly due to incorrect storage temperature.
Light-barrier properties – The packaging medium should protect the food from adverse effects as light-mediated oxidations and color changes.
Microbial contamination – The packaging medium should prevent microbial contamination of the packed product from the environment and the package itself. The microbial growth may also take place inside the package due to inappropriate water activity. This needs to be taken care of while designing the product and the package.
Sealing and lid closure – Proper procedures for sealing and lid closure and, if needed, online leak detection tests shall be adopted to ensure safe product and to avoid recontamination.
Migration aspects – All relevant components of the package should meet the migration limits as per the standards and regulations, thereby taking into account the properties of the specific product and the conditions of filling, distribution, storage and preparation.

Pasteurization

T Deák, Corvinus University, Budapest, Hungary

Glossary

***D* value** Decimal reduction time: the time ins minutes at a given temperature to inactivate 90% (one log cycle) of a microorganism leaving one tenth of survivors.

HTST High temperature short time heat treatment, bulk pasteurization at 70–80 °C for 15–20 s.

Pasteurization units (PU) The cumulative lethal equivalent expressed in the reference temperature, generally 80 °C.

UHT Ultrahigh temperature treatment at 130–150 °C for a few seconds.

***z* value** The temperature change required to change the *D* value by a factor of 10.

Introduction

Pasteurization treatment should be sufficient to kill all non-sporeforming pathogenic bacteria. The more general objective of pasteurization is to extend product shelf-life and maintain keeping quality by inhibiting microbial or enzymatic spoilage. Pasteurization typically applies temperatures 65–70 °C for 15–30 min for products filled in bottles, jars, or cans. Nowadays, however, most liquid foods, such as beverages, fruit and vegetable juices, milk, and some dairy products are pasteurized in bulk by the high-temperature short-time (HTST) method, also called flash pasteurization. In the HTST process, liquids are streamed through heat exchangers (metal plates or pipes) and heated to 70–73 °C for 15–20 s.

Pasteurization is commonly associated with milk for which it is used all over the world. Pasteurization is carried out at temperatures approximately 80 °C for some meat products such as sausages, pickles and sauerkraut, tomatoes, fruit products, juices, and preserves, which have generally low pH below 4.5. To be effective in inhibiting microbial or enzymatic spoilage, pasteurization is frequently combined with other means of preservation such as acidification, concentration, and chemical preservatives.

Scope

Heat treatment with high temperatures is the most important method of preservation that is used widely in the food industry. Pasteurization means a comparatively low order of heat treatment, generally at a temperature below the boiling point of water. In the recent times, however, thermal treatment applying temperatures far over 100 °C only for seconds is also called pasteurization. The process is named in honor of Louis Pasteur, who found that microbes were responsible for the putrefaction of meat and milk, as well for 'disease' of wine, and developed a heat process (later called pasteurization) to preserve wine.

The aim of pasteurization is manifold. Firstly, the heat treatment should destroy most foodborne pathogenic microorganisms except those forming heat-resistant spores. Secondly, the heat destruction should decrease the number of surviving microorganisms to a degree to slow down, delay, or stop the spoilage of food, assuring the product an acceptable shelf-life. Further, heating should inactivate enzymes within the food, which otherwise would cause unwanted organoleptic change. Finally, the moderate heat treatment is able to retain the food quality at a higher degree compared to the more severe sterilization process.

Thermal Death of Microorganisms

The method of pasteurization rests upon the principles of thermal death of microorganisms, according to which the death of a cell population follows the kinetic of a first-order reaction. When the logarithm of surviving cell number is plotted against time, a straight (linear) line is obtained, the slope of which is related to the death rate coefficient. The decimal reduction time *D* is the time in which the number of survivors decreases to one tenth. The value of *D* (in minutes) is independent of the size of population but depends on the degree of temperature. Thus, the *D* value is also a measure of the heat resistance of a given kind (species or strain) of microorganism. The dependence of *D* on temperature is expressed by the value of *z* (in °C or °F) defined as the degree of temperature causing a decimal change of *D*.

The extent of microbial destruction during the process of heat treatment depends on the combined action of temperature and time. Analogously to the calculation of the sterilization requirement and efficacy in F_o value, in the case of

pasteurization the D and z parameters are to be related to fixed reference values, and the cumulative thermal destruction equivalent of changing temperatures and times is expressed in pasteurizing units (PU) or pasteurizing equivalent (P). The reference temperature should be marked; for example, at 80 °C the value is P_{80}:

$$P_T = \int_{T_w}^{T_c} 10^{(T-T_r)/z}\,dt$$

where P_T is the pasteurization equivalent at T, the temperature of heating, integrated between the cooling temperature T_c and the warming temperature T_w, related to the reference temperature T_r and t is the time of heating.

Heat Resistance of Microorganisms

The heat resistance of microorganisms is primarily a genetically determined specific characteristic that can be modified by the environmental conditions. In general, heat resistance is in proportion to the growth temperature (Table 1). Psychrophilic vegetative bacteria become inactivated already at approximately 40 °C, whereas mesophiles have a decimal reduction time of approximately 1 min at 55–60 °C. Certain thermoduric bacteria (e.g., *Enterococcus*, *Microbacterium* species) may survive 30 min heating at 60 °C, with a fairly large z value of 15–20 °C. Heat resistance of most vegetative pathogenic bacteria occurring in foods is similar to those of mesophiles, and they can be inactivated with the conventional pasteurizing treatments at temperatures below 100 °C. Unusually high heat resistance approaching that of thermoduric species is shown by the serotype *Salmonella* Senftenberg.

The majority of yeasts and molds possess heat resistance similar to mesophilic vegetative bacteria. Heat resistance of sexual spores or asexual conidia does not surpass that of vegetative cells. However, ascospores of certain molds, such as species of *Byssochlamys*, *Neosartorya*, and *Talaromyces*, have rather high heat resistance with 7–22 min D value at 88 °C, and these can survive 30 min heat treatment at 90 °C, causing spoilage of pasteurized fruit juices and canned fruits.

Although the vegetative cells of sporeforming bacteria are equally sensitive to heat as other bacteria, their endospores possess high heat resistance (Table 2). The thermophilic sporeforming species are remarkably more heat resistant than mesophiles. Heat resistance of mesophilic spores is characterized with $D_{121\,°C}$ of 0.01–0.1 min, whereas that of thermophiles may reach 2–5 min decimal reduction time at this temperature. From the point of food safety, *Clostridium botulinum* is the most important of the pathogenic sporeformers, having 0.1–0.2 min $D_{121\,°C}$. Among the sporeformers causing spoilage in canned foods spores of *Geobacillus stearothermophilus* and *Clostridium thermosaccharolyticum* have D_{121} values of 3–5 min, and these can survive heat treatments calculated for the destruction of *C. botulinum* (see commercial sterility). Heat resistance of spores is also characterized with z values two or three times higher than that of vegetative cells, in the order of 8–12 °C, and some spores may reach 20–30 °C.

Table 1 Average heat resistance of vegetative microorganisms

Physiological group	D *value (min)*		
	40 °C	*50 °C*	*60 °C*
Psychrophilic bacteria	0.3	–	–
Psychrotrophic bacteria	–	1–5	–
Mesophilic bacteria	–	5–40	0.2–1
Thermoduric bacteria	–	–	1–30
Thermophilic bacteria	–	–	100
Yeasts and molds	–	1–5	0.02–0.4

Factors Influencing Thermal Resistance

The thermal resistance and thermal death of microorganisms and their spores are influenced by several environmental factors. Moreover, although the heat resistance is a specific characteristic, it may differ between strains of a species, and may change according to the physiological state of cells. Cells in the exponential phase of growth are usually more sensitive to heat than those in stationary phase. Spores developed at elevated temperature are somewhat more heat resistant. For the practice of heat processing, the most important factor influencing heat resistance is the composition of product, in particular its water activity and pH.

Decrease of water activity significantly increases thermal resistance (Table 3). This is often the case in foods with high sugar concentration or containing many proteins or fats (Table 4). Spores embedded in drops of fat become subjected to the effect of dry heat, against the effect of which they are more resistant than to moist heat (steam). Acidic environment and low pH also decrease heat resistance (Table 5). Product pH is of outstanding importance for heat processing. pH 4.5 signifies a dividing line; products with pH lower than 4.5 can be pasteurized at 100 °C or below, whereas foods of higher pH than 4.5 must be sterilized over 100 °C. The fundamental safety reason for this is that the most important pathogenic endosporic microorganisms, *C. botulinum*, cannot grow or

produce toxin at pH <4.5, and the spores that may survive heat treatment cannot germinate either.

Factors affecting heat resistance are in force before, during, and after heat processing. Cells surviving heat treatment become damaged, which could be repaired only under optimum conditions but not in a product that may contain certain chemicals, such as preservatives and nitrite or stored at low temperature. These products, although they may contain living bacteria, however they are not able to start growing, and such products remain in a state of 'commercial sterility' without spoilage.

Methods and Equipment

There are two basic methods, batch or continuous, and these can be applied for bulk products or filled in containers. The batch method operates with a jacketed vat heated by circulating hot water or steam, or by heating coils. The vat is filled with bulk liquid food (e.g., milk), heated for the holding period, during which it is agitated. Thereafter the product is cooled in the vat and filled into containers. Similar batch process can be used for products distributed in containers before heating. Some liquid foods (beers and fruit juices) are pasteurized after filling into cans or bottles. Batch pasteurizer for bottles is a simple water bath in which containers in crates are immersed and the water heated to approximately 20 °C higher than the temperature at filling to avoid thermal shock. After the appropriate holding time containers are cooled to 40 °C. Hot water bath can be operated continuously when containers carried by a conveyor are immersed into heating than cooling parts. Another continuous method applies hot water spray on containers conveyed through the heating zone of a tunnel, followed by cold spray in the cooling zone.

A simple way of pasteurization is the hot-fill method by which the product is heated to pasteurization temperatures (above 60 °C) and filled directly into containers, destroying the microorganisms by the heat of the product. After sealing, the closures are decontaminated by turning upside down the container. This method can be applied for high acid products (sauces, purees, and dressings), whose pasteurization can be achieved by the residual heat of the filled product.

Continuous pasteurization saves time and energy over the vat method. For most cases of HTST (see Modes of Pasteurization) pasteurization heat exchangers are used. These equipment offer uniform heat treatment, greater energy efficiency, flexibility for product types, high throughput rates, and control and automation of pasteurization conditions. Continuous heating can be done directly and indirectly. For direct method the heating media (steam) is directly introduced into the product (steam injection), or the product is injected into steam (infusion); whereas by the indirect method the heat is transferred through a surface between the product and the heating media (Figure 1).

There is a large variety of heat exchangers falling into three main types: plate and tube systems and the scraped-surface models. A plate heat exchanger consists a stack of stainless steel plates bounded in a frame. Through the plates flows the liquid, which is heated outside by hot water in a counter current providing $>90\%$ energy regeneration. A tubular system may consists of strait tube surrounded by an outer tube, and can be of spiral or coiled double and triple tubular set. These work under high pressure to assure high flow rates, and bends and wall corrugations effect turbulence to maintain uniform heating and avoid overheating. Scraped-surface heat exchangers are more suitable for viscous foods with particles (e.g., stew). The product flows through a jacketed tube with the heating medium is scraped from the sides with a rotating knife. Modern heat exchangers operate fully automatically and

continuously, and are cleaned in place. With heat exchangers temperatures can be achieved up to 135 °C, and can be used for HTST and ultrahigh temperature (UHT) treatment as well. Heat exchangers are discussed in more detail by Emond in 2001.

Containers for thermally processed canned products can be constructed of metal, glass, plastic laminates or composites of plastic, cardboard, and metal laminates. The most frequently used form of packaging for canned products is tinplate, which is fabricated into two and three piece cans of a wide variety of shapes and sizes. Glass can be equally used for processing canned products. Jars, bottles, and flasks of glass are widely used for pasteurized products (tomato juice, fruit juices, etc.). Plastic or plastic and aluminum foil pouches are now available to withstand pasteurization. Containers used for aseptic filling after heat sterilization are not exposed to heat and pressure, hence a great variety of materials and size are suitable, including laminated cartons, plastics, pouches, cups, and other packs. The first aseptic filling plant for milk was established in Switzerland in 1961. The Tetra Pak Company later became one of the leading suppliers of processing and packaging equipment.

Modes of Pasteurization

There are two main types of pasteurization according to the temperature and time applied. One is a slow process using low temperatures for long time, the other is a flash process using high temperatures for short time (HTST). Important are also the modes of pasteurization being either batch or continuous, and whether the heating process is applied for unpackaged bulk product or after packaging in containers. Pasteurization treatment should suffice to kill all nonsporeforming pathogenic bacteria. The more general objective of pasteurization is to extend product shelf-life and maintain quality. To be effective in inhibiting microbial or enzymatic spoilage, pasteurization is frequently combined with another means of preservation such as acidification, concentration, and chemical preservatives.

Traditional slow pasteurization typically applies temperatures 65–70 °C for 15–30 min for products filled in bottles, jars, or cans. Jacketed vats or tanks can be used for batch process, whereas tunnel pasteurizers are used for continuous heat treatment. However, nowadays most liquid foods, such as beverages, fruit and vegetable juices, milk, and some dairy products are pasteurized in bulk by the HTST method. In the HTST process, liquids are streamed through heat exchangers (metal plates or pipes) and heated to 70–73 °C for 15–20 s. This thermal treatment should achieve 5 log reductions in the number of viable microorganisms, destroying almost all spoilage bacteria, yeasts, and molds, and nonsporeforming pathogens, with the exception of heat-resistant spore formers. Flash pasteurized bulk liquids are filled into containers after heat treatment under rigidly maintained sterile conditions, similar to aseptic processing.

Table 6 Comparison of parameters of various methods of pasteurization

Method	*Temperature (°C)*	*Time (min s)*
Batch (vat)	65	30 min
HTST	72	15 s
Ultrapasteurization	89–100	1 s
UHT	138	2 s

Applications

Pasteurization is commonly associated with milk, for which it is used all over the world. Milk pasteurization was first applied by Franz von Soxhlet in 1886, and since then it has remained the most important operation to extend its shelf-life. Pasteurization is also widely applied to various liquid and certain viscous and particulated foods such as juices, soft drinks, beer, cider, wine, cream and processed cheese, liquid eggs, syrups, sauces, soups, and some ready meals.

For the pasteurization of milk temperatures below boiling temperature are typically used because at very high temperatures casein micelles will irreversibly aggregate (or 'curdle'). There are two main types of milk pasteurization used today: the conventional batch method, by which the milk is heated in a vat at 63 °C for not less than 30 min, and the HTST method, by which the milk is pasteurized at 72 °C for 15 s using a continuous heat exchanger. In the recent times, UHT is also used for milk treatment. It is in fact a sterilization process at 135 °C for 2–5 s only before packaging of milk, which is then filled into containers aseptically (Table 6).

Batch pasteurization is usually made for milk already bottled and has a shelf-life of several days when refrigerated. HTST pasteurized milk typically has a refrigerated shelf-life of 2–3 weeks, whereas UHT milk can last much longer even when unrefrigerated, sometimes 6–9 months.

The HTST pasteurization should achieve a 5-log reduction of the number of viable microorganisms in milk, killing almost all yeasts, mold, and common spoilage and pathogenic bacteria. Exceptionally, some heat-resistant vegetative pathogens, such as *Mycobacterium tuberculosis*, and *Coxiella burnetii*, may survive pasteurization. UHT treatment is expected to destroy bacterial spores as well.

Ultrapasteurization (UP) is a process similar to HTST pasteurization, but using slightly different equipment and higher temperatures. UP pasteurization results in a product with longer shelf-life but still requiring refrigeration. Another method, UHT sterilization, raises the temperature of milk to at least 280 °F for 2 s, followed by rapid cooling. UHT-pasteurized milk that is packaged aseptically results in a 'shelf stable' product that does not requires refrigeration until opened.

Pasteurization regimes for certain dairy products differ depending on the fat content of the product. Ice cream, dairy dessert mix, cream, or processed cheese require more robust treatment, for example, 70 °C for 25–30 min or 80 °C for 25 s.

Most meat products, cured or uncured, are often subjected to heat treatment during or at the end of processing or both times. Pasteurization is carried out at temperatures of approximately 80 °C for sausages filled in natural and artificial casings, resulting in a limited shelf-life and the need for refrigeration. Although cooking would destroy vegetative pathogens and most spoilage bacteria, heat-resistant lactobacilli and streptococci may survive, and psychrotrophic species (e.g., *Lactobacillus viridescens*) may cause spoilage. If stored above 10 °C spoilage can involve mesophilic sporeformers, *Bacillus licheniformis*, *Bacillus cereus*, and *Clostridium putrefaciens*, whereas if heating is lower than 45 °C inside the sausage batter, *Listeria monocytogenes* and *Escherichia coli* O157:H7 would survive.

Most vegetables are low acid products with pH >4.6 and have to be sterilized with the exception of pickles and fermented vegetables, which represent high acid products. Acidified pickled products in salt brine with 0.6–1.0% vinegar and also containing sugar are pasteurized at 80–85 °C. Examples of such acidified vegetables are cucumbers, onions, peppers, and various mixed vegetables.

Tomatoes are fairly acidic with a pH value of approximately 4.6 or less, hence they can be preserved by mild heat treatment generally with pasteurization (e.g., 45 min at 85 °C). Tomato paste is a main product obtained by removal of peel and seeds from tomatoes, followed by concentration of juice by evaporation under vacuum. From the evaporators the paste is passed continuously through a tubular heat exchanger, from which it emerges at a temperature of 90–92 °C. Hot-filling can be applied without further pasteurization. Other tomato products (juice, sauce, soup, and ketchup) are usually pasteurized, assuring the microbiological stability. Depending on the concentration and ingredients (vinegar, sugar, and spices) in addition to pasteurization, further measures can be necessary (e.g., cold storage or salt addition).

Fruit products, juices, and preserves have generally low pH of 3.2–3.8, and can be preserved by pasteurization. Hot filling or tunnel pasteurization can be used for bottled juices; modern thermal processes use the HTST technology and aseptic packaging. Pasteurization of beverages should assure a 5 log cycle reduction of vegetative form of pathogens (*E. coli* O157:H7, *Salmonella enterica*, *L. monocytogenes*). These bacteria, at the usual pH of fruit beverages lower than 4.0, have D values of a few seconds at 71 °C, and z value of 5 °C; however, the heat resistance of spoilage yeasts far surpasses these values, in particular in ascosporic forms. Hence, yeasts are the primary spoilage agents in fruit-based beverages and soft drinks. Heat-resistant molds and alicyclobacilli may also survive pasteurization; however, being aerobic organisms, their spoilage potential in carbonated beverages is limited.

Most canned fruits have a pH lower than 4.5, and these are packed in whole, halved, diced, or sliced cans or jars, and are usually pasteurized at 70–75 °C. Resistant spores of the acid tolerant *Bacillus coagulans* are possible organisms surviving heat treatment and causing flat sour spoilage. Frequently, heat-resistant ascospores of certain fungal species may survive the heat treatment and cause spoilage. Among these are *Byssochlamys fulva*, *Byssochlamys nivea*, *Neosartorya fischeri*, *Talaromyces flavus*, *T. bacillisporus*, and *Eupenicillium baarnense* and some other *Eupenicillium* species. Fruit preserves (jams, jellies, and marmalades) with a sugar concentration of at least 60% and pH between 3.2 and 3.8 can also be pasteurized for 1–5 min at 80 °C.

Among other foods and beverages, pasteurization of beer is widely used. Normally, draft and keg beer is not pasteurized, only the beer filled and sealed in cans and bottles is subjected to mild heat treatment. The process involves running the package in a tunnel through a hot water spray (approximately 140 °F or 55 °C) for 2–3 min. Pasteurization definitely extends the shelf-life of beer; however, its impact on the taste and flavor is debated.

Wine is traditionally stabilized by racking and filtration and its high alcoholic content. However, if the alcoholic content is less than 12 vol%, chemical stabilization may be necessary. Heat treatment of wine is less frequent than that of beer; it is sometimes practiced for religious reasons.

Eggs are important ingredients for several foods. Shell eggs are nearly always contaminated by pathogenic bacteria like salmonellae. Instead of shell eggs, industry prefers to use processed egg products in the form of whole eggs, egg yolk, egg white in liquid (pasteurized), and dried (powered) preparations. Recently, pasteurization of shell egg without cooking has been developed and patented in the US by applying controlled temperature regime.

Pulsed Ultraviolet Radiation Processing

MC Lagunas-Solar, University of California, Davis, CA, USA, and RF Biocidics Inc., Vacaville, CA, USA

Glossary

Ablation The ability of high-intensity light to remove materials from a surface or a liquid due to the absorption of pulsed light energy causing sudden ionization (charging) and electrical repulsion that prompts the particle's removal from the surface.

Advanced oxidation processes In general, it refers to a set of chemical reactions designed to remove organic and sometimes inorganic materials in water and wastewater by oxidation through reactions with hydroxyl radicals ($^{\bullet}$OH). UV radiation generates hydroxyl radicals in any moist environment including the surface of fruits and thus advanced oxidation processes is a mechanism for disinfection induced with UV radiation.

Cavitation An enhancement of range of penetration in materials due to pressure differentials, hydrodynamic factors, or to high intensity, high-power light sources.

Diffuse reflectance Diffuse reflectance is the reflection of a single incident UV light photon from a surface in multiple angles and depends somewhat on the properties of the surface.

Electromagnetic radiation spectrum The complete range of the wavelengths of electromagnetic radiation (waves), beginning with radio waves, radiofrequency, microwaves, infrared, visible, ultraviolet, X-rays, and gamma rays.

Fluorescence Part of a group of luminescence processes in which susceptible molecules or atoms emit light photons from electronically excited states created by physical, mechanical, or chemical mechanisms.

Specular reflectance The mirror-like reflection of UV (or other kinds of waves) from a surface in which UV from a single incident direction is reflected into a single outgoing (reflected) direction.

UV fluence It refers to the amount of UV energy (mJ, J) per unit area (cm^2) and per unit time (s) emitted by a UV source. For pulsed UV sources, UV fluence may be expressed as per pulse instead of per unit time.

Introduction

Ultraviolet radiation (UV) is a form of wave energy (photon) generally recognized as a form of light belonging to a specific portion of the electromagnetic radiation spectrum (ERS). Photon energies in the ERS are directly associated with specific wave properties such as frequency (v) in Hz or cycles per second [cycles per s] and wavelength (λ) in meters (m). Wave properties are related according to Einstein's classic expression

$$E = hv = hc/\lambda \qquad [1]$$

where E is the photon energy (Joules or electron volts [eV]; 1 J = 1.609×10^{-19} eV); h is the Planck's constant (6.626×10^{-34} J s; 4.136×10–15 eV s); v is the frequency (Hz or cycles s^{-1}); c is the speed of light (2.998×10^8 m s^{-1}); and λ is the wavelength (m).

In the ERS, UV photons belong to a wavelength range between 10 and 400 nm (1 nm = 10^{-9} m) and therefore possess wavelengths shorter than visible light (400–800 nm) but longer than X-rays (< 10 nm). Photon energy and wavelength are also related by eqn [1], but the relationship can be simplified and expressed as

$$E\,(\text{eV}) = \frac{1240}{\lambda}\,(\text{nm}) \qquad [2]$$

International standards (ISO-21348 – Process for Determining Solar Irradiances. (http://www.spacewx.com/ISO_solar_standard.html) identify UV bands as given in **Table 1**.

UV light is present in solar radiation (sunlight) and is therefore a natural source of radiation energy invisible to the human eye that propagates at the speed of light and in straight paths. As the earth's atmosphere absorbs most of the space (solar) UV radiation, any UV application is based on man-made UV sources.

In the solar spectrum, the high-energy UV photons (10–120 nm; 124–10 eV) are capable of ionizing molecules by a single-step energy transfer process to electrons which, when lost, leave molecules (or atoms) with positive charges in a process called ionization. Molecular oxygen (O_2) and other gases (i.e., ozone, sulfur, and nitrogen oxides) in the earth's atmosphere are effective in absorbing (blocking) high-energy solar UV photons. Therefore, only low-energy non-ionizing UV photons reach the earth's surface. However, the absorption of low-energy UV photons leads to an excitation process in which the absorbing molecule (or atom) is excited to higher vibrational and rotational levels increasing the reactivity and onset of a photochemical reaction.

Today's ultraviolet C (UVC) applications ranges from industrial to medical areas and are summarized in **Table 2**. For food safety applications, the germicidal UVC radiation has

Table 1 Ultraviolet (UV) bands, boundaries, and general properties

UV band	*Notation*	*Wavelength (nm)*	*UV photon energy (eV)*	*Chemical effects*
Before UV	Visible	>400	<3.10	None
Long wave UV	UVA	400–315	3.10–3.94	Excitation
Near UV	NUV	400–300	3.10–3.94	Excitation
Medium wave UV	UVB	315–280	3.94–4.83	Excitation
Short wave UV (germicidal)	UVC	300–100	4.1–12.4	Excitation Ionization
Far UV	FUV	200–122	6.20–10.2	Ionization
Vacuum UV	VUV	200–100	6.20–12.4	Ionization
Low UV	LUV	100–88	12.4–14.1	Ionization
Super UV	SUV	150–10	8.28–124	Ionization
Extreme UV	EUV	121–10	10.2–124	Ionization
Beyond UV	X-rays	<10	>124	Ionization

Table 2 Applications of ultraviolet (UV) radiation in different energy ranges

UV energy (eV)	*Wavelength (nm)*	*Applications*
6.2–3.1	200–400	Forensic analyses, drug detection
5.6–4.4	220–300	UV disinfection (germicidal band)
5.4–3.4	230–365	UV identification; barcodes; label tracking
5.4–3.1	230–400	Optical sensors; UV spectrophotometry
4.6–3.4	270–360	Chemical analyses (proteins; DNA)
3.3–3.1	280–400	Medical imaging (cellular structures)
4.1–3.1	300–400	Solid-state lightning
4.1–3.9	300–320	Medical therapy
4.1–3.4	300–365	Polymer and printer ink curing
3.5–3.4	350–370	Insect controls
92	13.5	Lithography

special affinity for some proteins and enzymes and in particular, for the nucleic acids. Therefore, UVC is considered as a desirable technology to disinfect foods.

Its effectiveness in controlling the growth of single-cell organisms (i.e., fungi, bacteria) and viruses is well established. However, a lesser known fact is UVC's effectiveness with complex, multicellular organisms like nematodes and arthropod (insects and mites) pests. The inactivation occurs as a result of exposing a pest with UV energy intensity (I) over a certain time of exposure (t). This $I \cdot t$ factor varies between organisms but once a threshold value is reached, the UVC radiation is an effective sanitation technique.

However, UVC radiation has limited depth (range) of penetration in most materials and especially in biological (plant) tissue. In air, UV penetrates thousands of meters and several meters in optically clear water. However, its penetration is severely limited (few microns) in biological tissues due to the presence of absorbing chemicals. Therefore, UVC inactivation is restricted to the surface of solids or to a narrow depth in liquids.

Historical Background

Since the early part of the twentieth century, UV radiation from mercury (Hg) lamps was used successfully for the sterilization of drinking water. In 1903, Niels Finsen was awarded a Nobel Prize for the work on using UV radiation to treat tuberculosis.

Since its inception, UVC disinfection competed with chemical disinfectants, particularly with chlorine alternatives (established in the nineteenth century). Since the 1970s, in most developing nations, UV techniques were chosen to sterilize potable (drinking) water. With improved designs, higher power, and reliability, the electronics industry was involved in the commercialization of the Hg lamp technology, a trend enhanced by health apprehensions related to the use of chlorination, in particular for wastewater disinfection. Concerns were due to the formation and carcinogenic activity of disinfection by-products (DBPs) by UV-induced photolytic effects on the organic-rich wastewater streams. New regulations were adopted for the enhancement of worker, general public, and environmental health protection. (In 1974, the US Congress passed the Safe Drinking Water Act. In 1979, the US EPA developed drinking water rules of tetra-halo-methane (THMs) DBPs allowed in drinking water.)

Since the late 1970s, the pharmaceutical, cosmetic, liquid food (beverages), and food sectors successfully incorporated Hg lamp UVC systems to provide higher quality disinfected water. In addition, air- and insect-control techniques were incorporated (UVC is effectively blocked by the Earth's atmosphere. Therefore, applications require man-made UVC radiation sources.).

Today, UVC radiation has a small portion of the potable water disinfection market although food disinfection is considered as an emerging opportunity due to the increased consumer awareness regarding microbial contaminants in foods as well as by concerns with pesticide residues. (In 2012, the Center for Disease Control in the US reported that one out of six consumers (~48 million) are affected by foodborne diseases; ~128 000 need medical assistance resulting in ~3000 deaths. (www.cdc.gov/foodborneburden.)) UVC technology, as a physical energy process, is viewed as a non-invasive (residue free) technical alternative.

UVC Source Technologies

The food safety applications are based on two man-made sources of UVC radiation: (1) Hg germicidal lamps (black lights) to deliver continuous UV power; and (2) arc or flash lamps for pulsed UV (PUV) applications. New potential applications for food safety rely at present on the readily-available Hg germicidal lamps, on arc lamps with continuous emission, and on flash lamps operating with PUV emissions. Limited power and facility (space) cost are the major concerns with Hg lamps but a major factor for their use is the past record of operation in water disinfection. The presence of toxic Hg in food processing facilities is a lesser concern.

Hg Germicidal Lamps

Mercury UV lamps emit long wavelength UV with a small fraction of visible light. Quartz tubes containing a set of electrodes and liquid Hg have become a technology of choice for low- to medium-intensity fluorescence sources of continuous UVC radiation. Fluorescence is an energy absorption process of certain atoms or molecules exposed to high-energy photons (lower wavelength) or particles which excite their electronic energy levels to higher levels, followed by the emission of lower energy photons (longer wavelength) through a subsequent de-excitation process. Remaining energy in the absorbing molecule (or atom) is converted into higher vibrational and rotational energy levels (www.bing.com/Fluorescence). The quartz tube could be coated and the interior surface modified with a deep bluish-purple glass (a nickel oxide doped glass) to enhance UV emission while stopping visible photons (i.e., black light lamp).

Fluorescent lamps without any phosphor coating (i.e., clear quartz Hg lamps) emit 253.7 nm (85–90%) and 185 nm (5–10%) photons and few other emissions. The 185 nm photons are absorbed by a special coating, thus the formation of ozone (O_3; a powerful oxidizer) from photoactivation of oxygen (O_2) is prevented. The 253.7 nm emission is very near the most absorbent UV wavelength for deoxyribonucleic acid (DNA) and provides an efficient process to damage DNA and prevent its replication. This is the rationale for using this UV source technology to provide germicidal effects.

Germicidal lamps use liquid Hg that vaporizes when a steady voltage is applied causing a low-pressure Hg vapor to form and normally operate at approximately 30 °C with 30–35% overall efficiency in converting electric to UV power. The applied current excites the Hg electronic levels which return to the ground (standard) states by emitting noncoherent (all directions) characteristic UV rays.

UV emission can be enhanced with Hg amalgams that increase the operating temperature to near 100 °C doubling or tripling the UVC output. Total emission power is dependent on the arc lamp length allowing a range of germicidal lamps to operate in the 100–400 W UV power range.

Germicidal lamps are readily available from many manufacturers/distributors worldwide (www.globalsources.com/manufacturers/Mercury-Lamps.html). As a result, design and UV power range are broadly based on intended use and throughput needs. Support and services for the Hg-based UVC sources are also well developed and available for most disinfection and air- and insect-control applications.

A schematic of a low-pressure Hg lamp is shown in Figure 1.

Arc or Flash Lamps

Arc or flash lamps are a specialized group of gas discharge lamps mostly filled with xenon (Xe) in which an electric

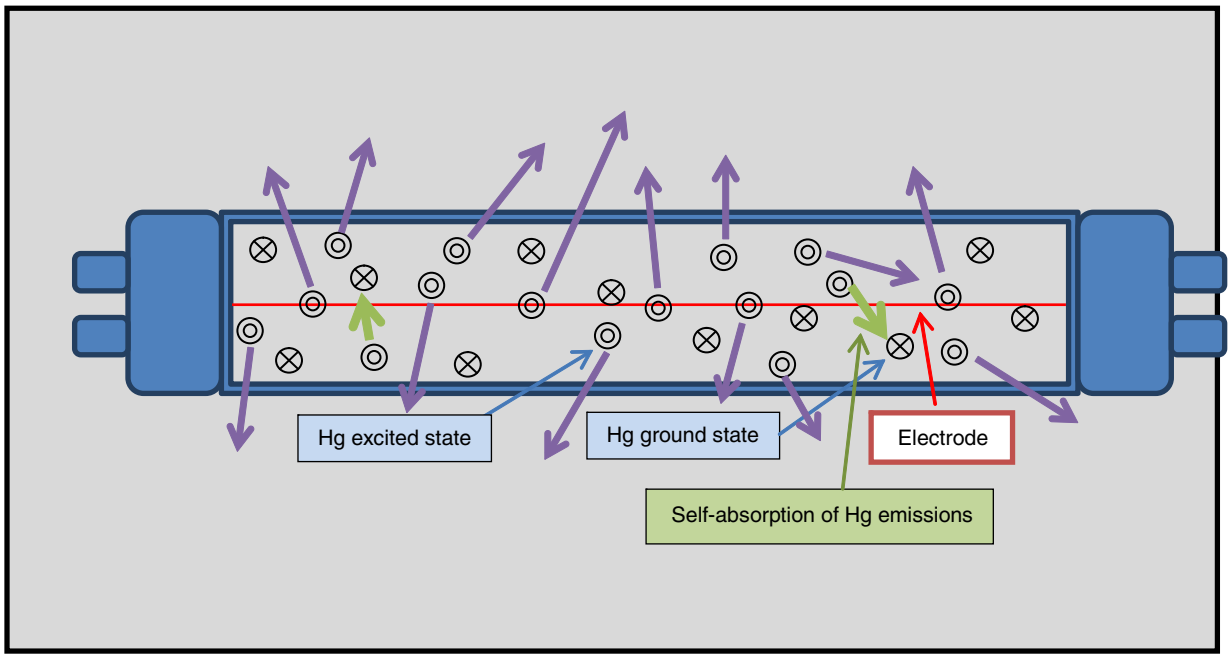

Figure 1 Schematic of an Hg-based germicidal lamp. Emission of UV photons is noncoherent (all directions) and self-absorption occurs by ground-state Hg, a limiting factor in pressurizing Hg lamps for higher output.

current is applied to a pressurized gas (up to 30 atm). (Because of the high gas pressure, the operation of these arc lamps presents worker safety issues requiring special handling to prevent accidents due to explosion.) The gas ionizes allowing the passing of electricity and producing a bright white broadband radiation emission (light). A typical Xe-filled arc lamp with continuous emission of UV and visible light is shown in Figure 2.

The emission spectrum from arc or flash Xe lamps contains not only a significant band of UV radiation but also visible light and some infrared radiation (see Figure 3). Other gases may be used to generate different emission spectra shifted to other UV bands (i.e., nitrogen gas for vacuum UV). The emission spectrum is broad and similar to the solar radiation spectrum (natural sunlight) and is used in producing natural lightning conditions for illumination and projection applications. These lamps are made with glass or fused quartz tubes to prevent absorption of UV photons and with tungsten metal electrodes at both ends. Some arc lamps with high power (> 10 kW) ratings require water cooling as a significant fraction of the generated power is converted to thermal (heat) power.

Xenon-filled arc lamps were developed in Germany in the 1940s and introduced commercially in the early 1950s. Today, Xe arc lamps with continuous emissions for use in illumination, projection, and research applications, operating in the 10 W to ~20 kW power range are commercially available.

However, recent developments have incorporated a pulsed power Xe 'flash' lamp option using ultra-short pulses (milliseconds) for similar applications but using high peak UV power (several megawatts per pulse). Overall, Xe arc and flash lamps generate a substantial UV radiation that reaches up to 18–20% of the total emission spectrum per pulse.

A comparison of the emission spectra from Hg-based germicidal lamps, several excimer lamp systems, and the broadband high-power Xe-filled flash lamp, is also shown in Figure 3.

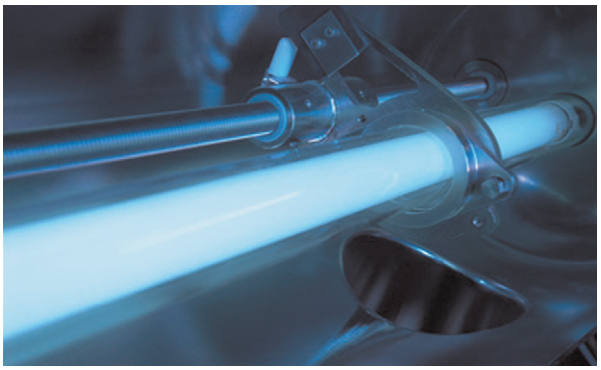

Figure 2 Typical Xe-filled excimer lamp UV with external water cooling. http://halmapr.com/news/aquionics/files2007/03

Mechanisms of UV Disinfection

Photochemical Reactions

UV radiation is effective in altering the chemical structure of biological molecules including the nucleic acids. DNA represents the most likely target as its nucleotide bases (purine [adenine; guanine] and pyrimidine [thymine and cytosine] derivatives) are highly UV-absorbent chromophores (i.e., sites). Therefore, UV-induced DNA changes are critical and

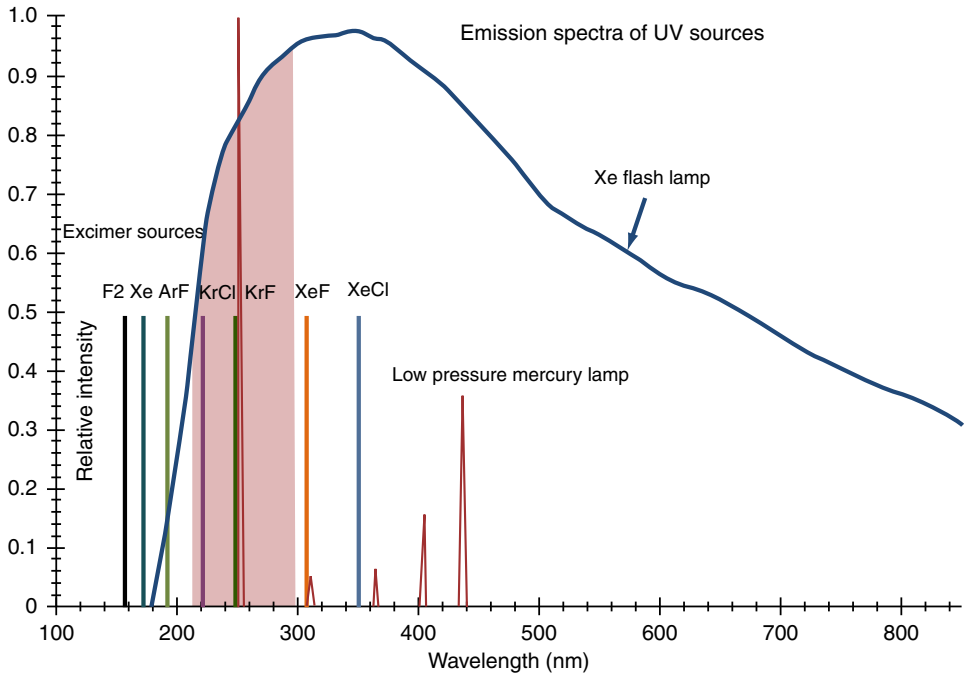

Figure 3 Comparison of emission spectra for different UV radiation sources. The shaded area indicates the germicidal UV photons emitted from the broadband high-peak power PUV Xe flash lamps.

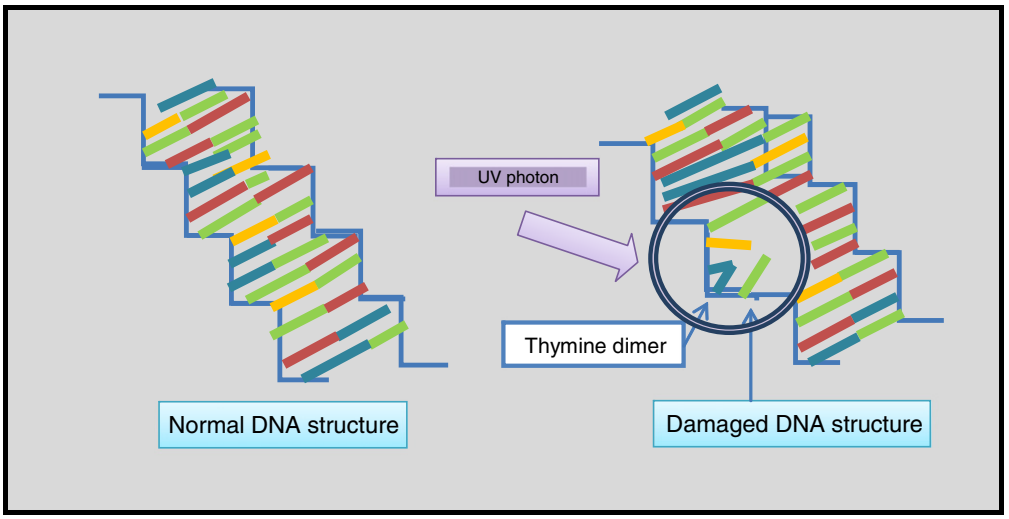

Figure 4 Thymine-dimer formation by photochemical-induced lesions in DNA with UVC radiation.

responsible for the disinfection action of UV photons. DNA has a maximum UV absorption band at 265 nm and the photobiology effects results in DNA mutagenic and cytotoxic lesions that damages microbes and humans.

By comparison, proteins absorb mostly at ~280 nm and at equal concentrations are lower absorbents than the nucleic acids. Other lesser chromophores include porphyrines, carotenoids, steroids, and quinones.

The structural alteration of UVC radiation in DNA is illustrated in Figure 4, and is based on the formation of cyclobutane pyrimidine dimers (CPD), known as thymine dimers. This lesion occurs when neighboring thymine bases holding DNA's helix structure are excited by the absorption of UV energy, breaking bonds and prompting the formation of new bonds between thymine base pairs as opposed to across the individual single strands as in the normal DNA structure. This results in the deformation (distortion) of DNA's helix structure restricting its effective coupling with catalytic enzymes, a critical initial step in the cell's transcription and replication processes.

UVC-Induced Cellular Lesions

Two major UV-induced lesion mechanisms in cells form CPDs and/or 6–4 photoproducts (6–4 PPs) and their valence isomers. These are the principal lesions leading to mutagenesis. The formation of 6–4 PPs also may result in changes in cell metabolism as they can inhibit or induce other combined cytotoxic effects.

Other lesions are usually initiated by: (a) alkylating agents that play an essential role in many biosynthetic reactions but that can modify the structure of nucleotides into a mutagenic compound, a miscoding alteration, or even a lethal noncoding damage; (b) by hydrolytic processes that deaminate nucleotide nature; and (c) by formation of short lived but highly reactive free radicals including reactive oxygen species induced by UV (i.e., photolysis reactions).

Any UVC source is effective in inducing critical lesions that inactivates vital cell processes. Therefore, all UVC radiation sources are potentially useful for food safety applications as will be discussed below in Section Applications of Pulsed UVC (PUVC) Radiation in Food Sanitation.

Repair Mechanisms

The initial controlling action of absorbed UVC radiation may be totally or partially counteracted by cell mechanisms to repair the initial photochemical lesions. These repair mechanisms (dark and/or enzymatic) allow for cell survival and may lead to mutagenesis. The cell's capability to repair also leads to different resistance (tolerance) levels to UVC absorbed radiation doses.

The ability to repair lesions is governed by second-order kinetics with the limiting reactant being the specific chemical initiating the repair process. Therefore, to overcome repair and mutagenesis, the choice of UV source technology is critical. High peak of UV power is preferred as it leads to the short timed formation of excited DNA at concentrations above the capability of repairing molecules. This is further discussed below in Section Potential Uses of High-Power PUVC Radiation Sources.

The different consequences following UVC exposure in generating DNA lesions are further illustrated in Figure 5.

Applications of Pulsed UVC (PUVC) Radiation in Food Sanitation

By nature, the UV process is a physical method of photon energy transfer that offers nonthermal and nonchemical (residue free) sanitation alternatives apt for temperature-sensitive commodities (i.e., fresh produce); for processed foods (i.e., fruit juices and milk) and for other food and agriculture commodities. UV disinfection of air and water is already practised and extension of its use to irrigation, processing (washing), recycled, and waste water is being developed.

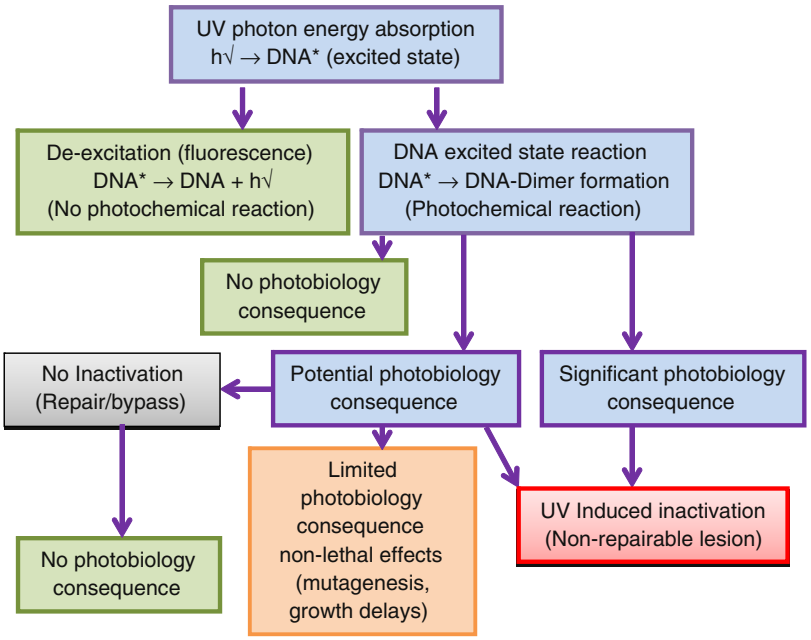

Figure 5 Photochemical, repair, and cell mechanisms following absorption of UVC radiation.

Continuous and PUVC Sources

Today, commercial scale Hg lamp technologies for water and air disinfection are successful and credible processes are providing a strong basis to consider new UVC applications. However, the choice of UVC technology is again critical. For example, for surface disinfection of fresh fruits, Hg lamps have limited power with limited throughput that imposes substantial changes in infrastructure and practices. By contrast, new and reliable PUV systems are now available commercially and operate with high repetition rates at competitive costs. More importantly, their compact modular designs and small physical profile allows implementation within the existing infrastructure.

Potential Uses of High-Power PUVC Radiation Sources

Studies at the University of California, Davis, since 1992, have firmly established the potential uses of PUVC sources for many applications in food and agriculture. Results and rationales for potential commercial uses with liquid and solid commodities are discussed in Sections Liquid Foods (Volumetric Disinfection) and UVC disinfection of fruit juices

Liquid Foods (Volumetric Disinfection)

The UVC disinfection action with liquid commodities is volumetric as pathogens are dispersed throughout the entire volume of a commodity. However, for process uniformity, special mixing techniques are required. For fruit juices, several prototype UVC reactors have been considered. For larger volumes (i.e., irrigation water), reactors are simply combined to achieve the needed flow throughputs.

UVC disinfection of fruit juices

Today, the leading commercial method for the sanitation of fruit juices is pasteurization, using a mild thermal process ($\sim$72 °C [162 °F] for 15 s) efficient to inactivate vegetative microorganisms including *Escherichia coli* spp., *Listeria* spp., and *Salmonella* spp., but not heat-resistant spores (e.g., *Bacillus* spp.). However, pasteurization reduces the nutritional value of fruit juices by destroying some essential vitamins (i.e., C, B1, B2, and natural enzymes) and noticeably changing flavor. Nevertheless, the lack of alternatives has forced the industry to adopt pasteurization although in full recognition of its shortcomings. However, pasteurization in the US is not mandatory and therefore the development of alternative methods has been encouraged including the use of nonthermal UVC irradiation (US Food and Drug Administration-approved 21 US Code of Federal Regulations 179) to achieve >5 $\log_{10}$ reductions. UVC radiation processing of liquid milk has already been investigated and it is a nonthermal potential alternative to heat pasteurization.

Nonthermal UVC disinfection of fruit juices is not new but is conducted with Hg germicidal lamps limiting the flow rate capabilities. High processing rates are required, thus several hundred Hg lamps are used adding complexity in operation and maintenance. In addition, special handling methods (i.e., annular, concentric, and rotating tubes) and reflecting devices are needed to process the juices effectively and uniformly.

Current turbulent-flow UVC reactors include $\sim$90 m ($\sim$300 ft) of UV transparent tubing surrounded by hundreds of Hg lamps. By comparison, if laminar flow conditions are used, very thin layers of juices may be exposed but this simpler approach is restricted to optically clear, low viscosity fruit juices, thereby limiting throughput.

A PUVC reactor system Figure 6, was designed based on tests with a single PUV Xe flash lamp at the University of California, Davis. It combines six Xe-filled flash lamps for a total peak UV power of $\sim$2.4 kW pulse^{-1} at 10 pulse per sec(pps) repetition rates. It uses Spectralon^{TM} reflectors, a commercial fluorinated polymer with $>$99% diffuse

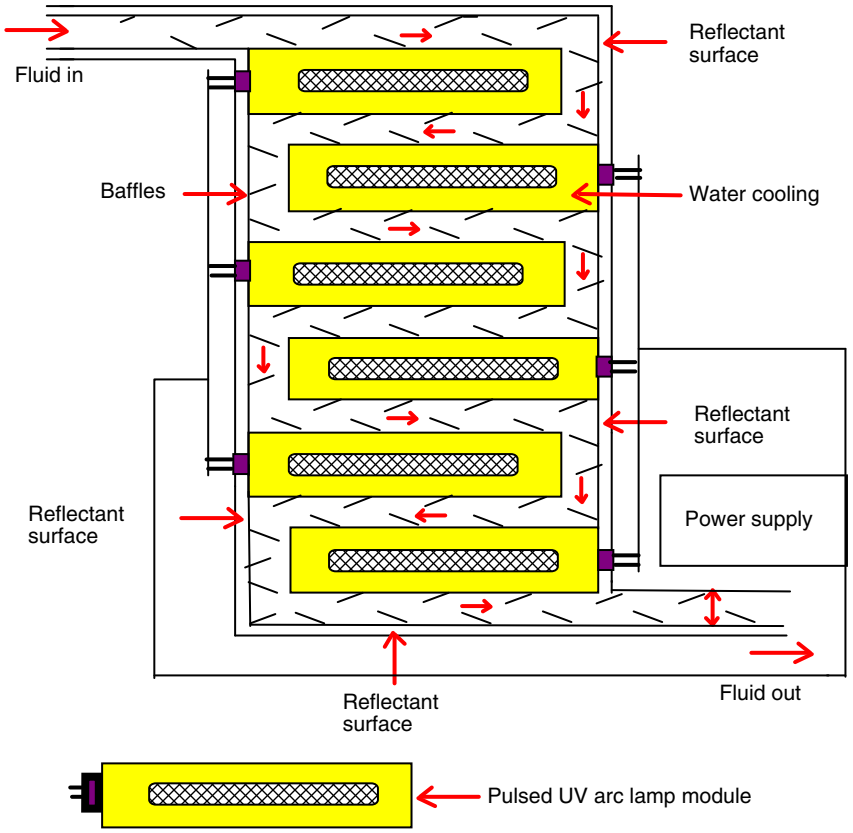

Figure 6 Multiple Xe arc (flash) lamp UVC reactor for the disinfection of liquid products.

Figure 7 PUV Xe arc (flash) lamp system used in experimentation at the University of California, Davis. Power supply and pulsing control system (left) and Xe-filled water-cooled quartz (right). Picture courtesy of UC Davis.

reflectance (www.en.wikipedia.org/wiki/Spectralon). The liquid channels also contain baffles to force a turbulent-flow process.

The single, Xe-flash lamp prototype system Figure 7 used in evaluating process efficacy and throughput for disinfecting food surfaces and liquid products operates reliably for >5 million pulses/lamp and its throughput equivalence is several hundred Hg germicidal lamps. This UVC reactor operates at highly competitive costs as compared with other emerging techniques. Cost estimates with alternative disinfection techniques range from ~USD$0.15 gal^{-1} (hydrostatic pressure) to ~US $0.05 gal^{-1} for carbon dioxide and pasteurization

Table 3 Pulsed ultraviolet (PUV) disinfection of fruit juices

Fruit Juice	*Type of inoculum*	*Initial inoculum (cfu ml^{-1})*	*Threshold ultraviolet (UV) energy (mJ cm^{-2})*	*Observations (Up to 5 J cm^{-2} UV doses)*
Apple	*Escherichia coli* O157:H7	3.9×10^7	600–800 >5 $\log_{10}$ reduction	High UV tolerance, no color or flavor changes
Orange	*Salmonella typhimurium*	1×10^6	800–1000 >5 $\log_{10}$ reduction	High UV tolerance, no color or flavor changes
Raspberry	Natural flora	$\sim 5 \times 10^3$	400–600 >3 $\log_{10}$ reduction	High UV tolerance, no color or flavor changes

treatments; to $\sim$USD\$0.002 gal^{-1} for conventional Hg germicidal lamps (In: 'Fresh today, Safe next week,' Food Engineering, Feb 2001). Current estimate for PUV Xe flash lamps is $<$USD\$0.001 gal^{-1}.

Results of several investigations at the University of California, Davis, using a PUV Xe-flash lamp UVC reactor, are summarized: Apple, orange, and raspberry juices: Freshly made, nonpasteurized apple juices (filtered and unfiltered) prepared from Granny Smith varieties (inoculated with *Escherichia coli* O157:H7); orange juice (no pulp; thermally pasteurized) obtained from commercial markets (inoculated with *Salmonella typhimurium*); and fresh raspberry (Heritage) juice containing a natural contamination flora were tested.

Microbial assays, before and after UVC processing, were conducted using standard methods. Above the threshold UVC energies, bioassays of the UV-treated samples indicated no pathogenic colony formation. Results of these experiments under optimized mixing conditions during PUV exposure are summarized in Table 3.

Results with fruit juices have indicated that UVC disinfection is effective and technically feasible. Besides, the tested fruit juices showed high UVC tolerance and maintained quality attributes with minimal effects on nutritional quality. Therefore, this new approach offers a new UVC alternative for the disinfection of fruit juices and offers increased and broad range capabilities; low profile compact systems technology development is underway at RF Biocidics Inc., Vacaville, CA (www.rfbiocidics.com).

Disinfection of Irrigation and Wash Water

Irrigation and wash (processing) water are critical resources in agriculture but they may be direct sources of plant pathogens (i.e., microbes and nematodes). Contaminated irrigation water affects productivity, forces the implementation of disease management strategies (usually pesticides), whereas the wash water used in postharvest sanitation needs disinfection to assure safety and quality of many fresh commodities. Furthermore, due to new regulatory and economic concerns, the nursery and greenhouse industries have adopted recycling as a water conservation strategy that prompted new risks by an increased reliance on prophylactic fungicides, filtration (slow and limited efficiency), chlorination (worker and public safety risks), ozonation (worker safety risks and limited efficacy), and Hg lamp UV irradiation (limited throughput and efficacy).

Plant pathogens like fungi (i.e., *Pythium* spp. and *Phytophthora* spp.) and plant parasitic nematodes (i.e., *Aphelenchoides* spp., *Meloidogyne* spp., and *Pratylenchus* spp.) are naturally present in many crops. Besides, sources of irrigation water have limited UV optical transparency even when filtered. Therefore, the potential for UVC disinfection of irrigation water has similar challenges as described before for fruit juices, and requires a large processing capacity.

Hg germicidal lamp systems are available for disinfecting irrigation and processed water for greenhouse and nursery operations. UVC processing of 2000–8000 l min^{-1} with 30–60% UV transmission at 30–50 mJ cm^{-2} UV doses is used, but increased dissolved organic matters reduces throughput as higher UVC doses (200–600 mJ cm^{-2}) are required.

Advanced oxidation processes are also considered for wash water disinfection by combining UVC radiation with added hydrogen peroxide which forms short-lived but powerful oxidizing (disinfecting) species like hydroxyl peroxide (HO_2) and hydroxy radicals ($^{\bullet}OH$) known to be powerful antiseptics.

As for disinfection of fruit juices, high-power, PUV sources are advantageous when combined with ozonation or with vortex techniques to remove suspended solids. A single PUV Xe-filled flash lamp (shown in Figure 7) delivers approximately 4 MW of germicidal UV ($\sim$50% UVC). This UVC power output is equivalent to several hundred $\sim$400 mW cm^{-2} Hg lamps. An exact equivalence is not given as other factors include reactor design, fluid optical quality, and flow. Finally, reduced chlorination levels may be added to provide residual disinfection effects.

Efficacy of PUV disinfection in irrigation water was demonstrated with mixtures of zoospores and cysts of *Phytophthora spp*. (i.e., *citrophthora*, *nicotianae*, and *capsici*) treated with a 248 nm PUVC beam from a KrF excimer laser. Results are given in Figure 8 and indicate full inactivation in the 10–30 mJ cm^{-2} UVC dose range.

A schematic of a potential UVC combined process for the disinfection of large volumes of irrigation and processing water is shown in Figure 9.

In summary, PUVC combined with available technologies may help provide alternative disinfection for water resources in the food and agriculture industry. The ability to safely recycle many water resources and reduce recontamination of soils, crops, and harvested commodities would greatly enhance food safety for many food commodities presently at risk.

Potential Uses of High-Power Pulsed UVC Sources in the Disinfection of Solids

Fresh produce is a preferred choice for consumers based on their attributes as being healthy, tasty, convenient, and fresh.

Over the past 20+ years, the fresh produce industry (conventional and organic) has experienced solid growth and is estimated to reach an USD$150 billion retail and service market in the USA with a similar growth scenario around the world. However, the industry also faces challenges as it needs to protect consumers against microbiological hazards as it operates with multiple scenarios related to regional, national, and international markets with many practices and opportunities to introduce microbial contamination.

Options to attempt safety include chemical pesticides (fungicides and bactericides), direct chlorination, ozonation, and/or a combination of disinfectants. Others are directed to produce disinfected or activated wash (processing) water to directly eliminate pests in the commodity's surface.

Combination of various disinfection approaches have also been attempted using chemical and physical methods. Furthermore, physical methods including brushing surfaces and ultrasound, hot water treatments for somewhat temperature-tolerant fresh commodities have also been considered.

Among these approaches, PUVC sources offer again many comparative advantages similar to those indicated for the disinfection of liquid commodities. Besides, PUV will again be capable of offering large-scale processing capabilities unequaled with Hg lamp technologies and with low-profile compact systems.

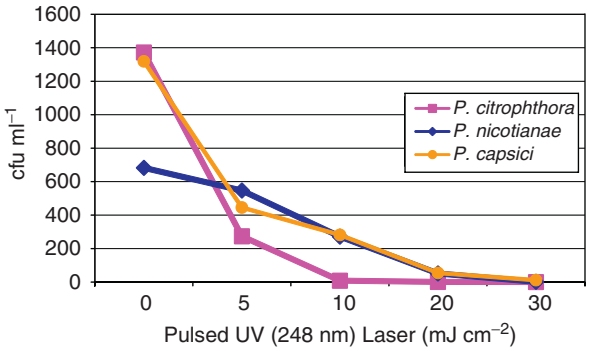

Figure 8 PUV (248 nm) disinfection effects on mixtures of zoospores and cysts of *Phytophthora spp.* using high-power UV radiation.

UVC Photon Interactions with Fresh Fruit Surfaces

UVC radiation can effectively disinfect the surface of many foods including temperature sensitive, high moisture fresh produce, and temperature tolerant, low-moisture nuts, grains, and seed products. However, the nature of the exposed surface determines the practical effectiveness of UVC radiation to reach exposure levels for adequate disinfection.

In fruits and in many vegetables, the presence of high UV-absorbent chemicals limits UVC depth of penetration of the surface (epidermis) to 10–40 μm. In addition, natural and added waxes (lipids) contribute to diffuse and specular UVC reflectance. Specular reflectance is the mirror-like reflection of UV (or other kinds of waves) from a surface in which UV from a single incident direction is reflected into a single outgoing (reflected) direction (www.en.wikipidia.org/wiki/Specular_reflection) and decreases UVC exposure levels. No measurements of reflectance in fruits and vegetables have been reported and therefore no quantitative estimation of this energy loss mechanism is known. A natural physical barrier is also present as trichomes combine with the natural waxy layers in some cultivars and with some physical roughness (i.e., holes and crevices). This combination results in effective shadows or shields for microbes to UVC photons and therefore establishing UVC exposure conditions is limited to experimental observations. Other limitations are due to the

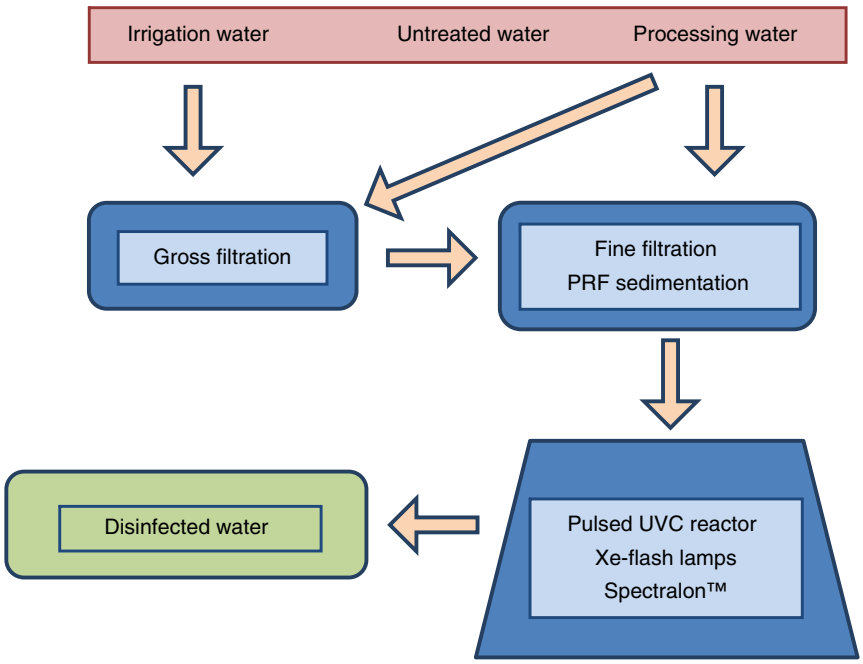

Figure 9 Combination technologies for a PUVC reactor system for disinfection of irrigation and/or wash (processing) water.

geometric characteristics of some fresh fruits and vegetables (e.g., bunches of fruit, folded leaves in vegetables, etc.) as again biological tissue is an effective barrier to UVC penetration. Finally, as UVC photons move in straight-path trajectories from their source, the round or oval geometry of many commodities provides effective shielding that force the need to expose a surface with different UV-path incident angles. The round surfaces, particularly when moving (rotating), enhance the natural shielding or shadowing effects and minimize the direct interaction of the straight-path incident UVC photons with the targeted pathogens. These natural and combined effects on fruit surfaces are illustrated schematically in Figure 10.

For bulk processing of nuts, grains, and seed products, other physical barriers are present due to additional UV shielding provided by the grouping of the commodities unless effective single layering and UV exposure uniformity techniques are applied. Furthermore, the choice of UVC source and the availability of techniques to assure homogeneous, surface-uniform UV exposure are critical.

Despite these limitations, the combination of high-peak power UVC sources from Xe-filled flash lamps with specialized UV reactors operating with diffuse reflectance allow for adequate uniformity of UVC exposure of fruit surfaces when combined with readily available surface randomization techniques. This approach offers an emerging alternative capable of large throughput as well as reliability. This rationale is explained in Section Effects of PUVC Radiation on Fruit Commodities with the support of experimental data including trials with several different fruit commodities.

As many fruits are climacteric and have physiological activity after harvesting and during storage (i.e., respiration and ripening) and many are colored with UV-sensitive pigments, studies to evaluate fruit tolerance and the overall sensory and physiological response to UVC exposure have been conducted with commercial-quality fruits. The results of these investigations have provided a strong rationale to place this approach as a new alternative process with practical, logistical advantages and competitive economics.

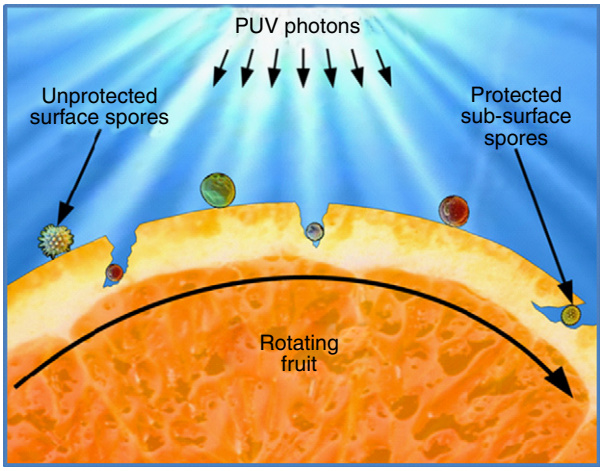

Figure 10 Schematic representation of UV shadowing effects on rounded rotating fruit surfaces. Surface, unshielded microbes should be easily inactivated by UVC radiation. Rotation during UV exposure allows changing the angle of incidence on the fruit surface and the orientation of a crevice or hole hosting microbes may provide an effective shield to UVC exposure.

Effects of PUVC Radiation on Fruit Commodities

Selected fruits of commercial quality were included in a study conducted at the University of California, Davis. The choice of fungal organisms was based on their relevance and impact on the spoilage of the selected fruits. The threshold PUV exposure energies (mJ cm^{-2}) used to completely inactivate the fungal organisms were also determined in appropriate culture media, on fruit surfaces, or in distilled/deionized water using a 248 nm KrF excimer laser. Results are given in Table 4.

Clearly, the presence of effective UV barriers in some fruit surfaces does increase the level of UVC exposure when compared with nonshielded surfaces (i.e., culture media) or in water (optimal UV transparency). Therefore these measurements provided an experimental determination of the practical levels needed to be used in achieving a desired level of disinfection. Factors ranging from 2 to 6.5 were determined except for *Aspergillus niger* which has melanin, a highly UV-resistant coloring pigment. Other limiting UV barriers include rotation effects and the presence of surface injuries. Therefore, under commercial (large scale) operations, even higher PUV exposure

Table 4 Threshold pulsed ultraviolet (PUV) (248 nm) energy doses for effective control of fungal organisms on fruit surfaces, in water, and on culture media[a]

Fungal organisms	*Host media*	*Threshold PUV energy (mJ cm^{-2})*
Alternaria alternata	Fruit surface (apple, pear)	500
	Solid culture medium	200
Aspergillus niger	Fruit surface (grape)	1900
	Solid culture medium	300
Botrytis cinerea	Fruit surface (apple, kiwi)	150
	Solid culture medium	30
Fusarium oxysporum	Fruit surface (pear, peach)	100
	Solid culture medium	35
Fusarium roseum	Fruit surface (pear, peach)	100
	Solid culture medium	35

levels are anticipated and the commodity's UV tolerance needs consideration.

Tolerance and Quality Effects in Fruits Exposed to PUVC Radiation

The potential sensory and physiological effects in PUVC-treated fruits were studied with 11 different cultivars and a total of 14 varieties. Fruit quality was evaluated before treatment as well as at +15 and +30–40 days after exposure while at the refrigerated storage under simulated commercial conditions. Fruit quality evaluations including flesh firmness, skin color, soluble solids, pH, titratable acidity, respiration, ethylene production, decay, external/internal injury, and weight loss for both control and PUVC-treated samples were done in duplicate. The general conclusions of this study are summarized in Table 5.

PUVC Reactor for Fruit Disinfection

To reach the expected potential for PUVC radiation for surface disinfection of solid products, an efficient UVC reactor is needed. The UVC reactor needs to safely house single or multiple Xe flash lamps to allow for a broad range of processing capacity and to maximize the UV-energy use efficiency of the emitted (available) radiation energy. In a UVC reactor, diffuse reflectance is therefore a critical operational feature to allow for directing the noncoherent UV radiation toward the target and as a means of randomizing fruit surfaces to allow uniform exposure. The design and engineering features of such a PUVC reactor is illustrated Figure 11.

With the exception of table grapes, all fruits handled in conveyorized operations may be treated by PUV if all the needed operational features are introduced. Most importantly, the operating characteristics of PUV sources, particularly Xe flash lamps would have the potential for high disinfection rates as exposure can be varied to match product throughput and thus be able to disinfect large treatment areas in short times.

A yet to be documented potential effect of PUV is the ability of high-power energy deposition to cause the partial or total destruction of contact pesticide residues by photolytic effects including advanced oxidation processes. In principle, this potential can make the PUV technique able to simultaneously provide disinfection, disinfestation, and chemical decontamination effects in a single process.

Consumer response to the concept of PUV treated food was already studied and suggested a positive reaction by most consumers but indicated the need to further educate the conventional consumer.

Test Results of PUVC Exposed Fruit Surfaces

The disinfection effectiveness of high-power PUVC combined with diffuse all- direction exposure fields can be summarized in a few selected examples from laboratory experimentation.

The ability of an optimized PUVC (248 nm) radiation field on oranges inoculated with *Penicillium digitatum* spores and

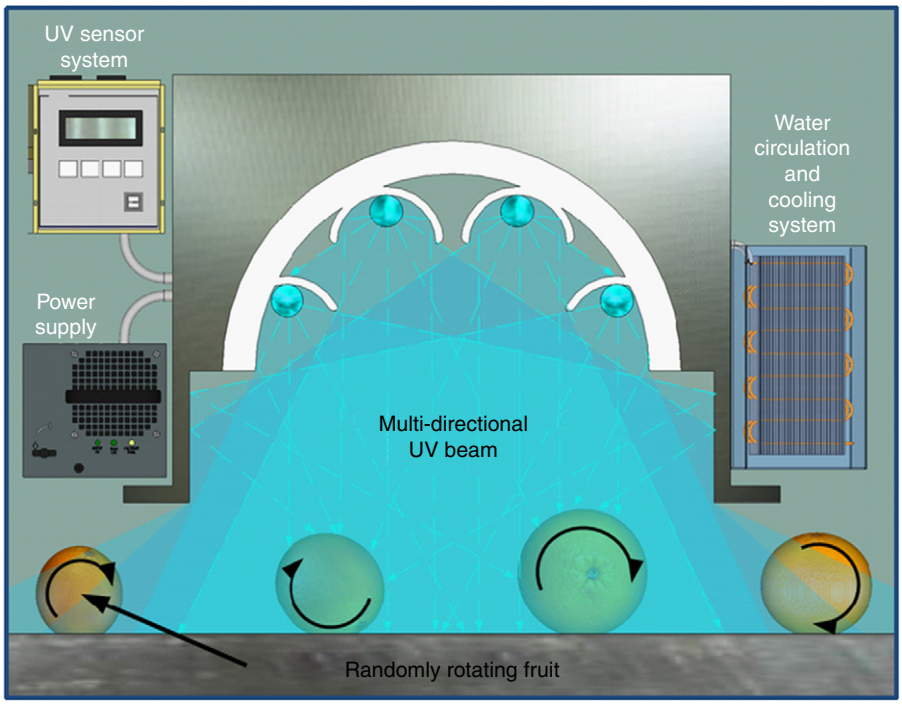

Figure 11 PUVC reactor for disinfection of fruit surfaces. All components are readily available from commercial sources.

Figure 13 Instant cavitation and ablation effects of high-peak power PUVC (248 nm) sources on table grapes (Ribier). Observation was after 2 days of treatment. Photo courtesy of the University of California, Davis.

exposed to a well-tolerated dose of 2000 mJ cm^{-2} is shown in Figure 12. Inoculum was injected ~ 5 mm deep (in three sites) and represented a common practical problem as wounded, deep infection sites can normally develop into larger infections and are inaccessible to sprayed pesticides or fumigants.

PUVC sources have the potential for enhancing disinfection effects by cavitation, ablation and reflectance events. Cavitation refers to a physical process in which increased UV penetration is obtained due to the multiple scattering of photons from diffuse reflecting surfaces including waxy fruit surfaces. Ablation is an instantaneous physical removal process of debris on fruit surfaces due to the absorption and charging of the UV energy by the materials covering or adsorbed on the surface. This includes soil particles and pesticide residues. Diffuse reflectance occurs from waxy, round surfaces, but the ablation effects remove the debris (soil dust and pesticide residues). These effects are fully dependent on the UVC power density only available with PUVC power sources. These effects are shown in Figure 13.

Conclusions

UVC radiation is clearly an alternative disinfection method with a potential role in processes directed to the treatment of liquid and solid commodities. However, the choice of UVC source is important and determines the practical application conditions for the different commodities. Both the conventional use of standard, low-power continuous emission Hg-based germicidal lamps and the specialized, high-peak power, PUVC sources have a role depending on throughput and infrastructure (space availability) requirements. Significant larger demand for space is required for Hg lamps, whereas PUVC sources are compact and low-profile units.

Economics was not largely addressed in this work but it is estimated that both types of UVC sources offer competitive economics and reduced costs as compared with other alternatives. However, Hg lamps are readily available and some operating systems are already operating in the field, yet there is no known commercial operation that is supported by PUVC sources, although some semi-commercial tests have been conducted and plans for commercial development are underway.

The UVC systems appear to be adequately capable for covering a broad range of operations with small (greenhouse and nursery) to large (industrial level, packing houses, etc.) product throughputs. As for the choice of UVC sources, Hg lamps are expected to dominate the small markets whereas PUVC sources have the features to meet demands for larger processing needs. However, because of efficiency and added effects, PUVC technology shall become available in smaller market operations.

Current research information is clearly dominated by reports based on using Hg lamps although many investigations, with similar results and limitations, are available and will continue to be generated using the more advanced (Hg free) PUVC technologies.

For liquid foods (fruit juices), whereas Hg lamps can render effective but limited throughput systems, the PUVC technologies offer better cavitation (increased range) and throughput capabilities. For irrigation water, the scenario is similar and both types of UVC sources appear to have a role and cover the needs of focused markets.

For solid foods (fresh produce), Hg lamps are limited to small throughputs than PUVC with the latter offering unique advantages associated with their capabilities for diffuse reflectance and reaching the shielded areas, to use cavitation, and to clean surfaces by ablation while providing much larger processing capabilities with compact systems.

For other solid commodities such as nuts, grains, and seeds, UVC radiation offers the potential for effective disinfection if process uniformity techniques are successful. Material handling techniques to assure single layering and randomization for these products are available but the design and engineering effort to integrate it with any UVC source has not been reported.

Finally, the advancement of UVC disinfection technologies is expected to continue and even expand as the entire fresh produce industry needs to rely on nonthermal, nonchemical processes to improve wholesomeness and safety of fresh produce.

Acknowledgments

The author wishes to acknowledge the support of the National Council of Science & Technology (CONICYT) of Santiago, Chile (FONDEF 2–63; FONTEC 97–1108 projects), and the participation of Drs. James MacDonald, Elizabeth J. Mitcham, and Edward Caswell-Chen at UC Davis in many aspects of these investigations. The technical assistance of Linda Bolkan, William V. Biassi, and Cecilia Piña, Burton Mehciz, and Charles Dresser (graduate student) of the research staff at UC Davis is also greatly acknowledged. Special thanks to Dr Robert G. Flocchini, former Director at the Crocker Nuclear Laboratory, UC Davis for his support and encouragement in these investigations.

D Knorr, Technische Universität Berlin, Berlin, Germany

Glossary

Electroporation Pore formation in the membrane of biological cells caused by the application of an external electric field.

Hurdle concept The concept of applying combined methods in order to have a series of preservation methods resulting in multitarget effects for microbial inactivation.

Numerical simulation Computational modeling used in pulsed electric field (PEF) process analysis and optimization, for example, for calculating electric field strength or temperature distribution in the treatment chamber. This requires experimental information as well as validation.

Sublethal injury Structural or functional damage of microbial cells that is repairable under optimum growing conditions resulting in a recovery of physiological fitness.

Treatment intensity The term 'treatment intensity' of a PEF treatment may encompass electric field strength level, number of pulses, frequency, treatment time, pulse energy, total specific energy input, and treatment temperature.

Introduction

Pulsed electric field (PEF) treatment is a nonthermal alternative to heat pasteurization of liquid products. Other applications are the disintegration of plant and animal raw materials and also the induction of stress responses in biological cells. However, because of considerably higher treatment intensities applied for PEF food preservation, the following outline on food safety aspects related to PEF will focus on this application.

According to several studies, the quality of PEF pasteurized food product is closer to that of the fresh product than the heat-pasteurized product and the safety of the fresh product is enhanced by the inactivation of vegetative pathogenic microorganisms. Because PEF is a novel technology, special legal requirements have to be fulfilled (e.g., for the European countries the regulation of the European Commission No. 258/97 on novel foods and novel food ingredients) and safety concerns have to be addressed. The first commercial PEF application was installed in 2005 in the US for fruit juice preservation. Clearance by the Food and Drug Administration was already available since 1996, indicating the techniques potential for safe and gentle preservation. However, to make further use of this promising technology and to advance its industrial implementation, several aspects need to be taken into account in order to guarantee a satisfying process performance.

To conduct a PEF safety assessment, two main starting points are suggested: (1) a product-based approach (substantial equivalence study) answering the question of alterations occurring in the composition of a PEF-treated product or (2) a process-based approach that identifies critical control points using available knowledge on mechanisms and the description of the process.

This article aims to give an overview of important hazards regarding food safety that may occur during a PEF treatment. Underlying phenomena will be discussed and possible control actions to improve the process performance will be pointed out.

PEF Basic Principles

PEF technology can be used to induce nonthermal permeabilization of cell membranes. Depending on the treatment intensity (external electric field strength, number, and duration of the electric pulses) and cell properties (size, shape, orientation, and conductivity), the pore formation may be permanent or temporary.

Treatment consists of the application of very short electric pulses (1–100 μs) at electric field intensities in the range of 0.1–1 kV cm^{-1} (reversible permeabilization for stress induction in plant cells), 0.5–3 kV cm^{-1} (irreversible permeabilization of plant and animal tissues), and 15–40 kV cm^{-1} for the irreversible permeabilization of microbial cells. These field intensities lead to the formation of a critical transmembrane potential (TMP), which is regarded to be the precondition for cell membrane breakdown and electroporation.

The irreversible electroporation results in a loss of turgor, the leakage of cytoplasmic content and lysis. Reversible permeabilization leads to the formation of conductive channels

across the cell membrane but electrically insulating properties will recover within seconds. The inactivation of microorganisms in liquid products or changes in the microstructure and texture of treated solid raw materials can be expected as a consequence of the irreversible permeabilization of cell membranes.

High-intensity electric pulses can be generated by the switched discharge of a suitable capacitor bank. The characteristics of the discharge circuit determine the shape of the time-dependent potential in the treatment chamber. Exponential decay pulses represent a complete discharge of the capacity. A rectangular shape of the pulse can be produced by using special switches, capable of interrupting the current at high potentials, or the implementation of a pulse-forming network. If an additional capacitor is used together with a parallel switch, bipolar pulses can be obtained. The geometry of the treatment chamber has a considerable effect on the electric field distribution and on the total resistance and therewith on the discharge circuit. The treatment chamber design needs to be optimized also taking into account a homogenous distribution of the electric field strength as well as characteristics of the fluid flow, viscosity, and particle sizes.

Microbial Inactivation by PEF

Effect of PEF on Microorganisms

Till date there has been no clear evidence on underlying mechanisms at a cellular level but the main effects have been described to be triggered by the electric field, ionic punch-through, and dielectric breakdown of the membrane.

The exposure of the biological cell to an intense external electric field leads to an increase of the TMP, which imposes an electrocompression of the membrane. When a critical level of the TMP – which depends on the compressibility, permittivity and initial thickness of the membrane – is exceeded, an electrical breakdown of the membrane occurs. The TMP induced by an external electric field depends on the intensity of the external electric field and cell size, shape, and composition of the membrane. The minimum field strength level of the external electric field that is required to increase the TMP and cause pore formation is defined as critical electric field strength E_{crit}, which depends on the before-mentioned cell and membrane characteristics. Hence, electric field conditions in the treatment chamber, especially consideration of the nonuniform distribution in most cases, needs to take into account the existence of such threshold values.

Effective inactivation for most of the spoilage and pathogenic microorganisms has been shown and colony count reductions depending on treatment intensity, product properties and type of microorganism in the range of 4–6 log cycles are comparable to traditional thermal pasteurization.

Most studies conducted in the past showed that PEF is only effective against vegetative microorganisms, yeasts, and molds as well as mold ascospores but ineffective against bacterial endospores and viruses. Recent investigation indicated increased inactivation of *B. subtilis* endospores when thermal treatment (75–115 °C) was combined with PEF application (15 kV cm^{-1}, 60–120 kJ kg^{-1}).

Relevant Impact Factors

The factors that affect microbial inactivation during PEF treatment are process related such as electric field intensity; pulse width and shape; treatment time; and temperature; as well as microbial factors such as type, shape, size, concentration and growth stage of microorganism, and media factors such as pH; antimicrobials and ionic compounds; electrical conductivity; and medium ionic strength.

The microbial inactivation by PEF depends on characteristics such as type, shape, growth phase, and inoculation amount of microorganisms.

The cells in the logarithmic growth phase are more sensitive to inactivation by PEF. Inactivation by PEF is therefore higher in the logarithmic growth phase than in the stationary phase. Principally, the effect of the electric pulses on the cell membrane is given by the membrane potential theory. This theory assumes that the electrical potential across the membrane (TMP) depends on the cell size. The cell size has an inverse relationship to the external electric field strength necessary to induce a specific TMP. It has been demonstrated by several authors that for smaller particles, higher electric field strength is necessary to reach the critical membrane potential.

Microbial inactivation by PEF also depends on the characteristics of the microorganism-containing medium or food. Factors such as the electrical resistance, pH, water activity, viscosity, presence of solid particles, bubbles, or oil droplets have an impact on the PEF effectiveness.

The conductivity of a medium, defined as the ability to conduct electric current, is an important variable in PEF technology. Treatment chambers with high conductivity foods have poor resistance and it is necessary to apply higher voltage to achieve similar microbiological inactivation that is achieved when processing low-conductivity foods. To obtain the same degree of microbiological inactivation in foods with very different conductivity, treatment conditions, such as the inter-electrode gap in the treatment chamber, pulse width, and voltage must be adapted.

The influence of pH on the microbial inactivation during PEF treatment plays an important role. Both acidic and alkaline pH values induce additional stress to cells, and consequently increases their susceptibility to physical and chemical treatments. The pH can be modified and alters the inactivation kinetics by PEF. Depending on the type of microorganism and strain how pH affects the microbial resistance against PEF has also been shown.

Sublethal Injury and Hurdle Concept

To obtain maximum food safety, a direct transfer of cells from the vital to the lethal fraction during microbial inactivation is favorable. However, because the impact on food quality characteristics limits the applicable treatment intensities, a limited number of dead cells may result. Membrane damage and inactivation of microorganisms due to PEF was first considered as an all-or-nothing event, but a differentiated approach is required even if the critical parameters for the electrical breakdown of cell membranes are exceeded. Membrane damage and sublethal injury was found to be repairable

under certain conditions and the extent to which cells repair their injuries was reported to depend on the treatment intensity, microorganism, and treatment medium pH. On the one hand, sublethally injured cell fractions are a risk from a food quality and safety point of view because these cells may recover and regain their initial vitality. On the other hand, sublethally injured fractions have a potential for subsequent complete inactivation by the application of additional hurdles such as suboptimal storage conditions or the other inactivation methods such as the application of antimicrobials or other food preservation technologies.

The microbial inactivation rates differ considerably between simple media and a complex matrix. This was partly attributed to the protective effect of some food compounds such as xanthan, proteins, or fat. Other studies did neither reveal differences in the microbial inactivation conducted in either buffer or complex media, nor detect the occurrence of sublethally injured cells after PEF treatment of complex food systems. However, inactivation kinetics obtained from PEF treatment in buffer systems have only limited comparability with real food products. In addition, model microorganisms used in most studies and the method of sample preparation differ significantly from the native state of microbial population present in the real food system. The diverse and heterogenous microbial flora present in real foods is not comparable to inoculated microorganisms in most cases due to the strong variability of microbial species and physiological state of microorganisms. Consideration of the microbial growth state, adaptation to treatment media, and existence of inhomogenous microbial populations with less sensitive subpopulations seem to be the most challenging aspects when transferring inactivation results to real products and industrial implementation. Assured food safety and stability, along with a desired level of microbial inactivation requires an accurately defined treatment intensity followed by a predictable microbial inactivation. The transfer of inactivation results from model systems to real foods and the determination of appropriate PEF treatment parameters require the consideration of existing particularities.

Protective Effects of Food Constituents

The impact of food constituents on PEF effectiveness is not fully elucidated. Some authors report a protective effect of xanthan, proteins, or fat. Other studies did not reveal differences in the microbial inactivation conducted in buffer or complex media. Investigation of *Escherichia coli* inactivation in an ovalbumin solution, fish egg suspension, dairy cream, and in phosphate buffer did not show any protective effect of emulsified lipids, soluble proteins, or conductive food particulate. However, inactivation of *Enterobacter sakazakii* in peptone water and infant formula milk by PEF at 40 kV cm^{-1} for 300 μs was found to cause 2,7 log-cycle and 1,2 log-cycle reductions, respectively; thus, showing an impact of the complex composition of infant formula milk in comparison to peptone water. When considering PEF effectiveness as a function of the treatment media, the critical field strength and treatment time required was found to be dependent not only on cell geometry but also on the properties of the media.

Inactivation in complex media like an orange juice–milk-based beverage was also under investigation. The authors concluded the need for further investigation on the effectiveness and mechanism of action of the complex food composition during PEF treatment, as the inactivation results obtained in the complex orange juice–milk based beverage were lower than in simpler substrates.

In addition to the protective effect of food constituents, food matrix properties such as electrical conductivity, heat capacity, and viscosity have to be considered. These parameters affect the power requirements necessary for the generation of a desired electric field level as well as the power consumption during operation. Viscosity will determine the flow behavior and residence time distribution in the treatment chamber resulting in treatment time variations and subsequently also in a nonuniform temperature increase with the occurrence of hot spots.

Shelf Life Studies

An effective microbial inactivation (5 $\log_{10}$) must not only be accompanied by a minimal impact on food nutrients and vitamins but also by a shelf stable quality. The shelf life of a product is defined as the period in which the product is still acceptable for human consumption. Products are spoiled by microbial, chemical, and physical processes. The shelf life is determined by the raw material quality, product formulation, processing, packaging, and storage conditions. Numerous researchers have studied the shelf life of a food product in terms of microbial spoilage.

Combinations of kinetic models which determine and predict the shelf life of a product after microbial or enzyme inactivation are described. The basis is an inactivation of up to 5 $\log_{10}$ units of vegetative pathogenic microorganisms. The pathogenic *Salmonella*, *E. coli*, and *Listeria monocytogenes* species can be considered as most important targets for inactivation due to its higher resistance to PEF treatments. In products with low pH values, spore-forming bacteria (*Bacillus* species) are not able to grow. This means that a pasteurization treatment is sufficient to achieve a microbiologically shelf stable product. In case the product is recontaminated, for example, during packaging after treatment, mainly yeasts and lactic acid bacteria will be introduced in the product. Because lactic acid bacteria are not able to grow in acidic pH foods, yeasts are considered to be the target microorganisms during storage. Therefore, a combination of the highest PEF-resistant microorganisms and the microorganism that is most likely to grow under the storage conditions are suggested for consideration.

Validation and Availability of Indicators for PEF Performance

Strategies for process validation may include a record of parameters to prove the appropriate performance of a treatment. The temperature increase as a result of the dissipation of the total specific electrical energy input can be used as another measure in order to evaluate the treatment intensity in terms of energy input. However, it only reflects an average dose

parameter. Measurement possibilities for the process parameters inside the treatment chamber would be necessary in order to detect nonuniformities but they are limited owing to the small dimension of the treatment chamber and the physical conditions. However, numerical simulation provides a capable tool in order to obtain relevant data on inhomogeneities of electric field strength, treatment time, and temperature. Other methods have been proposed to use enzymes or chemical indicators to detect thermal or chemical side effects occurring during PEF treatment. It has to be stated that sensitivity of microorganisms to PEF is different from their sensitivity to thermal treatment. Hence, matrix-specific inactivation kinetics have to be established in order to define product relevant treatment parameters for different target microorganisms.

Technical Aspects Relevant for Safety Considerations

Treatment Chamber Design

The treatment chamber is the key component of the PEF system for direct application of the electric field in contact with the treatment media. Its design should consider the uniformity of the electric field distribution in combination with flow characteristics in continuous applications as well as the extent of temperature increase.

Various treatment chamber designs such as parallel plates, coaxial cylinders, or colinear configurations have been used for PEF processing and some modifications of these basic designs have been proposed. A comprehensive overview of different treatment chamber configurations can be found in the further reading list.

Adequate shape of electrodes and the insulator is a prerequisite for an optimal electric field distribution and will reduce dielectric breakdown effects of the food, because local high electric field strength levels can be avoided, for example, by providing a round-edged insulator geometry. Dielectric breakdowns of food are undesired as they cause arcing, which leads to the destruction of the food, damage on the electrode and insulator surface, as well as explosion of the treatment chamber due to pressure increase. Electric field homogeneity and the avoidance of low field intensities are not only desirable from the microbial inactivation point of view but also from the fact that energy dissipation and power consumption will take place in low field regions without contributing to the microbial inactivation.

In addition to distribution of the electric field strength and flow velocity considerations, hygienic aspects need to be taken into account for the design and operation of a PEF unit.

General hygienic guidelines for the food industry (e.g. guidelines of the European Hygienic Engineering & Design Group, www.ehedg.org) apply and particular attention should be paid to treatment chamber design and the possibility of fouling and accumulation of deposits during processing and their removal during cleaning. Apart from construction elements, process aspects and in particular process start up with the incoming product after sanitation requires particular attention. PEF treatment needs to be started before a contaminated product passes the treatment chamber, to avoid recontamination of the presanitized processing line. However, the electric field can only be switched on when the treatment chamber is filled. Therefore, to avoid insufficiently treated product passing the treatment chamber and recontaminating the line, the installation must be filled with water of similar electrical conductivity to start the system at targeted process parameters.

Electric Field Strength Distribution

Microbial and media properties have been widely investigated. However, the treatment chamber design and its influence on processing parameters such as the electric field strength and its distribution have hardly been discussed. One of the main aspects related to chamber design is the insulator shape and its impact on the flow and electric field distribution. The insulator and its specific design have a considerable impact on the process performance as they affect the electric field strength distribution and therefore the microbial inactivation. The velocity profile in the treatment chamber (laminar, transitional, or turbulent) determines the residence time distribution and therefore the total treatment time of the product. Because the fluid velocity differs depending on the location in the treatment chamber, longer treatment times will occur near the wall owing to lower flow velocity and shorter treatment times occur in the center of the treatment chamber where there is higher flow of velocity. Examples for modifications as insulator gap/diameter for colinear treatment chambers can be found in literature, where it is stated that a gap increase will provide smaller electric field strength, but will also provide a more homogenous distribution.

The alteration of electric field distribution by modifying the insulator geometry can be used to improve the microbial inactivation results. However, this depends strongly on other processing conditions, such as number of pulses, media conductivity, and velocity profile, that have to be considered during the microbial inactivation process. Owing to high inhomogeneities presented in a continuous treatment system, PEF processing should be characterized in terms of the electric field strength, treatment time, and specific energy input. An average value from the previously mentioned parameters with their respective standard deviation as well as occurring maximum and minimum values should be described in detail for the process. The lowest value of electric field strength, treatment time, and energy input will be the limiting factors for food safety reasons and the maximum value for the resulting product temperature should be considered with regard to product quality. The modification of a colinear treatment chamber by inserting static mixing devices provides a possibility to improve electric field strength distribution, with the aim of increasing the average value and reducing standard deviation. This will result in an increased microbial inactivation. The insertion of static mixing devices also provides a more homogenous velocity profile (thus a more homogenous treatment time as well) and a more homogenous temperature distribution, which aims at higher retention of heat sensitive compounds.

Thermal Effects and Impact on Safety and Quality

Although the PEF treatment is a nonthermal food processing technology, there is a significant temperature increase during high intensity PEF treatment, when applied for pasteurization purposes due to Joule heating. Many authors have described the temperature distribution in a PEF treatment chamber and reported the occurrence of high local temperatures owing to inhomogenous field distribution of the electrical field, limited flow velocity, and recirculation of the liquid. For this purpose, numerical simulations using computational fluid dynamics have gained growing interest because experimental measurement of the related parameters is not possible in most cases due to small dimensions of the treatment chamber as well as the interference of the measuring device with the product flow and electric field. Apart from the overall liquid temperature measured at the outlet of the treatment chamber, treatment inhomogeneity and the occurrence of temperature peaks within the treatment chamber have to be considered as thermal impact factors. This is of particular importance when discussing PEF effects on functionality of heat sensitive compounds, such as proteins or when conducting inactivation kinetic studies. Additional thermal effects may occur in case of application of high total energy inputs, insufficient temperature control, or unfavorable treatment chamber design.

However, the application of PEF in combination with mild heat seems to be a promising technique for a gentle, multihurdle preservation process. The synergism between temperature and PEF membrane electroporation can be used to improve the inactivation efficiency. The phospholipid bilayer structure of the cell membrane changes from a gel-like to liquid crystalline state when increasing the temperature and increased membrane fluidity leads to reduced membrane stability and facilitates the electroporation of the cell membrane. The synergetic effect of temperature during PEF inactivation of microorganisms can be used to improve the inactivation results and/or to reduce the electrical energy costs.

PEF Impact on the Food Matrix

Food Constituents Affected by PEF

When PEF treatment of liquid or semisolid raw materials is used for microbial inactivation, the desired effect is primarily nonthermal pasteurization of the food product considering the microbial cell as target of the treatment. The modification of other food constituents as well as functional food properties may be considered as an unwanted side effect in most cases. However, potential applications to use the electric field effect to modify functional properties of food constituents will gain increasing attention.

The evaluation of the effect of PEF on food compounds is complex. Available reports are limited and different experimental setups and processing parameters make them difficult to compare. The consideration of electric field side effects such as temperature increase and temperature hot spots due to Joule heating effects within a nonuniform electric field and the occurrence of electrochemical reactions and pH shifts is the most challenging aspect within this context. The nonthermal inactivation of microorganisms by PEF is based on the electroporation of membrane structures. High-intensity electric fields are unlikely to affect covalent chemical bonds but the electric field application and related side effects may show an impact on food compounds and process modifications toward the inactivation of microorganisms and enzyme structures are also possible. Owing to the application of PEF, changes in the conformational state of proteins might cause changes in protein structure and enzyme activity.

In general, the mechanisms involved in the inactivation of enzymes and the modification of proteins by PEF are not fully understood. Possible mechanisms could entail polarization of the protein molecule; dissociation of noncovalently linked protein subunits involved in quaternary structures; changes in protein conformation so that hydrophobic amino acid or sulfhydryl groups are exposed; attraction of polarized structures by electrostatic forces; and hydrophobic interactions or covalent bonds forming aggregates. The effect of PEF on milk proteins may also be explained as a result of the modification of the apparent charge after exposure to intensive electric fields and subsequent modification of ionic interactions of the proteins. A comprehensive overview of PEF effect on food material properties can be found in the literature given below.

Electrochemical and Toxicological Aspects

In addition to the microbial safety and control of process parameters relevant for a high level of microbial inactivation, possible chemical, and toxicological safety issues related to PEF need to be considered.

In PEF systems working at electric field intensities are suitable for pasteurization applications, electrochemical reactions can occur at the electrode–solution interface. Related effects could be a partial electrolysis of the solution or the corrosion of the electrode material and an emission of metals from the electrodes in the liquid.

However, these unwanted phenomena can be limited or avoided by suitable selection of electrode materials and adaptation of the electrical pulse shape and duration.

The modification of the electrode material such as the use of titanium, which is oxidized to water insoluble titanium dioxide at the electrode surface or the application of innovative materials such as carbon loaded polymers have the potential to decrease the amount of metal release into the product.

However, to control the electrochemical reaction it is preferable to eliminate causes rather than eliminating results such as the corrosion of electrode material. Therefore, it is required to modify the electrical characteristics of the PEF systems in two ways: (1) avoiding direct leak currents by improving the electrical switching components and (2) reducing low frequency alternating voltages and currents by improving the pulse conditions.

In properly designed PEF systems working at adequate processing conditions, the metal release can be reduced far below the existing standards for maximum concentrations in drinking water or fruit juices.

Comprehensive studies on the impact of PEFs on food constituents are limited. Most studies focus on single compounds such as enzymes or vitamins. However, to conduct a product specific substantial equivalence study, a complex analytical approach has to be undertaken which also includes the formation of process induced contaminants. A statement

of the Senate Commission on Food Safety of the German Research Foundation on the treatment of food using a PEF is available since 2008 indicating the need for a case-by-case evaluation of PEF-treated products and for the availability of standardized process parameters and assessment criteria including indicators.

Summary

PEF technology was shown to effectively inactivate microorganisms in liquid foods resulting in shelf stable safe products. Because the PEF resistance of microorganisms is different compared to thermal treatment and strongly depends on matrix properties, inactivation levels between microorganisms and products differ significantly. In addition, technical PEF treatment parameters with impact on microbial inactivation are multifaceted and provide various adjustment options. Nonuniform distribution of these parameters in continuous industrial scale PEF units and occurring thermal effects result in complex process–product interactions. Hence, the design of a PEF process requires the consideration of process and product related characteristics to guarantee food safety. To have maximum process performance, process optimization needs to consider particularities regarding the microbial inactivation such as the occurrence of sublethally injured cells as well as the protective effect of a complex food matrix. In addition, process analytical tools such as numerical simulation are required to exactly define process conditions. Technological aspects such as pulse characteristics, electrode material, and treatment chamber design can be considered as key aspects to improve process performance.

Sterilization

T Deák, Corvinus University, Budapest, Hungary

Glossary

Botulinum cook Heat treatment to achieve 12 decimal reduction in the number of *C. botulinum* spores. If D_{121} of *C. botulinum* is 0.21 min, then a botulinum cook will have an F_0 value of $12 \times 0.21 = 2.52$ min.

Commercial sterility Commercial sterile food is not necessarily free from extremely heat-resistant viable spores, however, these are not capable of growing in the product under normal storage conditions.

***D*-value** Decimal reduction time, the time in minutes at a given temperature to inactivate 90% (one log cycle) of a microorganism, leaving one-tenth of survivors.

***F*-value** Time equivalent of different inactivation temperatures in relative fractions of 121.1 °C.

F_0-value Sum of the lethality of a heat process expressed in that of the reference temperature of 121.1 °C.

***z*-Value** The temperature change required to change the *D*-value by a factor of 10.

Scope

Sterilization means the near complete destruction of microorganisms usually by temperatures greater than 100 °C using equipment with pressure (autoclaves or retorts). Because the resistances of bacterial spores to heat are different, sterilization frequently means a treatment of at least 121 °C (250 °F) of wet heat for 15 min or its equivalent to inactivate to a large extent of spores of the pathogenic *Clostridium botulinum* and most of the spore-forming spoilage microorganisms. Sterilization also means that every particle of the food must receive the adequate heat treatment. Hence, the slowness of heat transfer through the food should also be considered in determining the overall heat destruction effect of the sterilizing treatment.

In practice, however, a product subjected to sterilization may not be sterile. From the principle of exponential death of microbial population it follows that absolute sterility cannot be achieved and there will not be zero survivor; only the probability of survival can be minimized to an acceptable degree. This has been set to be a 10^{-12} part survival of *C. botulinum* spores, called 12D concept. Even in this case, some more heat resistant spore formers, for example, *Clostridium thermosaccharolyticum* or *Geobacillus stearothermophilus*, may survive this and more intensive heat treatment. Being of thermophilic nature, these surviving microorganisms cannot grow under the normal condition of storage (at ambient temperature without refrigeration), and this condition is termed commercial sterility.

Food industry applies several environmental (extrinsic) factors for the inhibition and/or inactivation of microorganisms in order to manufacture safe product with long keeping quality and shelf-life. Among others, heating, freezing, drying, irradiation, high pressure, and other methods alone or in combination can be applied. Heat treatment at high temperatures is the most important method of preservation that is used widely in canning industry. The practice of canning started at the end of the eighteenth century, much earlier than when the scientific fundamentals of the heat sterilization process became understood. In 1795, motivated by a tender of Napoleon Bonaparte offering 12 000 francs for developing a practical way to preserve food, a confectioner named Nicholas Appert successfully preserved meat placed and boiled in glass bottles. He patented the process and this was the beginning of food preservation by canning. It passed 50 years until another Frenchmen, Louis Pasteur, demonstrated the role of microbes in food spoilage. He found that microbes were responsible for the putrefaction of meat and milk, as well for 'disease' of wine, and developed a heat process (later called pasteurization) to preserve wine. The sound scientific foundation for the process of sterilization was laid down in the 1920s by the Americans Ball, Bigelow, and others.

Fundamentals of Thermal Death of Microorganisms

In practice, we never deal with a single microbial cell but rather with the population of microbes consisting of numerous (often millions of) cells. The death of an individual cell is instantaneous; however, the destruction of microbial population is a continuous process in time. Also, for methodical reason, it is only the living cells that can be studied and enumerated; hence the death of cell population in time can be followed by counting of the cells *surviving* the destructive treatment. Thus, the death kinetics can be described on the analogy of a first-order reaction by the change of surviving cell count in time:

$$dN/dt = -kN$$

 doi:10.1016/B978-0-12-378612-8.00258-4

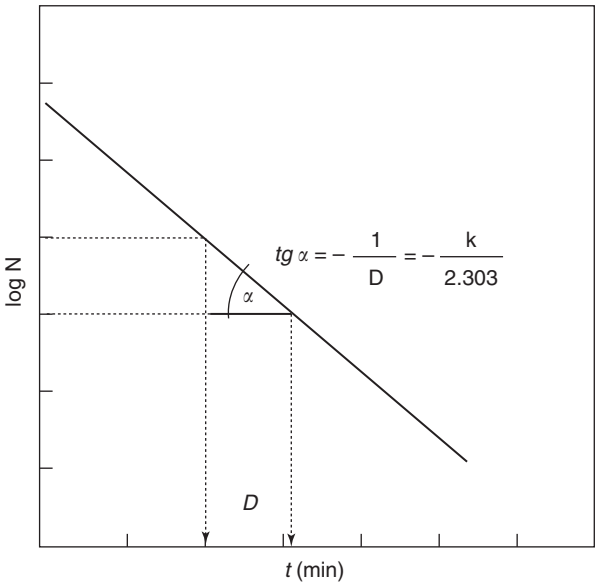

Figure 1 Survivor curve and the *D*-value. Reproduced from Deák T (2006) *Élelmiszer Mikrobiologia*. Budapest: Mezögazda.

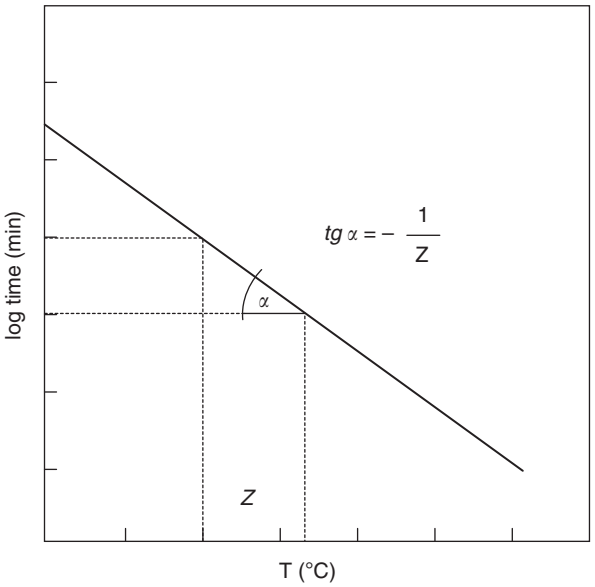

Figure 2 Thermal death curve and the *z*-value. Reproduced from Deák T (2006) *Élelmiszer Mikrobiologia*. Budapest: Mezögazda.

that is, the change in number of survivors (dN) in a given time (dt) is proportional to the actual number of living cells (N), where the k factor is called the death rate coefficient (with a negative sign as the cell number is decreasing). Integrating this equation between the limits of initial cell count (N_0) and surviving cell count (N_t) after t time, we arrive at the fundamental equation describing the death of microbial populations:

$$N_t = N_0\, e^{-kt}$$

often rewritten in logarithmic form, which is called the equation of survival curve:

$$\log N_t/N_0 = -kt$$

from which the death rate coefficient can be expressed as:

$$k = 2.303/t \log (N_0/N_t)$$

Accordingly, when the logarithm of surviving cell number is plotted against time, a straight (linear) line is obtained, the slope of which is related to the death rate coefficient (Figure 1).

The time through which the number of survivors decreases to one-tenth is the decimal reduction time, D:

$$D = t/(\log N_0 - \log N_t)$$

The decimal reduction time is also a measure for the degree of resistance of a microbe population to destruction; the longer the D-value, the more resistant the population against a destructive factor (heat or other).

When the log D-values are plotted against temperature, the thermal resistance curve is obtained (Figure 2). The slope of the line marks the change of resistance in function of temperature. This is represented by with the z-value, which represents the degree of increase in temperature through which the decimal reduction time (D) will decrease to one-tenth or one log order.

D and z are the two basic parameters defining completely the heat resistance characteristics of microorganisms.

Heat Resistance of Microorganisms

The heat resistance of microorganisms is primarily a genetically determined specific characteristic that can be modified by the environmental conditions. In general, heat resistance is in proportion to the growth temperature. Psychrophilic vegetative bacteria become inactivated even at approximately 40 °C, whereas mesophiles have a decimal reduction time of approximately 1 min at 55–60 °C. Certain thermoduric bacteria (e.g., *Enterococcus* and *Microbacterium* species) may survive 30 min heating at 60 °C, with a fairly large z-value of 15–20 °C. Heat resistance of most vegetative pathogenic bacteria occurring in foods is similar to that of mesophiles, and they can be inactivated with the conventional pasteurizing treatments at temperatures below 100 °C. Unusually high heat resistance approaching that of thermoduric species is shown by the serotype *Salmonella* Senftenberg. The majority of yeasts and molds possess heat resistance similar to those of mesophilic vegetative bacteria.

Although the vegetative cells of spore-forming bacteria are equally sensitive to heat as other bacteria, their endospores possess high heat resistance (Table 1). The thermophilic spore forming species are remarkably more heat resistant than mesophiles. Heat resistance of mesophilic spores is characterized with D_{121} °C of 0.01–0.1 min, whereas that of thermophiles may reach 2–5 min decimal reduction time at this temperature. From the point of food safety, *C. botulinum* is the most important of the pathogenic spore formers, having 0.1–0.2 min D_{121} °C; in particular the strains belonging to serotypes A and B, whereas the psychrotrophic E serotype

Table 1 Heat resistance of some spore-forming bacteria

Species	D_{121} *(min)*	z *(°C)*
Bacillus polymyxa	0.05	8
C. botulinum	0.21	10
B. subtilis	0.7	8
Clostridium sporogenes	1.5	10
Desulfotomaculum nigrificans	2–3	9–12
Thermoanaerobacterium thermosaccharolyticum	3–4	12–18
G. stearothermophilus	4	10

Source: Data from Stumbo CR (1973) *Thermobacteriology in Food Processing.* London: Academic Press, and Deák T, Farkas J, and Incze K (1980) *Microbiology of Canning-, Meat- and Freezing Industries (in Hungarian).* Budapest: Mezőgazdasági Kiadó.

strains are less resistant, characterized by D_{80} value of 0.3–3 min. Among the spore formers causing spoilage in canned foods, spores of *G. stearothermophilus* and *C. thermosaccharolyticum* have D_{121} values of 3–5 min, and these can survive heat treatments calculated for the destruction of *C. botulinum* (see commercial sterility). Heat resistance of spores is also characterized with *z*-values two or three times higher than those of vegetative cells, in the order of 8–12 °C, and some spores may reach 20–30 °C.

Factors Influencing Thermal Resistance

The thermal resistance and thermal death of microorganisms and their spores are influenced by several environmental factors. Moreover, although the heat resistance is a specific characteristic, it may differ between strains of a species. Decrease of water activity significantly increases thermal resistance. This is often the case in foods with high sugar concentration or containing many proteins or fats. However, acidic environment and low pH markedly decrease heat resistance. Product pH is of outstanding importance for heat processing. The pH of 4.5 signifies a dividing line; products with pH lower than 4.5 can be pasteurized at 100 °C or below, whereas foods of pH higher than 4.5 must be sterilized at temperature greater than 100 °C. The fundamental safety reason for this is that the most important pathogenic endosporic microorganisms, *C. botulinum*, cannot grow or produce toxin at pH <4.5 and the spores that may survive heat treatment cannot germinate either. In the canning practice, the interaction of heat with other preservative factors can be utilized favorably.

Determination of Heat Process Requirement

The most important field for application of the thermal death curve is the heat treatment in canning. In the practice of heat treatment, various degrees of temperature are applied. The values of *D* (or its multiple, the thermal death time, TDT) at any given temperature can be obtained using a reference value, *F*, at a reference temperature (Figure 3). For the latter, 121.1 °C was chosen, a temperature important in the sterilization practice (this value corresponds to a

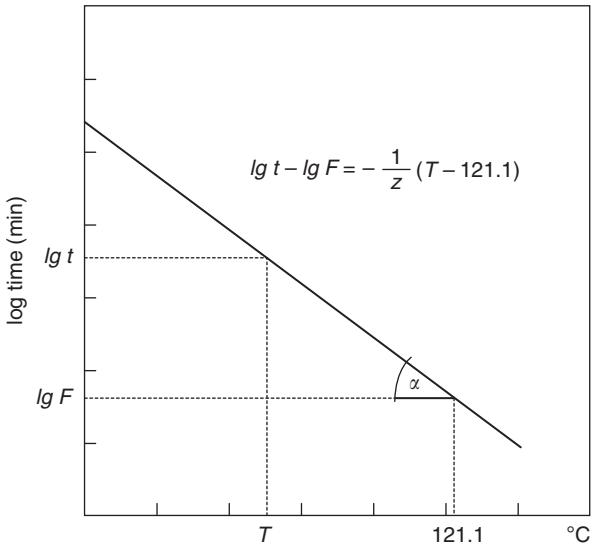

Figure 3 Reference thermal death curve. Reproduced from Deák T (2006) *Élelmiszer Mikrobiologia.* Budapest: Mezögazda.

round figure, 250 °F). Also, a *z*-value of 10 °C was selected as the slope of this particular thermal death curve. With these determined points, the equation of the thermal death curve is:

$$\log (t - F) = -(T - 121.1)/z$$

This equation is used for the calculation of the thermal processing requirement and the lethality of the sterilization process. For these calculations, the lethal effect of any other temperature should be compared to that at the reference temperature, 121.1 °C. From the above equation, the relative rate of heat destruction at various temperatures compared to that of 121.1 °C can be obtained as

$$F/t = \text{antilog}\,(T - 121.1)/z$$

In the practice of heat treatment (sterilization and pasteurization) the temperature is not constant but changes, increasing during warming up and decreasing during cooling. In calculating the heat process requirement, the task is to sum up the lethal effects of changing temperatures for changing time. This can be done if the TDT (or rate) at various temperatures is expressed in a similar manner to be integrated. As shown above, the death time of any temperature related to the reference temperature 121.1 °C is expressed as F/t, and the integrated time equivalent, F_i, of different temperatures in relative fractions of 121.1 °C can be obtained as

$$F_i = \int_0^t F/t\,\mathrm{d}t$$

For example, if the time equivalent of a thermal process is $F_i = 3$ min, it means that the sum of lethality of all corresponding temperature–time combinations during heat treatment will be equal to the effect of 3 min instantaneous treatment at 121.1 °C. In this interpretation, the F_i value does not relate to a given kind of microorganism but to a given heat process; hence it can be used to compare the efficacy of different thermal processes.

The heat resistances of microorganisms are, however, different, and also change with temperature (as expressed by the D and z values). For safety reason, the minimal degree of thermal process chosen should be adequate to kill the most resistant pathogenic microbe that may occur in the practice of canning. According to common experience, it is the toxigenic *C. botulinum* that constitutes the greatest health hazard and whose endospores have high heat resistance. The D-value of the most resistant spores of *C. botulinum* at 121.1 °C is 0.21 min, and its thermal dependence, the z-value is 10 °C. This has been chosen universally for the calculation of thermal process requirements, and the summarized lethality value of temperatures related to 121.1 °C is distinctively marked as F_0-value, and called equivalent sterilization treatment. In contrast to the F_i thermal time equivalent, which may refer to any TDT curve no matter which z-value, the F_0-value relates to a thermal process characterized with a thermal death curve of $z = 10$ °C value.

The F/t values can be graphically integrated by taking the relative death rates corresponding to different temperatures of the heat penetration curve, and plotting with time to obtain the so-called sterilization curve. The area below the sterilization curve will be equivalent to the sterilization treatment in minutes of F_0 (Figure 4). For practical reason the summing up of F/t values usually starts when the internal temperature reaches 100 °C and includes also the cooling part until 100 °C. The F/t values associated with temperatures below 100 °C are very small and hence do not contribute significantly to the overall amount of heat treatment. However, omitting the effect of high temperatures during cooling would result in oversterilizing of the product, possibly resulting in quality losses. In the recent times, with the development of computing technology, programs are available to determine thermal process requirements, and also online monitoring and controlling of the thermal process.

Based on the sterilization equivalent F_0-values, not only the efficacy of various thermal processes can be compared but also the minimal degree of heat treatment required for safety can be determined. It is a universally accepted practice to apply a heat treatment that should destroy the number of *C. botulinum* spores to 10^{-12} proportion. This is the 12D concept, which is equivalent to $12 \times 0.21 = 2.52$ min heat treatment at 121.1 °C, which is the F_0 for *C. botulinum* (also called 'botulinum cook'). This provides high safety for heat sterilization. Since it has been introduced for commercial canning from the end of the 1920s, only a few cases of *C. botulinum* intoxication occurred (unfortunately much more in home canning).

The 12D principle of sterilization should be applied for low acid products with pH >4.5 in which *C. botulinum* can grow. In these products, however, spore-forming bacteria may occur whose heat resistance is higher than that of *C. botulinum* (Table 1). Although these do not present health hazards, they can survive the minimal requirement of safe heat treatment (i.e., $F_0 = 2.52$ min), and can cause spoilage. For economic reason, the spoilage ratio should be kept lower than 0.1%. When thermophilic spore formers are to be accounted for as contaminants having D_{121} values of 3–5 min, the equivalent sterilization treatment should be much higher, sometimes reaching $F_0 = 15$–20 values.

However, for the sterilization of product whose pH is lower than 4.5 (the so-called acid and high-acid foods), not even the minimal requirement for botulinum cook ($F_0 = 2.52$ min) should be applied. Partly, *C. botulinum* cannot grow at or below pH 4.5 and the acidic environment will decrease the heat resistance of microbes. These products can be pasteurized by heat treatment lower than 100 °C.

Conventional Thermal Sterilization

Thermal sterilization is an established technology for canned foods. In the majority of cases, sterilization is applied for foods filled and sealed into containers. However, heat preservation can be applied in bulk food subsequently packaged aseptically. This technology is more frequently used for pasteurized products. Pasteurization temperature and time will vary according to the nature of product. Often high temperature (130–150 °C) is applied for very short time, less than 1 min. These modes of heat preservation are called ultra-high temperature (UHT) and high-temperature short-time (HTST) treatments.

The conventional process of thermal sterilization is made with foods filled in containers. Four main types of containers are used for sterilization: metal cans, glass jars and bottles, flexible pouches, and rigid trays. The length of time required to sterilize a food in container depends on:

- heat resistance and number of microorganisms,
- size and shape of container and penetration of heat into it,
- physical state of the food,
- pH of the food,
- means and conditions of heating.

In addition to the heat resistance of microorganisms, the other factor significantly influencing the efficacy of sterilizing process is the rate of heat penetration to the food container.

To effectively and safely preserve foods using heat treatment, two factors should be considered: (1) the required time–temperature combination to inactivate the most heat resistant pathogens and spoilage organisms in a particular food, and (2) the heat penetration characteristics in a particular food, including the type and size of container used. For the heat sterilization to be efficient, the lethal temperatures are to be achieved at the cold point of containers (Figure 5).

The course of temperature during thermal processing depends on several factors related to: (1) heating conditions (retort type, loading, and time–temperature formulae), (2) heating mode (still or agitated), (3) heating medium (water, steam, with/without overpressure), (4) product type (solid, liquid), and (5) container type, shape, and size. The thermophysical properties of the product, in particular its consistency, will influence the mode of heat transfer, and are of utmost importance for the speed of heat penetration. Basically, in solids it is by conduction and in liquids by convection; however, in real foodstuffs it is usually between the two extremes, and may change during the heating process.

Heat penetration is extremely important, because it is the determining factor for the success of the whole operation. The most suitable and practical method to speed up thermopenetration is the movement of containers during the thermal process. Rotation of containers around their axis is an efficient means to accelerate heat transfer, because this will rapidly mix the contents, enabling a more uniform heating of products, and reducing heating time and organoleptic degradation. Heat penetration is slow in glass containers compared to metal cans.

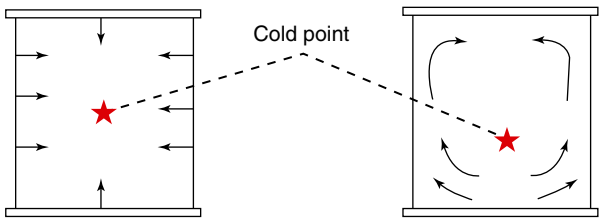

Figure 5 The slowest warming up cold point in containers. Heat transfer is (a) by conduction and (b) by convection. Reproduced by the authorization of the Food and Agriculture Organization of the United Nations from Heinz G and Hautzinger P (2007) *Meat Processing Technology*. Bangkok: RAP Publication.

In addition to the composition and moisture of the food, the acidity and pH value have tremendous impact on the efficacy of heat preservation. Foods can be divided into groups to receive different heat treatments according to their acidity. Acid foods have pH below 4.5 and low acid foods are those with pH above 4.5. Acid food includes most fruits, and pasteurization would suffice for preservation, and low acid foods are those like meat and most vegetables, which require sterilization treatment. Table 2 lists various types of foods and their pH value, together with the heat processing requirements.

Equipment for Heat Sterilization

Canned products are generally processed in a container that may be metal can, glass, or flexible pouch. Sterilization process at temperature greater than 100 °C is made under pressure in retorts or autoclaves. The heat transfer medium is usually saturated steam, hot water, or mixture of steam and air. As the pressure increases, the boiling point of water also increases, allowing superheating of water without boiling. Autoclaves are made in different sizes and shapes and function in different modes. Common types are vertical and horizontal, processing in batch and nonagitating mode; others are rotating the product during heating, and still others operate continuously. In rotary autoclaves the basket containing the cans rotate during sterilization. Cans move end-over-end while rotated. This technique is useful for cans with liquid or semiliquid content as it achieves a mixing effect of the content, resulting in accelerated heat penetration. Continuous retorts also include horizontal rotary models in which the containers conveyed through a spiral fashion within a vessel are heated. The cans rotate axially (side-over-side). Continuous retorts increase the rate of heat transfer in fluid products as well as increase the production rate.

A particularly efficient continuous and agitating sterilization arrangement is the hydrostatic sterilizer. It operates on the hydrostatic principle with the pressure of saturated steam maintained and balanced by the weight of water columns. Hence, a hydrostatic sterilizer consists of four or more towers with a height of up to 20 m (Figure 6). The first tower serves as a preheating section and the second one is the sterilizing section in which the temperature is directly related to the pressure of the saturated steam; by varying the pressure and water column height, the temperature can be controlled. After the sterilizing tower, the cans pass through the cooling tower,

Table 2 Heat processing requirements – dependence on product acidity

Acidity class	*pH value*	*Food commodity*	*Heat processing mode*
Low acid	5.3–6.0	Vegetables	High temperature sterilization
		Uncured meat, poultry, fish, soups	115–121 °C, 240–250 °F
	5.0	Tomato products	105–115 °C, 221–240 °F
Medium acid	4.5–5.3	Fruits, fruit juices	Pasteurization
			100 °C, 212 °F
Acid	3.7–4.5	Fruits	80 °C, 176 °F
High acid	3.0–3.7	Pickles, sauerkraut	80 °C, 176 °F

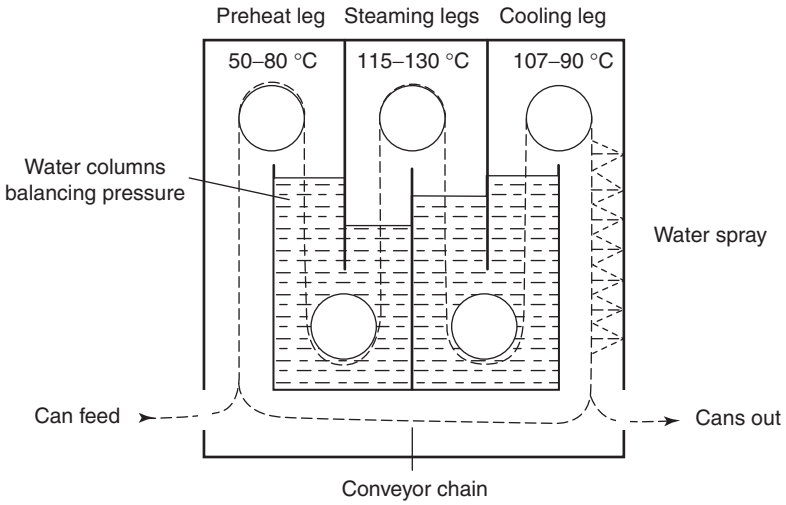

Figure 6 Scheme of a hydrostatic sterilizer.

where the pressure gradually decreases and the cooling is completed at atmospheric pressure. The cans rotate while being conveyed through the machine by endless stainless steel chains.

Aseptic system is a combination of processing and packaging whereby presterilized and cooled product is filled into sterilized container and sealed with a sterile cover under sterile (aseptic) condition. Products are processed outside the package and then filled under aseptic (sterile) conditions into a sterile package. This requires sterilizable equipment, sterile product, sterile packages, sterile environment, monitoring and recording equipments, and proper handling of finished products. Processing temperatures are generally high, 130–150 °C, applied for a short time (few seconds); hence it is called the UHT process. The process avoids the slow heat penetration inherent in the traditional in-container heating process as the food is heated in thin layers passed through a heat exchanger. The UHT process can be applied for liquid foods, including milk, fruit juices, and salad dressing; with liquids this aseptic technology has now almost completely replaced conventional sterilization in containers. It can also be adapted for foods that contain small particles (e.g., baby foods, tomato products, and soups). Containers used for aseptic filling after heat sterilization are not exposed to heat and pressure; hence a great variety of materials and size are suitable, including laminated cartons, plastics, pouches, cups, and other packs. They can be presterilized with UV or ionizing radiation, hydrogen peroxide, or steam.

The most frequently used form of packaging for canned products is tinplate, which is fabricated into two and three piece cans of a wide variety of shapes and sizes. The hermetic closing of cans by double seams is crucial to protecting the product sealed inside. Errors in double seaming can lead to loss of the hermetic seal and the possibility of postprocess contamination, giving rise to spoilage of canned food. Glass can be equally used for processing canned products although the thermal properties of glass would not tolerate rapid changes in temperature. Glass is also susceptible to breakage due to internal pressure and mechanical impact. Special lids and sealing are used for closing of glass jars and bottles.

Accurate filling is required for declared weight and filling also has an impact for subsequent heat processing. Hermetically sealed glass or metal cans are not filled completely; a headspace is left to form a partial vacuum after heating and cooling. Exhausting is made after filling and before closing cans or jars to remove air from the contents but leave a headspace for vacuum to be formed when the container is cooled.

Even if the thermal process schedule is strictly controlled to avoid underprocessing spoilage, product shelf-life will be compromised if there is postprocess leaker spoilage. Several factors may contribute to postprocess leaker spoilage; including contaminated cooling water, poor postprocess hygiene and sanitation, and container damage during handling and storage. Table 3 lists the possible causes of canned foods and the sign by which the cause of spoilage can be identified. Often the outer appearance of the containers indicates the possible cause of spoilage, in particular if gas development deforms the shape of the can with various degrees of swelling. Evancho et al. (2009) recently provided an overview on the microbiological spoilage of canned foods.

Canning

Food preservation by heat treatment is a common practice of the food industry called canning.

Although, from the microbial point of view, it would be ideal to employ such intensive heat treatment that would eliminate the risk of any surviving microorganisms, most canned food products cannot be submitted to such degree of heating because it would degrade the sensory quality and result in loss of nutritional value. Hence in practice, a compromise is looked for in order to provide a heat treatment intensive enough for the microbiological safety of the products and in the same time moderate enough for preserving the

Ready-to-eat foods	4.5–6.5	5.0–30.0

product quality. Commercial sterility is a generally accepted practice of canning.

As discussed in the section Determination of Heat Process Requirement, *C. botulinum* is used as a reference organism for manufacturing of safe and stable products by a heat treatment with a minimum F_0-value of 2.52 min. Based on microbiological considerations and including a sufficient safety margin, most sterilized canned products should be produced with F_0-values of 4.0–5.5. The retort temperatures to be used may vary between 117 and 130 °C (depending on the heat sensitivity of the individual products). It is known, however, that certain thermophilic sorganisms such as xG. *stearothermophilus* or *C. thermosaccharolyticum* are extremely heat resistant and may survive F_0-values of 4–5.5. In the case of survival they will not grow under normal storage conditions of up to 25 °C and do not pose a risk in countries with moderate temperatures. However, they may grow under tropical conditions in particular with storage temperatures of 25 °C and above. Hence, F_0-values of 12–15 have to be employed in cases containing this risk (Table 4).

Table 5 Some commercial F_0 values of thermal processing

Product	F_0

Traditionally, canned foods are understood as sterile or commercially sterile, shelf-stable food products packed in and sealed hermetically in containers. The name refers to the rigid metal canisters (cans) although the containers can be glass jars and bottles and also semirigid, flexible plastic materials (e.g., pouches). Today a large variety of canned foods are available and processed in cans or other containers. Many of them are fully sterilized products, which can be stored under ambient temperatures; others are only pasteurized and have limited shelf-life even under refrigerated storage condition. However, there are many kind of heat preserved foods manufactured beyond the traditional processes of canning. For example UHT milk in laminated cardbox, or pasteurized beer filled in metal can with pull tab. However, a cooked, vacuum packed, and chilled food (sous-vide product) of limited shelf-life hardly suits the notion of canned product.

Most canned meat and vegetable products fall in the category of low acid foods, and these must be submitted to heat treatment by the combination of temperature and time to be sterile or commercially sterile by applying a minimum botulinum cook ($F_0 = 2.5$ min) or higher. There are other foods of medium or high acidity (pH below 4.5) for which the application of botulinum cook is not necessary and can be sterilized at lower temperature and/or shorter time (e.g., tomato and most fruit products; see **Table 5**). These are also considered canned foods when packed and heated in hermetically sealed containers.

The fully canned foods are expected to have a shelf-life of at least two years from the date of processing. However, canned foods could retain safety and nutritional value well beyond two years, but they may show some change in quality, such as color and texture. Practically, a canned food has an almost indefinite shelf-life at moderate temperatures (20–25 °C, 68–77 °F). In fact, canned food as old as 100 years has been found in sunken ships and was still microbiologically safe for human consumption. Canning has remained a reliable, well proven technology, and the popularity and consumption of heat processed foods is only increasing. Acceptability of canned product can be attributed to the excellent safety record although the range of heat processed products has tremendously widened.

Glossary

Control measure Action used to prevent, eliminate, or reduce a food safety hazard.
Cross contamination Transfer of microorganisms from one surface or food to others.
Human pathogen An organism able to cause diseases in humans.
Postharvest Processes following harvest of the crops.
Preharvest Processes on the field or farm before harvest of the crops.

Introduction

Fresh fruits, vegetables, and herbs play an important role in human nutrition and contribute essentially to public health. This is reflected in many health promoting programs of health agencies in many countries in order to protect against many diseases, for example, cancer, cardiovascular diseases, diabetes, and chronic diseases, which in turn increased the demand

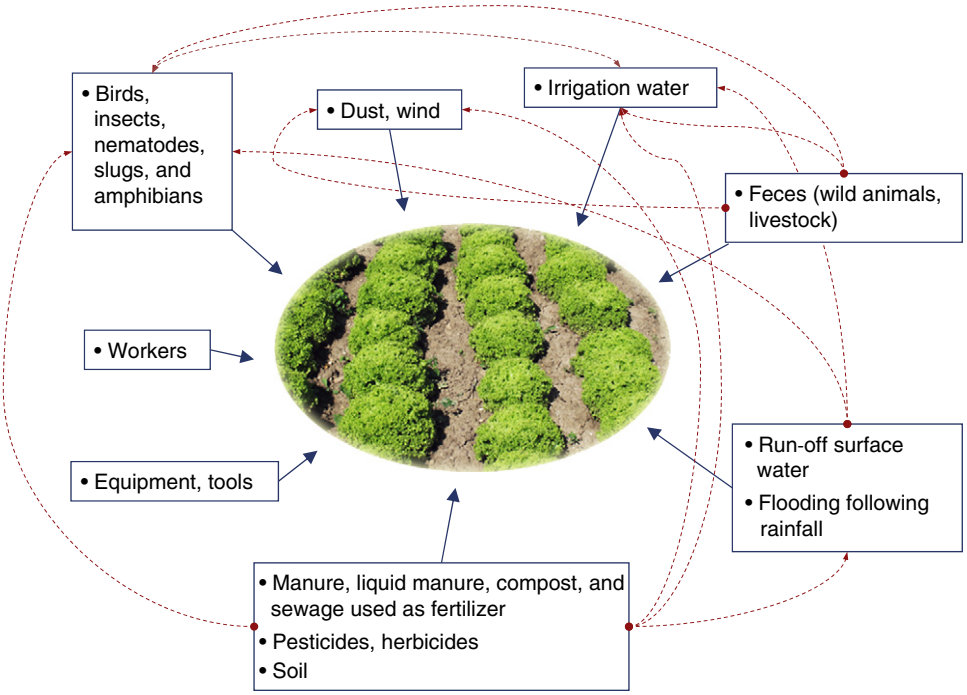

Figure 1 Possible sources of human pathogenic contamination in preharvest produce production.

for fruits and vegetables enormously. Therefore, human consumption of fruits and vegetables increased by 4.5% per year between 1990 and 2004. Global distribution and trading chains as well as the product varieties and minimally processed produce, for example, fresh-cut lettuce and fruit salads, have been widened. However, fresh fruits and vegetables, when consumed raw, caused several disease outbreaks in recent years including multicountry outbreaks – the number and frequency of foodborne outbreaks and the number of people affected because of such outbreaks revealed by epidemiological data increased in parallel to the increased production and consumption. Fresh produce eaten raw is therefore considered as high-risk food. Microbial contaminations may occur during pre- and postharvest stages. Severe outbreaks have been found to be caused after consumption of a wide variety of contaminated produce, for example, sprouts, spinach, lettuce, pepper, tomato, cantaloupe, and berries. Such outbreaks not only affect health but also economic aspects (growers and processors) due to recalls and loss of consumers' trust in fresh produce. There is a need to improve knowledge of the ecology of human pathogens and to adapt farm-to-fork strategies in order to enhance microbial safety of fresh produce. Over and above microbial agents there is a risk with chemicals, for example, pesticide residues or mycotoxins, which may be a major issue particularly in developing regions. Thus, this article focuses on the microbial food safety risks.

Preharvest Contamination

On the field, pathogens may find their way onto fruits and vegetables from contaminated water (run-off, flooding, and irrigation), soil, insufficiently composted manure used as fertilizer, feces from livestock and wildlife, through animals (e.g., insects and amphibians) having been in contact with contaminated water and intruding fields, workers, equipment, dust, and water used to apply herbicides and pesticides (Figure 1). It is known that human pathogens are able to survive and grow in herbicide-, insecticide-, and fungicide solutions. The contamination risk in production of fresh produce is dependent on the crop plant. Plants grown close to the ground, such as lettuce or cantaloupes, bear a higher risk than aerial fruits. Pathogens can grow on leaves or fruits of the crops or can enter the plants via root lesions. Obviously, the risk of internalization of pathogens via soil is lower than via leaves.

As is the case of outbreaks of foodborne pathogens associated with meat, milk, and other food, animals (cattle, swine, sheep, poultry, and wildlife species) play a key role as carriers of pathogens like *Escherichia coli*, *Salmonella enterica*, and *Campylobacter jejuni*. Transmission of pathogens occurs through the fecal–oral pathway. Colonization of animals by pathogens depends on the uptake pathway via feed, grass, and drinking water, as well as on pathogen factors (survival in the environment, soil, water, and intestinal tract) and animal factors (immune system, moving, defecation, and population density). Climatical conditions may increase or decrease the incidence of pathogens in environmental niches. Livestock in close proximity to agricultural land, where produce is grown, poses a threat for potential contamination and wild animals that may be present at feedlots might contribute to the spread of pathogens. Birds' feces were shown to contain a range of pathogens and insects; nematodes and slugs were shown to uptake and excrete pathogens.

Recent studies reported incidences of *E. coli* O157:H7 in 0.2–28% of cattle feces samples depending on the sampling

site (feedlot, pasture land, and slaughter) and kind of feeding. Surveys of pigs revealed 1.2–8.9% of samples being positive for *E. coli* O157:H7. *S. enterica* could be identified in 1.4–9% of cattle feces samples, in 23.4% of pig feces samples and in up to 13% of poultry samples. *Listeria monocytogenes* has been shown to appear in up to 50% of fecal samples from animals like cattle, sheep, goats, pigs, and poultry. Incidence of *C. jejuni* in animals mentioned above is similar to that of *E. coli* O157 and *Salmonella*. However, incidence in produce is absent or much lower. This is reflected by only a few outbreaks of *C. jejuni* associated with produce (lettuce, sweet potatoes, cantaloupe, strawberries, and cucumber). This might be explained by lower fitness of *C. jejuni* in environments linked to produce production. Compared to total foodborne infections, *Campylobacter*-related outbreaks associated with fresh produce are rather rare.

Persistence of *E. coli* O157, *E. coli* O157:H7 or *Salmonella* spp. in soil, water, or manure has been reported in several studies. Accordingly, these pathogens survived in some samples between more than 30 days and several months; an outbreak strain of *Salmonella* Enteritidis was detectable for more than 4 years in soil from an almond orchard. It has been shown that survival of *Salmonella* Typhimurium and *E. coli* O157:H7 in manure of cattle fed with high-fiber and low-energy diet was significantly lower than in manure of cattle fed with low-fiber and high-energy diet. Survival of theses pathogens is greater in dairy slurry than in solid dairy manure.

Quality of irrigation water plays an essential role in produce production as water is a key vector for transmission of pathogens. Quality of well- or surface water used is affected by geography, hydrology (salinity, nutrients, fecal dispersion, and concentration of pathogens), ecology (vegetation), and meteorology (temperature, rain fall, and floods). Flooding of fields following strong rainfall intensity is supposed to increase contamination through spread of feces, contaminated water, or soil. This is particularly critical after periods of drought.

Harvest and Postharvest Contamination

During harvesting, vegetables, herbs, and fruits may get contaminated by the field environment (e.g., soil and dust), by contact with harvesting equipment, and in case fruits and vegetables are harvested by hand, there is also an increased risk of transmission and spread of pathogens through workers. In particular, leafy vegetables and herbs are susceptible to mechanical injury leading to opening of the plant tissue, which in turn favors microbial growth and internalization. During subsequent processing, populations of pathogens having emerged on vegetables and fruits during preharvest stages or harvesting are able to proliferate. Postharvest processes in the packing house (grading, washing, cutting, and storage) play important roles as possible sources of contamination. Contamination may also occur through ill workers during processing or through rodents and contaminated containers during storage and transport. Fecal contamination, that is heterogeneously distributed in fields, orchards, on fruits, and vegetables, may lead to the spread of pathogens during postharvest handling. The postharvest microbial community on the surface of fruits and vegetables and storage conditions must be considered as critical factors because growth of human pathogens is affected by postharvest plant pathogens, for example, *Botrytis cinerea* or *Glomerella cingulata*. The latter was shown to promote growth of *L. monocytogenes* inoculated in decayed apple tissue in part due to an increase in pH from 4.7 to 7.0 in the infected tissue.

Cross-contamination during transport, at processing plants, for example, regarding fresh-cut produce, at markets or in restaurants needs to be taken into account. Packing technology and material must be carefully selected to avoid growth of pathogens. Leafy vegetables and herbs often exhibit high respiration. When packed under modified atmosphere for extending shelf life, levels of O_2 and CO_2 may change in a way favoring growth of, for example, *Clostridium botulinum* or *L. monocytogenes*. Proper processing of fruits and vegetables is a prerequisite to obtain safe food products. There have been outbreaks of spore-forming bacteria associated with faulty processing of fresh produce such as outbreaks of botulism associated with improper preservation of garlic-in-oil (pH >4.5, prepared without heat treatment or chemical or acid additives) or associated with canned bamboo shoots.

Outbreaks: Sources, Transmission, and Examples

Reasons which contribute to the observed increase in outbreaks may not simply be due to increased consumption of fresh vegetables, herbs, fruits, and ready-to-eat products. Several factors are discussed. An increase in contamination may contribute to higher numbers of outbreaks and illnesses. Production, processing, kind of produce, cultivar, and physiological state of plant and pathogens are critical factors and probably multiple events have to take place to cause an outbreak. In case an outbreak occurs, lack of information on consumed produce often hinders rapid identification of the product causing it. This is especially true as many salads including sprouts are consumed as mixtures. In addition, the number of consumers eating food prepared outside their home is increasing, thereby contributing to a greater risk of foodborne diseases. Global production, trade, and distribution of a wide variety of produce and its perishability pose major challenges for tracing the source of contamination and its mechanism. Longer food supply chains, enhanced pathogenicity of microorganisms due to genetic adaptation (greater virulence or drug resistance) or the more vulnerable older human population due to weakened immune systems may also lead to the increase in produce-associated diseases. More sensitive and specific identification and typing methods for elucidation of outbreaks and their sources are required (e.g., PulseNet in the US, national surveillance network).

The spectrum of microorganisms linked to produce-associated outbreaks comprises viruses, bacteria, protozoa, and helminths (Table 1). Originally, viruses have been reported to account for 20% of outbreaks. However, today, the number of norovirus-associated outbreaks has increased significantly, also due to improved surveillance and novel diagnostic and identification methods used. Most norovirus and hepatitis A infections caused by contaminated food are due to insufficient hygiene of infected workers on farms, in postharvest processes, or in gastronomy. Norovirus- and hepatitis A-related gastroenteritis has been reported to be

associated with raspberries, strawberries, cantaloupe, onions, or lettuce, respectively.

Protozoan parasites have been reported to account for 16% of the outbreaks related to produce in the US, mainly due to *Cyclospora cayetanensis*, *Giardia lamblia*, and *Cryptosporidium parvum*. *Toxoplasma gondii*, a ubiquitous occurring parasite with a wide host range among warm-blooded vertebrates causing toxoplasmosis poses a particular risk to pregnant women and their fetuses due to vertical transmission if infection occurs during pregnancy. Infections with *T. gondii* have been associated with consumption of unwashed produce that may have become contaminated with oocysts through cat feces in home gardening. Among eukaryotic parasites it is worth to note the possible risk with *Echinococcus multilocularis* causing alveolar echinococcosis, a severe liver disease. Raw fruits and vegetables from fields and gardens contaminated with eggs of *E. multilocularis* are likely to act as infection routes in humans. Carnivorous species like the fox are definitive hosts that excrete eggs with their feces which can contaminate the produce. It is therefore recommended not to consume unwashed produce from field or garden and not to pick low-hanging wild berries.

Pathogenic bacteria transmitted traditionally via food of animal origin have been linked to 60% of the outbreaks related to fresh produce between 1973 and 1997 in the US. Bacterial variety comprises pathogenic *S. enterica*, *E. coli*, *Campylobacter* spp., *L. monocytogenes*, *Shigella* spp., *Yersinia* spp., *Bacillus cereus*, and *Staphylococcus aureus*. *Salmonella* has been the major cause for outbreaks associated with fruits and vegetables – responsible for half of the bacterial outbreaks. Regarding the produce range reported to be linked with outbreaks of different *Salmonella* serovars, the following are documented most frequently: tomato, cantaloupes, peppers, rocket leaves, basil, and sprouts (e.g., alfalfa, mung bean, and radish).

Outbreaks caused by preharvest contamination have been reported from the US, Mexico, and Europe and comprise *E. coli* O157:H7, enteroaggregative *E. coli* (EAEC) and *Salmonella* associated with leafy greens, tomato, cantaloupes, sprouts, carrots, peppers, and almonds. But also outbreaks of *Shigella* spp. and *Yersinia pseudotuberculosis* associated with lettuce, parsley, tomato, or carrots have been linked with preharvest contaminations. An outbreak of *Shigella sonnei* infections associated with eating parsley has been linked with on-farm postharvest cooling processes. Postharvest contamination of lettuce through contaminated shredding equipment caused an outbreak of salmonellosis.

Several outbreaks of *Salmonella* and *E. coli* including Shiga toxin-producing *E. coli* worldwide have been associated with sprouts produced from contaminated seeds, which in turn have been produced in an agricultural environments not being sufficiently controlled for microbial safety. In subsequent steps of sprout production, conditions are also optimal for growth and multiplication of pathogens present on or in seeds, even after long storage periods. In Germany 2011, EAEC O104:H4 caused the largest outbreak of hemolytic uremic syndrome (HUS) and bloody diarrhea ever described worldwide, which has been linked with sprouts. This outbreak affected 3842 people (855 cases of HUS and 2987 cases of acute gastroenteritis). Of the HUS patients 35 died, and of the patients with acute gastroenteritis 18 died.

In many cases, preharvest contamination could be verified by isolating and identifying the same strain both in clinical specimens and environmental samples. This has been demonstrated particularly for several outbreaks linked to vegetables and the irrigation water used.

L. monocytogenes is considered as a major agent causing foodborne diseases as it differs from other foodborne pathogens by its ability to grow under diverse conditions (low pH, high osmolarity, low temperature, and low oxygen). A multistate outbreak of listeriosis in the US 2011, affected 146 persons. Thirty people died and a woman pregnant at the time of illness had a miscarriage. Cantaloupes from a farm in Colorado were identified as the source of the outbreak.

The situation with regard to developing countries is of particular importance, as standards of sanitation and Good Agricultural and Manufactory Practices (GAP and GMP) are often lacking or are less well established. Therefore, several agents are prone to be spread with fresh fruits, vegetables, and herbs. Infections with *Salmonella* Typhi and Paratyphi A occurring only in humans and causing typhoid fever are still common in developing countries. Fruits and vegetables can cause typhoid fever if they have been improperly handled by infected persons shedding the bacteria or if plants have been irrigated with water contaminated by sewage containing *S.* Typhi and Paratyphi A. Outbreaks of *Shigella* and *Vibrio* spp. related to fresh produce have been reported. Besides norovirus and hepatitis A, rotavirus is a major cause for gastroenteritis, particularly among children. It is likely that raw fruits and vegetables handled by infected persons cause illnesses. Foodborne parasitic infections due to several helminths often occur in developing countries through consumption of raw produce that has been contaminated with feces, soil, irrigation water, sewage, improper handling, or processing. Up to 10% of people in developing countries are infected with intestinal worms. Helminths as eukaryotic parasitic worms comprise cestodes, trematodes, and nematodes. Symptoms range from nonspecific symptoms, diarrhea, muscle pain, cough, skin lesions, malnutrition, weight loss, and neurological and other symptoms.

Data on Incidence of Pathogenic Contamination of Produce

The incidence of foodborne pathogens in fresh produce surveys has been reported in several studies ranging from 0% to 10%, occasionally up to more than 20%. *Salmonella* was found in 0.3% (range from 0.1% to 2.3%) of produce samples tested in 2007 within the European Union, of which mainly the precut ready-to-eat products revealed highest proportions of contamination. In total, 1.5% and 2.2% of sprouts samples were contaminated in the Netherlands and in Germany, respectively. *Salmonella* was found in 0.4% to 0.5% of herbs and spices from Hungary, UK, and Netherlands. A survey on minimally processed vegetables in Brazil showed 2.2% of the samples being contaminated with *Salmonella*.

A study by the US Department of Agriculture (USDA) (2002–2007), monitoring microbial safety of fresh produce (>59 000 samples) showed that the incidence of *E. coli* with virulence traits including Shiga toxin 1 and 2 ranged from 0.1% to 0.4%. A survey for generic *E. coli* on produce items (1183 samples) from Canada (2004) demonstrated that 0%, 1.3%, 6.5%, 11.6%, 4.9%, and 13.4% of tomato, cantaloupe, conventional lettuce, organic lettuce, cilantro, and parsley, respectively, were contaminated. Highest concentrations were found in cilantro (up to 7600 colony forming units (CFU)/g) and parsley (16 000 CFU/g). In another study, bagged precut spinach and lettuce mixtures from conventional and organic culture in the US were analyzed – 12.1% and 16.6% as well as 23.1% and 6.3% of the respective samples were tested positively for *E. coli*. Another survey from South Africa showed 2.2% of fresh vegetables to be contaminated with *E. coli* O157:H7. In general, results of these studies show a high variability of produce quality with respect to region, year and probably also to the methods used for identification and quantification. Significant data on correlations between incidence of generic *E. coli* and enteric human pathogens on produce are largely lacking. However, incidence of generic *E. coli* can be used as a marker for potential pre- and postharvest contamination. *C. jejuni* is rarely detected in produce grown in the Western world, but frequently in fruits and vegetables in developing countries. *L. monocytogenes* and *Listeria* species were found in cabbage, cucumber, potato, and radish. In addition, *L. monocytogenes* was isolated from ready-to-eat vegetables including beans, tomato, artichoke, peas, and cauliflower.

Microbial Attachment, Colonization, Survival, and Transmission

After attachment of microorganisms to the surface of fruits and vegetables, they are able to colonize further parts of the plant and to proliferate, and thus being transferred to the host. Proliferation is supported by high temperatures, humidity, and ideal nutrient status. Bacteria are not only able to attach to the surface of plants, but several studies showed that they are also able to internalize into inner tissue of plants via leaves, roots, or flowers. Studies showed that *E. coli* and *Salmonella* can persist for months after application on leaves. Serovars of *S. enterica* are able to colonize seeds, sprouts, leaves, and fruits. It has been reported that serovar-specific behavior in attachment and several modes of action during attachment of *Salmonella* exist. Pilus curli, the O-antigen capsule and cellulose synthesis are essential factors for adhesion. Curli and cellulose also promote the formation of biofilms, which was shown to strongly support adhesion and persistence on leaves. Obviously, flagellae also promote adhesion of the bacteria to leaves as shown for *Salmonella* Senftenberg. *E. coli* O157, in contrast to nonpathogenic strains, has been shown to attach to tomato fruit surface, spinach leaves, and sprouts via curli. Additionally, filamentous type III secretion system and flagella have been shown to be involved in adhesion to leaves. Human pathogenic bacteria, after having attached to the plant surface, are able to integrate into the phyllosphere microbial community. Several studies used *E. coli* and *Salmonella*, which have been sprayed or applied on leaves, inoculated into seeds and roots or applied directly in the soil. Furthermore, the rhizosphere might serve as another plant environment, where human pathogens are able to establish.

Risk and Control Measures

The application of GAP and GMP, Good Hygiene Practices, and implementation of Hazard Analysis and Critical Control Point systems are essential measures to assure safety of fresh produce from the farm to the consumer. As farming procedures exhibit diverse characteristics due to the kind of vegetable and fruit as well as production conditions (soil, irrigation, harvesting, sorting, packing, transportation, and storage), a well-designed food safety plan pointing to hazards and risks is required. The US Food and Drug Administration has published guides to minimize microbial food safety hazards of fresh fruits and vegetables, tomatoes, melons, and leafy greens comprising GAPs to reduce hazards along the entire food chain. It is worth mentioning that current technologies and practices are able to reduce microbial risks, but all hazards associated with fresh produce cannot be eliminated completely. Therefore, prevention of contamination from the field onwards is the most important issue to assure food safety.

Seeds used in produce production should be considered as an early critical point in hazard analysis as pathogens are able to survive on or in dried seeds. Appropriate storage conditions and exclusion of rodents from storage facilities to avoid fecal contamination are vital. It is worth mentioning that postharvest decontamination processes such as treatments with solutions containing chlorine do not fully prevent from bacterial regrowth. This is due to inaccessible sites of seeds and produce where pathogens are protected. It has been shown that chlorine in combination with ozone or ionizing radiation is efficient to reduce microbial load and to increase shelf life of leafy green vegetables. However, restrictions on using disinfectants with produce in some countries need to be considered.

To maintain and regularly control quality of water used in irrigation, crop protection, washing, and packing are prerequisites for safe production and processing of fruits and vegetables. The WHO standard for irrigation water in production of crops eaten raw is $<10^3$ coliform bacteria per 100 ml. Studies implicate that overhead irrigation increases the risk of contamination of vegetables as compared to drip irrigation.

Sufficient treatment of animal wastes by composting and heat treatment according to regulatory requirements decreases the risk of contamination when manure is applied to fields as soil amendment. Recommendations from national programs for time intervals between application of manure and harvest, for example, 90 or 120 days for fruits and vegetables whose edible parts have no or have contact to the soil, respectively, should be followed.

Access of livestock and wildlife species to produce and sprout seed production fields as well as irrigation water should be restricted to avoid fecal contamination of produce. Feces of birds was shown to contain pathogens. Avoidance of flooding of fields supports safety in the preharvest stage.

At harvest, sorting, and packing, the hygiene and health of workers is critical to prevent contamination of produce. Proper use of gloves, disinfectants, and toilets as well as efficient hand-washing significantly reduces the risk of contamination.

During processing of harvested produce, the equipment used in washing, sorting, cutting, and packing as well as the surface of facilities being in contact with produce need to be made of appropriate material allowing easy cleaning and regular disinfection. Washing water should be of drinking water quality. Formation of biofilms by nonspoilage, spoilage, and pathogenic microorganisms on equipment surfaces must be avoided as biofilms are difficult to eliminate, even when sanitized water is used. Regular surveillance, sampling, and analysis of surface samples help to reduce the risk of contamination and biofilm formation. Because temperature is the key factor for bacterial growth, control, and maintenance of appropriate temperature within the cold chain including precooling by icing, hydrocooling, or vacuum cooling, and during processing and distribution are essential measures to guarantee safety. Clear instructions and operating procedures for the process steps mentioned above need to be implemented, documented, and controlled.

Personnel at all levels of the chain must be educated and regularly trained, appropriate supervision must be arranged and management of the farms and processing plants must actively support a commitment of food safety and be aware of microbial hazards. Independent audits on farms and processing plants help to ensure that GAPs are implemented. Besides agricultural workers and food handlers, consumers are expected to follow guidelines that help to maintain food safety during transport, storage, and preparation at home. Selection at retailers should exclude damaged or slimy produce and subsequent transportation to home should be as rapid as possible using appropriate insulated transport bags. Leafy vegetables and herbs are recommended to be stored in a clean refrigerator at temperatures below 5 °C. Outer leaves should be removed and produce placed in plastic bags within the refrigerator. Good hygiene during handling of fresh produce includes application of proper hand washing techniques using soap and clean water for 20 s before and after preparing produce, use of hygienic utensils, cutting boards, and sinks in the kitchen protecting produce from cross-contamination, and finally potable running tap water should be used for washing just before eating. However, washing will never remove all microorganisms – it has limited effects on attached microorganisms. It should be a goal of consumers' education to increase their awareness of microbial risks related to fresh produce and to improve knowledge in hygienic handling of fresh and fresh-cut fruits, vegetables, and herbs. Stakeholders (government, industry, media, and consumer organizations) should communicate relevant information consistently and in an easily understandable manner.

There are promising results giving rise to the development of alternative practices on the field using natural antagonistic bacteria inhibiting growth of human pathogens in the phyllosphere. This has been shown for species of *Bacillus*, *Pseudomonas*, *Aeromonas*, *Pantoea*, *Klebsiella*, *Burkholderia*, and *Enterobacter*. Traceability systems of products as well as state-of-the art methods for sensitive, rapid, and robust identification and typing of human pathogens on fresh produce are prerequisites for preventing and elucidating outbreaks.

Currently, knowledge on contamination sources and spread of pathogens in the fresh produce chain as well as on colonization, internalization, and proliferation is still limited. These processes are less well-understood in fruit production than in vegetable production. Better insights into plant–microbe interactions, environmental conditions, and food processing and distribution are necessary to further reduce the risk of microbial contamination and to understand the occurrence of pathogens previously not associated with raw fruits and vegetables. This is particularly important when introducing new processes and when launching new products on the global market.

SAFETY OF FOOD AND BEVERAGES

Seafood

A DePaola, US Food and Drug Administration, Dauphin Island, AL, USA
H Toyofuku, National Institute of Public Health, Saitama, Japan

Glossary

Bivalve mollusks Filter-feeding lamellibranch mollusks.
Candling A method to detect worms embedded deep in the flesh of fish, which are not immediately obvious. It usually involves shining a bright light through the fillet. In commercial practice, candling is effective in detecting Phocanema in thin skinless fillets of white fish, particularly cod; the method does not work well on thick fillets with the skin on. Candling is less effective in detecting *Anisakis*. The simplest kind of candling table is a box about 50 cm square with a ground glass or Perspex top about 6 mm thick. The inside of the box is white, and is lit by two fluorescent tubes giving a white (not colored) light.
Decomposition The deterioration of fish, shellfish, and their products, including texture breakdown. It causes a persistent and distinct objectionable odor or flavor.
Harmful algal blooms (HABs) Rapid proliferation of single-cell algae causing environmental harm such as anoxia, objectionable odors, lethality to aquatic fauna, or accumulation of marine toxins in seafood species.
The Codex Alimentarius Commission The Commission was created in 1963 by the Food and Agriculture Organization of the United Nations (FAO) and World Health Organization (WHO) to develop food standards, guidelines, and related texts such as codes of practice under the Joint FAO/WHO Food Standards Program. The main purposes of this Program are to protect the health of consumers, ensure fair trade practices in the food trade, and promote coordination of all food standards work undertaken by international governmental and nongovernmental organizations.

Introduction

Seafood is the only major food commodity that is extensively harvested from the wild. Additionally, aquaculture is the fastest growing sector of the food supply. The marine and aquaculture environment is a rich source of seafood hazards including bacterial and viral pathogens, parasites, marine toxins, heavy metals, and other chemical contaminants from anthropogenic sources, such as pesticides and pharmaceuticals. Almost every category of known biological, chemical, and physical hazard can occur in seafood and is also a common cause of food allergies. Some hazards that have been introduced preharvest can increase following postharvest handling, whereas others may be effectively mitigated. Additional hazards may be introduced postharvest, during production, or during processing, and vary considerably among seafood commodities. Of all available seafood commodities, live and raw bivalve mollusks are among the most risky products consumed by humans. Bivalve mollusks filter large volumes of seawater and bioconcentrate suspended particles including pathogens and harmful algal species when present in the water column. The risk is further exacerbated by certain cultural and social practices such as consumption of the entire bivalve mollusk, in either the live, raw, or lightly cooked state. Hazards associated with fish, crustacea, and other seafood commodities are largely related to species, trophic status, production region, habitat, harvest practices, and consumption patterns.

Preharvest controls are the most effective means to address microbial and chemical hazards that are introduced via the seafood production environment. Monitoring programs vary according to hazard and the circumstances of its introduction. Monitoring approaches include measurements either from the water column directly or in the seafood species affected. For instance, in the case of shellfish toxins, harmful algal bloom species are monitored by state health agencies and/or those responsible for fish and wildlife on a regular basis (e.g., weekly or biweekly) and harvests and growing areas are placed under temporary closure based on these cell density thresholds until toxin testing in shellfish/fish can be performed. Likewise, levels of indicator organisms such as fecal coliforms in bivalve mollusks or their overlying waters are used to manage risks associated with enteric pathogens. In some cases direct measurement of the hazard is not effective because analytical procedures are too slow or resource intensive and measurement of indicators are more appropriate. In an effort to provide early warning, predictive models incorporating climate and ocean conditions such as rainfall, water temperature, and salinity are under development for control of hazards including harmful algal blooms and naturally occurring pathogens such as *Vibrio* spp. Permanent closures are necessary for hazards that may be continuously introduced or persist in

 doi:10.1016/B978-0-12-378612-8.00281-X

edible flesh of the seafood species, for example, industrial chemicals and heavy metals.

Commodity definitions are described in the Codex Code of Practice for Fish and Fishery Products (CAC/RCP 52-2003) and the associated hazard controls are published in this code and similar codes adopted by the Codex Committee for Food Hygiene. In the US, European Union and other developed countries, the safety of harvested seafood is controlled by a hazard analysis critical control points (HACCP) system and is also applied to developing countries that export seafood to developed countries. HACCP is a science-based systematic approach to the identification of significant food safety hazards and measures for their control or prevention to ensure the safety of food. In the seafood industry, business operators use the HACCP system and its prerequisite programs such as good hygienic practices to control hazards. One key element for successful HACCP development, implementation, and ongoing verification is to provide appropriate training for seafood processing plant employees.

This article presents an overview of seafood hazards and provides sources of information for assessing risk, control guidance, regulations, and advice on approaches for testing seafood for prominent hazards.

Pathogens

Pathogenic bacteria indigenous to the aquatic environment and naturally present in animals consumed as seafood, include *Vibrio cholerae, Vibrio parahaemolyticus, Vibrio vulnificus, Plesiomonas shigelloides, Aeromonas* spp., and *Clostridium botulinum*.

Vibrio spp. are ubiquitous in coastal environments and are a leading cause of illness and death associated with seafood consumption worldwide. Vibrio illnesses range from relatively mild diarrhea from ingestion of *V. parahaemolyticus* to life threatening diarrhea or septicemia from *V. cholerae* or *V. vulnificus*, respectively. Other than choleragenic *V. cholerae* that is typically transmitted via the fecal-oral route, nearly all human vibrio illnesses worldwide are associated with seafood consumption. Bivalve mollusks are typically the dominant vehicle of vibrio infections in the US and other western countries. In some Asian countries such as Japan, where fish (sashimi) and seafood other than bivalve mollusks are commonly consumed raw such as sea urchin and octopus, these products are a more significant cause of *V. parahaemolyticus* gastroenteritis than bivalve mollusks. The first *V. parahaemolyticus* outbreak ever reported was linked to a small salted fish product, shirasu, in Japan in the early 1950s and led to more careful oversight to assure appropriate salt content. Other articles of this volume are devoted to each of the above species. The Food and Agricultural Organization (FAO) and the World Health Organization (WHO) have published several risk assessments addressing vibrios in seafood.

Vibrios are most abundant in warm and moderately saline areas and outbreaks in temperate climates occur primarily during summer months when seawater temperatures are $>15\,^{\circ}C$. Monitoring of vibrios in the environment or the food supply is resource intensive and provides little public health value because products are generally consumed before analytical results are available. Vibrio abundance varies greatly but can be estimated based on water parameters such as temperature, salinity, and turbidity, which can be conveniently measured *in situ* or by remote sensing using satellite imagery. However, vibrio levels are not a reliable indicator of risk as the proportion of the vibrio population that is pathogenic is typically small and varies between the *Vibrio* spp. and regions.

Virulence in *Vibrio* spp. is multifaceted and much research remains to fully elucidate the mechanisms of pathogenicity. There are some well-established virulence determinants or markers in *V. parahaemolyticus* and *V. cholerae*. Greater than 90% of clinical *V. parahaemolyticus* isolates produce a thermostable direct hemolysin and/or a related toxin coded by the *tdh* and *trh* genes, respectively, but usually $<1\%$ of isolates from the environment or seafood contain either of these genes. Certain populations such as pathogenic *V. parahaemolyticus* (*tdh* and *trh*-positive) in the US Pacific Northwest or members of the pandemic clone of *V. parahaemolyticus* (*tdh*-positive, *trh*-negative) appear to have an attack rate that is more than 1000-fold greater than other pathogenic strains.

Cholera epidemics are caused by choleragenic *V. cholerae* strains possessing the cholera toxin gene, *ctx*, and belong to either serogroup O1 or O139. Contaminated drinking water and poor hygienic practices fuel epidemics in developing countries but epidemic strains also have reservoirs such as copepods in the aquatic environment. Shedding of *V. cholerae* in fecal material from infected humans is considered a major source of seafood contamination and detection of toxigenic *V. cholerae* is rare in nonendemic areas. Non O1/O139 serogroups of *V. cholerae* are frequently found in brackish water and cause mild to moderate gastroenteritis and are among the most common vibrio infections in developed countries. With the exception of a few serotypes such as O141 and O75, clinical strains of non O1/O139 *V. cholerae* rarely possess the *ctx* gene and their virulence mechanisms are poorly understood.

V. vulnificus primary septicemia has most often been associated with consumption of oysters harvested from coastal areas of the US Gulf Coast when water temperatures exceed 20 °C. They possess numerous putative virulence factors but their mechanism of virulence is poorly understood. The organism invades through the intestinal mucosa into the circulatory system causing primary septicemia. The disease progresses extremely rapidly and has the highest death rate of any foodborne organism. Foodborne cases occur almost exclusively in individuals who are immunocompromised including those with liver disease. Infection is relatively rare even with exposure rates of more than a million organisms.

Other than a zero tolerance (nondetectable in 25-g portion) for toxigenic *V. cholerae* for all foods including seafood, there are no internationally recognized standards for *Vibrio* spp. in seafood. In 2001 the EU Scientific Committee on Veterinary Measures relating to Public Health (SCVPH) concluded in their report that current scientific data did not support setting specific criteria for pathogenic *V. vulnificus* and *V. parahaemolyticus* in seafood. Few countries have official standards for *V. vulnificus* and *V. parahaemolyticus* but certain northern European countries reject lots of imported seafood with any detectable *Vibrio* spp. (25-g portion).

Seafood is a highly perishable commodity and typically spoils at storage temperatures permissive for pathogen proliferation before pathogens can reach risky levels. Unlike other seafood species that are slaughtered at harvest, bivalve mollusks survive for extended periods out of the water. After harvest, vibrios multiply readily in mollusks under improper temperature storage. Risk assessments indicate that these improper storage practices can greatly increase risk of illness. Control plans have recently been implemented in the US to require refrigeration within 1 h after harvest to control *V. vulnificus* growth in oysters harvested from the Gulf of Mexico during summer months. However, in most countries much longer duration of refrigeration after harvest of bivalves is allowed and time–temperature controls do not exist in many countries. A number of postharvest processing approaches including mild heat, freezing, ultra high hydrostatic pressure and irradiation have been used to mitigate vibrio levels in oysters. These processes have been shown to maintain raw sensory characteristics and greatly reduce vibrio levels and the risk for oyster consumers. Vibrios are highly susceptible to heat but illnesses are occasionally reported from consumption of lightly steamed or fried breaded oysters.

Aeromonas spp. are in the family Vibrionaceae and favor freshwater over marine and estuarine environments. *A. hydrophila* is commonly found in fish and fish products, meat, milk, poultry, and vegetables. Several studies have implicated *Aeromonas* species as spoilage organisms of raw meat, raw packed salmon, fish from warm tropical waters, and milk. Although aeromonads are mesophiles, they grow well in refrigerated seafood often reaching levels of 10^7–10^9 cfu g^{-1}. Growth of aeromonads is well controlled in foods with pH <6.5 and $>3\%$ NaCl. They are occasionally isolated from individuals with gastrointestinal symptoms and some strains possess putative virulence factors. However, their role in human pathogenicity is not clear and there are few established surveillance systems for these organisms.

The genus *Plesiomonas* also belongs to the Vibrionaceae family and consists of a single species, *P. shigelloides*. It is a natural inhabitant of both freshwater and marine waters and is commonly isolated from seafood. There appears to be seasonal variation, with the peak occurring during the warm summer months and does not grow $<8\,^{\circ}C$. *Plesiomonas shigelloides* can cause wound infections and septicemia. It has been isolated in those with gastroenteritis but failed to cause diarrhea in human volunteers after ingestion of 10^9 organisms.

C. botulinum is an anaerobic, Gram-positive, spore-forming bacterium that produces botulism toxin, one of the most potent toxins in nature. The spores of nonproteolytic types B, E, F *C. botulinum* are common in aquatic environments and have been found in the gills and viscera of finfish, crabs, and shellfish and can enter the processing plant on raw materials. *C. botulinum* type E is the most common form found in freshwater and marine environments. Illnesses associated with seafood have been reported from Egypt in 1991 (91 hospitalized and 18 fatal cases), Finland in 2006 (one case associated with vacuum-packed smoked whitefish), Germany in 1997 (two cases, hot-smoked vacuum-packed whitefish), Japan from 1951 to 1987 (479 cases), two outbreaks in Russia in 2004 and 2005 and two outbreaks in the USA in 1985 and 1987. Types A and B are generally found on land, but may also be occasionally found in water. Although the toxin is heat-sensitive, the destruction of spores requires commercial sterilization. The botulism risk usually appears after inadequate heat processing or loss of container integrity. This hazard in canned products can be controlled by limiting proliferation and contamination during processing and ensuring adequate heat processing, container integrity, sanitary postprocess cooling water and clean wet conveying equipment. These measures have been extremely effective in controlling *C. botulinum* in canned products and most illnesses occur in Native American and Asian cultures from traditional foods prepared with whole fish preserved by salting, smoking, or fermentation. Evisceration of fish before preservation by these processes greatly reduces this hazard. *C. botulinum* cannot grow and produce toxin at or below $3\,^{\circ}C$ or below a water activity of 0.94. If artificial smoked flavor blends are used as ingredients, then 5% aqueous phase salt would provide complete protection at temperatures between 3 and $10\,^{\circ}C$ and 10% aqueous phase salt would be required at any temperature over $10\,^{\circ}C$. Smoke-dried fish with a water activity of 0.75 or below (moisture content $<10\%$) inhibits the growth of all foodborne pathogens including *C. botulinum* and refrigeration is not required.

Listeria monocytogenes is considered indigenous to most nonaquatic environments, and is abundant on decaying plant material. It is seldom found in offshore waters or from fish caught or cultured in such waters but occurs at low levels in fish produced in waters impacted by agricultural runoff. The risk of infections from raw seafood products intended for cooking is negligible. *L. monocytogenes* grows at refrigeration temperatures in cooked or processed products like picked crab meat and smoked fish. *L. monocytogenes* prevalence in processed ready-to-eat products is 3–40%. Smoked fish is considered to be the riskiest seafood product; up to 80% of the samples at some processors are positive. In the US there is a zero tolerance (25-g portion) for *L. monocytogenes* in foods that support its growth and this is one of the most frequent causes of regulatory action against seafood businesses. *L. monocytogenes* most often affects the unborn fetus causing still birth but can also infect the elderly and immuocompromised. Although risk assessments consider ready-to-eat seafood products to be at high risk, there have been only a few instances in which seafood products have been implicated in *L. monocytogenes* illnesses and most have been with smoked products with long refrigeration shelf-lives. Product controls begin with reducing potential contamination, rinsing, and disinfecting fish surfaces and package instructions for consumers to freeze or to discard or thoroughly cook after a date when this pathogen could reach risky levels under typical refrigeration conditions. The processing environment is a common source of *L. monocytogenes* contamination. Frequent cleaning and disinfection of equipment, drains, and floor mats are recommended to control this hazard. Codex Alimentarius has established microbiological criteria including and recommendations for sampling plans in the Guidelines on the Application of General Principles of Food Hygiene to the Control of *L. monocytogenes* in food.

Clostridium perfringens is an anaerobic, Gram-positive, mesophilic spore-former widely distributed in the environment with highest levels in soil. It can also be isolated from water,

sediments and from feces of healthy individuals. Vegetative cells surviving gut passage can sporulate in the small intestine and produce an enterotoxin that causes nausea, abdominal pain, diarrhea, and sometimes vomiting 8–24 h after ingestion. In the US, approximately seven annual cases of *C. perfringens* are reported with links to seafood and it is estimated that approximately 200 seafood-caused cases occur every year. *Clostridium perfringens* growth can be controlled by chilling, pH <5, NaCl $>6\%$, and water activities <0.95. Observing proper time–temperature conditions and avoiding cross-contamination to heated foods are essential for the control of this hazard.

Bacillus cereus is an aerobic, Gram-positive spore-forming bacteria widely distributed in the environment. The spores are resistant to drying and are easily spread with dust. *Bacillus cereus* is found in a variety of foods but typically occurs only in low numbers, especially in raw foods. *Bacillus cereus* can cause either diarrhea in 8–16 h by producing a toxin in the intestine similar to *C. perfringens* or can cause nausea and vomiting by a toxin preformed in the food 0.5–5 h after ingestion. Seafood subjected to a mild heat-treatment combined with subsequent cold-temperature storage such as in the production of *sous-vide* products, may increase risk as heat processing induces spore formation. Except for the few psychrotrophic strains, *B. cereus* growth is well controlled by chilling.

Animals and humans are the major reservoirs of pathogens such as *Salmonella* spp., *Shigella* spp., *Escherichia coli*, *Campylobacter jejuni* and other mesophilic *Campylobacter*, and *Staphylococcus aureus.* Humans are the only known source of enteric viruses such as norovirus (NoV) and hepatitis A virus (HAV).

Contamination of fish products is almost always due to poor hygiene (poor personal hygiene, poor processing hygiene or poor water quality). Feces is the main source of most of these pathogens and seafood contamination usually occurs in production areas via direct discharge or after inadequate sewage treatment. Bivalve mollusks present the greatest risk to consumers for bacterial and viral pathogens of fecal origin as they concentrate these organisms through filter feeding and they are often consumed raw. Bacterial pathogens have been recognized as an important cause of illness due to consumption of raw bivalve mollusks for almost a century. Most developed countries have well-established control systems for bivalve mollusks and/or their growing areas based on analysis of certain populations of the coliform bacteria group. Early in the twentieth century, outbreaks of typhoid fever linked to consumption of raw oysters and clams were reported often in the US. Improved wastewater treatment, incorporation of better hygienic practices and a system that included sanitary surveys and continual testing of the overlying waters for coliform bacteria virtually eliminated shellfish related typhoid fever outbreaks in the US in less than a decade. Similar systems are used in the European Union, Canada, Mexico, and New Zealand based on testing of shellfish meats alone or combination of testing shellfish meats and overlying waters and this approach has been equally successful for controlling enteric bacterial pathogens. These systems rely on levels of indicator bacteria including total coliforms, fecal coliforms, and *E. coli*.

Sanitary controls have been much less effective in the control of viral outbreaks, especially those caused by NoV. Apparently, many enteric viruses including NoV and HAV survive various sewage treatments, persist much longer in the tissues of bivalve mollusks than indicator bacteria and have a lower infectious dose than the bacterial pathogens. In countries with cooler climates such as those in Europe outbreaks from NoV are much more common than those caused by all other pathogens and are primarily associated with consumption of raw oysters. HAV outbreaks are rarely reported in developed countries with modern sewage treatment facilities and well-established shellfish sanitation programs. However, an HAV outbreak associated with consumption of raw clams in China during the 1990s may have infected as many as a half of million individuals. NoV infections are characterized by mild to moderate diarrhea and vomiting, whereas HAV affects the liver and causes a more severe illness characterized by jaundice. There are currently no culture methods available for NoV and culture methods are not reliable for wild HAV strains and thus there are no means to reliably determine survival or infectivity of these viruses. These are RNA viruses and recently developed reverse transcription real time PCR assays are being increasingly applied to the detection of viral RNA in bivalve mollusks. NoV detection rates range from $<5\%$ to $>50\%$ in bivalve mollusk and higher levels are usually found during colder periods of the year and in shellfish implicated in outbreaks. There are no established tolerances for either NoV or HAV. The US and Canada are currently conducting a joint NoV risk assessment in bivalve mollusks and Codex guidance documents are under development. Bacteriophages specific to *E. coli* also referred to as coliphage appear to behave more like enteric viruses. RNA male-specific bacteriophages are of similar size and shape as the most common enteric viruses such as NoV and HAV and are most often used to model survival, uptake, and elimination of enteric viruses but have had limited application in official control programs. The most effective means for controlling enteric viruses is to prevent their introduction into shellfish growing areas and to restrict harvest after events that may lead to contamination of the growing waters. Enteric viruses are rarely associated with seafood products other than bivalve mollusks.

Salmonella is occasionally detected in finfish and shrimp reared in warm water, especially in fresh or brackish water species but has rarely been linked to human illnesses. The extent to which hygienic practices contributes to Salmonella contamination is uncertain as there are many natural reservoirs such as birds, reptiles, and amphibians that are in frequent contact with both wild and aquacultured species. The presence of Salmonella or other bacterial pathogens in finfish or shrimp is of much less concern than with bivalve mollusks as only muscle tissue is typically consumed and usually after cooking that inactivates most pathogens. The frequency of Salmonella detection in bivalve mollusks produced in countries with well-established shellfish sanitation programs generally ranges from 1 to 2% but has been reported to be as high as 30% in developing countries such as India. Considering the relatively high frequency of Salmonella occurrence in bivalve mollusks, these products are infrequently associated with outbreaks but there may be a significant risk for sporadic cases. It is not known whether Salmonella grows in live bivalve mollusks after harvest but the lack of outbreak reports suggest that significant postharvest growth is unlikely.

Although Salmonella testing is required in some countries, sampling plans are likely to provide only negligible additional protection unless numerous samples are analyzed and are not generally recommended.

Four species of *Shigella* are known and all are human pathogens. The primary route of infection is the fecal-oral route with person-to-person being the most common route of transmission. Unlike *Salmonella*, *Shigella* is not associated with particular food raw materials but its presence is exclusively a question of poor hygienic handling and humans are its natural reservoir. Outbreaks have been caused by a multitude of food products, including shrimp and clams. Although *Shigella* is not naturally present in water, but may survive for up to 6 months if water is contaminated and persists for long periods in clams and oysters. Similarly, the presence of pathogenic *E. coli* and *Campylobacter* spp. in seafood or production waters is indicative of human and animal pollution but these pathogens are seldom associated with illnesses from seafood consumption.

Staphylococcus aureus is Gram-positive bacterium that inhabits the skin and mucous membranes of animal and man. This organism is not a significant hazard associated with seafood production or processing of raw products. The main hazard is with crab meat that is usually handpicked after cooking. The presence of *S. aureus* on crab is an indication of postharvest contamination due to poor personal hygiene and its presence indicates a potential for food poisoning. Time–temperature abuse will allow rapid proliferation of *S. aureus* and formation of heat stable toxins in cooked foods such as crab meat. There is also the potential risk during canning of postprocess contamination with *S. aureus* if container integrity is compromised and containers are handled in an unsanitary manner.

Parasites

Although we are not aware of documented transmission of parasites of intestinal origin from consumption of bivalve mollusks, some studies have shown that oysters can accumulate Giardia and Cryptosporidium and these parasites can remain viable in shellfish tissues for significant periods. Few of the outbreaks of Giardia and Cryptosporidium can be attributed to a specific food commodity and further study is needed to better understand the significance of these findings to human health.

Some species of fish can serve as relatively specific intermediate hosts to a variety of parasites including trematodes, nematodes, and cestodes and can transmit these parasites to humans if fish are consumed raw or are inadequately cooked. Anisakiasis is a significant cause of acute gastrointestinal diseases from consumption of salt-water fish infected with nematodes of either *Anisakis* species or *Psudoterranova decipiens*. Human infection typically occurs by ingesting raw or undercooked fish such as tuna, salmon, herring, or mackerel for *Anisakis* species and cod or squid for *P. decipiens*. Inadequate fish treatment can allow *Anisakis* to attach to the human stomach and intestines where it can cause lesions and may require surgical removal. It is estimated that there are more than 2000 cases of Anisakiasis per year in Japan. Cases have also been described in coastal areas of the Netherlands, Germany, France, Spain, and US, but are much less prevalent than in Japan. Consumption of raw, lightly cooked, or pickled freshwater fish may cause an estimated 70–100 million infections globally with trematodes consisting of *Clonorchis* species. China, Japan, Korea, Taiwan, and Vietnam are the leading countries for trematode infections. Trematodes of other genera can infect humans including *Opisthorchis* spp. (prevalent in Poland, Eastern Germany, and in parts of the old Soviet Union), *Heterophyes heterophyes* and *Metagonimus yokogawai* (commonly occur in Japan, Laos, Thailand, Korea, Hawaii, Balkans, Philippines, China, Taiwan, Turkey, and Siberia) and, *Echinostoma* spp. including *E. ilocanum*, *E. revolutum*, *E. malayanum*, *E. echinatum* and *E. hortens* (commonly occur in Korea, the Philippines, Indonesia, Malaysia, and Thailand). *Capillaria philippinensis* causes infections in the Philippines and Thailand from consumption of raw or undercooked freshwater fish and appear to be spreading to other regions. The cestode, *Diphyllobpthrum latum* has caused infections in northern regions of Europe and North America, mainly from consumption of raw or undercooked lake trout. Similarly, *Diphyllobpthrum nihonkaiense* has been associated with infections in Japan, linked to consumption of salmon and trout.

Most parasites are very susceptible to heat inactivation and freezing with brief storage times. Cooking is generally sufficient to inactivate most parasites. Freezing of fish intended for raw consumption at $-20\,^{\circ}C$ or below for 7 days or at $-35\,^{\circ}C$ for 15 h also kills parasites. Other procedures such as brining, pickling, trimming away the belly flaps or candling, and physically removing parasites may reduce the hazard in fish but will not eliminate all parasites or reduce the hazard to an acceptable level.

Decomposition

Seafood commodities are among the most perishable of all foods and rapidly produce numerous compounds associated with objectionable odors such as ammonia and trimethylamine when improperly refrigerated. Decomposition is primarily a quality issue with most seafood commodities and readily detected by smell. However, scombroid (e.g., tuna and mackerel) and some nonscombroid (e.g., sardine and herring) fish contain relatively high levels of free histidine in their tissues for osmoregulation. Certain histamine forming bacteria (e.g., Enterobacteriaceae, *Clostridium*, *Lactobacillus*, *Vibrio*, and *Photobacterium*) can decarboxylate histidine into histamine if postharvest temperatures permit their growth. Although histamine can be produced in fish captured by drift nets or long lines if they die and soak in warm waters for extended periods before harvest, the most significant problems occur by delayed or inadequate cooling after harvest. Histamine is heat stable and is not inactivated by cooking or canning. Therefore, good hygienic practices for the preservation and handling from capture to consumption are essential to prevent histamine production. Human reactions to histamine vary from rashes and breathing difficulties to severe shock. The Codex Alimentarius Commission adopted a standard for some fish species for maximum histamine levels of 20 mg/100 g fish flesh.

Seafood producers or processors sometimes attempt to hide visual evidence of decomposition. For example, antioxidants such as sulfites can be used to disguise evidence of

spoilage such as black spots in shrimp; these compounds can cause allergic reactions in sensitive consumers. Carbon monoxide treatment is often used to produce a bright red color in tuna that can mask decomposition colors. The origin, postharvest history and supplier assurance certifications provide important information on whether one of these particular hazards is reasonably likely to occur.

Marine Toxins

Diverse and widespread marine microalgal species produce a variety of biotoxins that can be accumulated in bivalve mollusks. These can cause human illness syndromes including diarrhetic shellfish poisoning (DSP, caused by okadaic acid), paralytic shellfish poisoning (PSP, caused by saxitoxin), neurotoxic shellfish poisoning (NSP, caused by brevetoxin), amnesic shellfish poisoning (ASP, caused by domoic acid), or azaspiracid shellfish poisoning (AZP). The phytoplankton associated with these syndromes are typically bloom forming dinoflagellates and diatoms, known collectively as harmful algal blooms (HABs). These organisms are bioaccumulated by shellfish during filter feeding and then release their toxins into the shellfish tissues. In most cases a complex suite of toxins can be produced by a given phytoplankton species and these can be further metabolized by the shellfish, producing in some cases more potent derivatives of the precursor molecules. The existence of multiple toxin classes and multiple congeners within a given class complicates monitoring and analysis. For this reason, the mouse bioassay continues to be the basis of most national safety standards for these toxins due to the ability to detect total composite toxicity. The majority of shellfish toxins are heat stable and are not inactivated or degraded by cooking. For the PSP toxins, cooking can in fact increase toxicity by converting the less toxic derivatives into more toxic forms. Thus, it is crucial to monitor and control this hazard in the shellfish growing areas. In most cases, harmful algal blooms are visible in the water before shellfish become toxic but identification and enumeration of the toxic phytoplankton requires special skills and costly equipment so routine monitoring using the mouse bioassay is usually recommended in areas where HABs frequently occur. With the increasing availability of advanced instrumentation, such as mass spectrometry, paired with observations by electron microscopy, there have been numerous discoveries of new toxic algal species and novel toxins and derivatives. Additionally, well-studied toxins such as PSP appear to be expanding in range and some suggest that ballast discharge from international shipping and climate change are at least partially responsible for expansion in the geographical ranges of some toxic algal species. The control of this hazard in bivalve mollusks depends largely on knowledge of shellfish origin, environmental status of the harvest area, and monitoring efforts and controls in that area. When biotoxins are detected above safe thresholds in the tissues of bivalves, the growing area must be temporarily closed for harvesting, and shellfish tested until toxin levels return to safe levels. The Codex Alimentarius Commission adopted the following standards maximum tolerable levels (per kg) in bivalve mollusk tissues: saxitoxin group $\leq$0.8 mg; okadaic acid group $\leq$0.16 mg; domoic acid group $\leq$20 mg; brevetoxin group $\leq$200 mouse units or equivalent; azaspiracid group $\leq$0.16 mg.

Predatory reef fish such as barracuda, grouper, snapper, and amberjacks from tropical areas can bioaccumulate ciguatera toxin. Ciguatera toxin precursors are produced by dinoflagellates of the genus *Gambierdiscus* that colonize sessile macroalgae, corals, and seagrasses which are grazed by herbivorous fish. These toxins are metabolized and biomagnified by piscivorous fish and transferred to higher trophic levels of the coral reef food web. Toxin structure and associated toxicity varies substantially by region with structural variants identified in the Pacific, Caribbean, and Indian Oceans. More than 400 species of fish are known to be vectors of ciguatoxins. Likewise the fish species in which the toxin accumulates is important. For instance, Nassau grouper have rarely been implicated with ciguatera fish poisoning in the Caribbean, but the closely related yellowfin grouper is almost always toxic in this region. Ciguatoxins are among the most toxic compounds in nature and can cause serious and often long-term health effects. Ciguatoxins causes disease at levels below 1 ppb in the flesh of the fish. Clinical symptoms vary widely but are characterized by gastrointestinal, neurological, and cardiovascular disturbances not only within 10 min but also up to 24 h after ingestion of toxic fish, but death is rare. Controls are mostly limited to identification of the fish species and harvest restrictions in known 'hot spots.' Ciguatoxins are heat stable and cooking provides no protection and there are no effective treatments. The mouse bioassay may be used to detect ciguatoxins from fish but few laboratories have the analytical capabilities for their detection.

Tetrodotoxin (TTX) is a potent marine neurotoxin with a similar activity to the paralytic shellfish toxins. This toxin has been primarily associated with puffer fish in the marine environment but can also be found in the blue ringed octopus, newts, frogs, and a variety of freshwater fish. Consumption of these fish can cause severe foodborne intoxication. TTX is heat stable and is not affected by cooking or freezing. Certain puffer fish species are considered a delicacy and a special culinary license is required in order to prepare the fish flesh safely for consumption. Avoidance of known TTX-containing species and/or known toxic parts is the primary control measure for this toxin class as it is not associated with phytoplankton blooms or other known microorganisms.

PSP, DSP, ASP, AZP, TTX, and palytoxin may be found in the viscera of a variety of crab species in certain geographical regions; PSP can also occur in the hepato-pancreas of lobsters.

Chemical Contaminants

There are numerous classes of chemical contaminants present in seafood production environments and these vary greatly in their route of introduction, geographical distribution, and toxicity to humans. Some heavy metals and petroleum hydrocarbons have both natural and anthropogenic sources, others such as pesticides and industrial chemicals are always associated with human activity and some such antimicrobials are introduced intentionally as therapeutic or growth promotion agents.

Table 1 Tolerances and critical limits of environmental chemical contaminants in fish and fish products for US, EC and Codex

Substance	*Maximum levels*			*Food commodity*
	US (ppm)	*EU (mg per kg wet weight)*	*Codex*	
Arsenic	76 (crustaceans), –86 (mollusks)			Mollusks, crustaceans
Cadmium	3.0 (crustaceans), 4.0 (molluskan bivalves)	0.05–1.0 (bivalves, cephalopods)	2 (marine bivalve mollusks and cephalopods)	Fish, mollusks
Lead	1.5 (crustaceans), 1.7 (molluskan bivalves)	0.3–1.0	0.3 (fish)	Fish, mollusks
Methylmercury	1.0	1.0	0.5 (fish), 1.0 (predatory fish)	All fish
PCB	2.0			All fish
DDT, TDE	5.0			All fish
Diedrin	0.0			All fish
Dioxin		0.000004		

Methylmercury is the most widespread and serious risk among anthropogenic and/or natural (volcanoes) contaminants and can cause nervous system disorders in the developing fetus, infants, and young children. In 2003, the FAO/WHO Joint Expert Committee on Food Additives (JECFA) revised the provisional tolerable weekly intake (PTWI) for methylmercury from 3.3 to 1.6 μg per kg of body weight per week. Highest levels are found in larger, long-living predators (e.g., sharks, swordfish, and king mackerel) but greatest exposure occurs with consumption of tuna as it is one of the most heavily consumed seafoods globally. Some government agencies issue an advisory on consumption of fish for women and young children, focused on the benefits of eating fish while rducing their exposure to the harmful effects of mercury. Other heavy metals such as arsenic, chromium, and lead can cause adverse human health affects and various international tolerance for these are shown in Table 1. Exposure of aquatic animals to petroleum products can occur from tanker accidents, blow outs of offshore wells, discharges from vessel bilge water and natural seeps from seafloor vents. Polycyclic aromatic hydrocarbons (PAHs) are the most toxic components of petroleum products including crude oil and their proportions vary considerably depending on the source and weathering of the oil. After a petroleum spill or discharge areas with a visible sheen on the water surface are generally closed for both commercial and recreational fishing. After the sheen disappears, human sensory analysis is usually sufficient to detect odor indicative of elevated risk and is often used to screen suspected seafood samples. In high profile spills, sensory results are often confirmed using analytical methods such as gas chromatography-mass spectroscopy. Formation of PAH during smoking and drying of fish and other seafood may increase cancer risk. PAH formation can be minimized by following practices described in the Codex Alimentarius Code of Practice for the Reduction of Contamination of Food with Polycyclic Hydrocarbons (PAH) from Smoking and Direct Drying Processes (CAC/RCP 68-2009).

Exposure to agricultural chemicals such as pesticides and industrial chemicals such as dioxin is typically from direct discharge into rivers, leaching from contaminated soil or from storm water runoff. The main risk is elevated cancer rates from chronic exposures. Some of these chemicals persist for long periods in the environment and permanent closures or advisories are the only options to control these hazards once the environment has become contaminated as these chemicals are stored for extended periods in fatty tissues and are heat stable. Various international tolerances for these chemicals are shown in Table 1.

The use of veterinary drugs such as antimicrobial compounds and other chemical treatments are widely used in production of aquacultured finfish worldwide primarily to control disease. Unregulated/unapproved veterinary drugs administered to aquacultured fish pose a potential human health hazard. These substances may be carcinogenic, allergenic, and/or may cause antibiotic resistance. Low levels of antimicrobial residues are often detected and are the basis of regulatory action in countries importing finfish and other seafood products but have rarely been linked to adverse human health effects. There are antimicrobial agents that have been deemed safe by international organizations but the problem often arises due to off-label use or unapproved drugs. The following Codex standards were established for MRL of chlortetracycline/oxytetracycline/tetracycline at 200 $\mu g\,kg^{-1}$ in fish muscle in general and specific species. Deltamethrin (used also as pesticide) at 30 $\mu g\,kg^{-1}$ in salmon muscle, and flumequine at 500 $\mu g\,kg^{-1}$ in trout muscle including normal proportion of skin.

SAFETY OF FOOD AND BEVERAGES

Meat and Meat Products

JN Sofos, Colorado State University, Fort Collins, CO, USA

Glossary

Bacteriophage A virus that infects its specific bacterial cell host.
Bovine spongiform encephalopathy A neurodegenerative fatal disease in cattle that results in the formation of a spongy degeneration in the brain and spinal cord.
Campylobacteriosis The infection caused by the bacterium *Campylobacter*.
Competitive exclusion Competing bacterial species with one having an advantage over the other.
Cross contamination Transfer of bacterial cells from one food, and/or its environment, to another food.
Enteric Intestinal.
Enteritis Inflammation of the small intestine.
Enterohemorrhagic Intestinal bleeding detected in diarrheal stools.
Hemolytic uremic syndrome A rare, but potentially fatal, condition that can lead to kidney failure, mostly in children and immunocompromised adults, caused by shiga toxin-producing bacteria such as *Escherichia coli*.
Hemorrhagic colitis A self-limiting, but sometimes fatal, bacterial infection, often attributed to strains of *Escherichia coli*, that is characterized by abdominal cramps and bloody diarrhea.
Hurdle technology Application of a combination of individually sublethal antimicrobial hurdles for control of microorganisms and assurance of safety and stability in food products.
Listeriosis Invasive infection caused by *Listeria monocytogenes*.
Meningitis Bacterial infection of the meninges (membranes of the brain and spinal cord).
Meningoencephalitis A condition resembling meningitis and encephalitis or inflammation of the brain.
Mycotoxins Acutely toxic or carcinogenic (depending on level of exposure) secondary metabolites of certain fungi or molds that may form under certain conditions in some foods.
Nosocomial infection Infection acquired in a hospital.
Outbreaks At least two linked cases of foodborne disease of the same symptoms and associated with the same food.
Prebiotics Nondigestible ingredients that stimulate growth and/or activity of certain bacteria in the digestive system resulting in interference with pathogenic bacteria.
Prion Abnormal transmissible, pathogenic agents, inducing abnormal folding of specific normal cellular proteins called prion proteins in the brain and leading to brain damage and the characteristic signs and symptoms of prion diseases (i.e., transmissible spongiform encephalopathies (TSE), such as bovine spongiform encephalopathy).
Probiotics Live microbial cultures that may be beneficial by interfering with pathogens.
Septicemia Bacterial invasion of the blood (bacteremia).
Serotype Group of closely related microorganisms reacting to a characteristic set of antigens.
Shiga toxins, shiga-like toxins, verotoxins, or verocytotoxins Toxins, produced by the strains of enterohemorrhagic *Escherichia coli* (EHEC), causing hemolytic uremic syndrome.
Toxicoinfection Illness caused by toxins produced by noninvasive bacteria growing in human intestines.
Water activity The amount of chemically unbound water in a food that is related to relative humidity and is available for growth of microorganisms.

Introduction

The major challenges associated with meat safety and quality are microorganism-associated issues. Microbial pathogens cause mild, severe, brief or chronic human illness, or death. Loss of quality is caused by spoilage-causing microorganisms, which by shortening shelf life lead to reduced food supplies and economic losses. The microbiological status of meat products is influenced by system failures or abuses during animal food production, product processing and distribution, and preparation for consumption. Despite recent improvements in meat processing, documented disease episodes and concern about meat products acting as vehicles of meat-borne hazards are increasing rather than diminishing. Reasons for this may include increased international food trade, consumer preferences for minimally processed products, increased worldwide meat consumption, increasing numbers of consumers at risk for infection, emerging pathogens of increased virulence and resistance to control or clinical treatment, advances in microbial detection methodologies, and

 doi:10.1016/B978-0-12-378612-8.00282-1

inadequate food handler and consumer education and training in proper food handling. In addition, there is increased interest, awareness, and scrutiny of foodborne illness episodes by news media, consumers, and consumer organizations. Major challenges associated with unsafe food include microbial foodborne illnesses and deaths, product recalls, and related issues of regulatory compliance.

The knowledge of sources of contamination and the properties of pathogens allows application of proper procedures for pathogen control and enhancement of food safety. As sensitive to contamination and microbial growth, meat products should be handled and preserved properly to maintain their quality and safety. Microbial control in meat products is accomplished through the implementation of interventions or procedures that: (1) prevent or minimize the access of microorganisms into the product; (2) reduce initial contamination by the removal or inactivation of microorganisms, which have gained access; (3) inactivate microorganisms on products; and (4) prevent, delay, or slow down growth of viable microorganisms, which have gained access and have not been inactivated. Proper implementation and management of such an approach ensures the safety of meat products or at least reduces the incidence of microbial meat-borne illness.

Contamination of Meat Products

The interior of muscle tissues in healthy animals is generally sterile before slaughter, whereas various organs (e.g., liver and lymph nodes) may sporadically contain low numbers of microbial cells. In contrast, animal surfaces exposed to the environment, such as hides, pelts, fleece, the mouth, and the gastrointestinal tract, are usually heavily contaminated. Sources contributing microbial contamination to animals and meat during animal slaughter and dressing of carcasses include feces, soil, water, air, feed, hides, intestines, lymph nodes, processing equipment, utensils, and humans. Identifying the sources and modes of meat product contamination is important in applying proper approaches and procedures for hazard control and enhancement of meat safety.

Overall, the cycle of contamination involves animal feces and manure, soil, decaying matter, water, air, pastures and other animal feeds, and animals and their products, as well as water and other foods or the environment. Additional vehicles of biological hazards within this continuum may include rodents, birds, insects, animal transportation crates and vehicles, and other equipment and utensils, which contribute to cross contamination. Animal manure may contaminate water used for drinking or to irrigate or wash plant crops resulting in cross contamination of other foods, as demonstrated by the increased occurrence of foodborne outbreaks with enteric pathogens present in vegetables. The extent of microbial transfer from the above sources to meat and other foods depends on sanitation and hygienic practices, product handling and processing procedures, and conditions of storage and distribution. In general, meat products become easily contaminated during animal slaughter, carcass dressing and cutting, meat processing, storage, merchandizing, preparation, and serving for consumption. Overall, animal production, and product processing and handling practices result in contamination, which may vary depending on animal type and age, geographic region, season of the year, and other variables; for example, *Escherichia coli* O157:H7 prevalence is usually higher during the warmer months.

As sources of contamination are diverse, and facilities and practices of slaughtering and processing operations are variable, there may be variation in the types of microorganisms introduced and, especially, in the extent (prevalence and density) of contamination of meat or other foods. Initial contamination of meat consists of Gram-negative and Gram-positive bacteria, yeasts, molds, parasites, and viruses. Presence of pathogens in animal products processed under sanitary and hygienic conditions should generally be infrequent and at low levels. As contamination is unpredictable, any raw, unprocessed, and uncooked meat product should be considered, treated, and handled as potentially contaminated with pathogens.

Food Safety Concerns in Meat Products

Chemical hazards that may be present in meat products include mycotoxins resulting from feeding animals with moldy feeds or due to uncontrolled mold growth in certain meat products aged improperly and for longer periods of time. Use of chemicals (e.g., antibiotics, hormones, and growth promoting agents) during meat animal production, for better growth, feed efficiency, and disease control, in some countries, is of concern to consumers, and causes trade conflicts among certain countries. Some consumers are also concerned with the use of additives (e.g., common salt, nitrate, nitrite, and other compounds) in processed meat products. In general, the contribution of additives and their residues to the overall food safety concerns in meat products is considered minor or negligible, particularly in industrialized countries where there is extensive legislation for their control. Presence of residues of certain toxic chemicals, such as dioxins, in meat products has caused major consumer scares from time-to-time. The debate over the positive and negative aspects of meat in the human diet also reemerges from time-to-time.

There is a long list of biological hazards, including bacteria, viruses, parasites, and prions that may potentially be present in animals and meat products, and sometimes transmitted to humans. Some hazards are transmitted to humans through consumption of meat products, whereas others have not been documented as being transmitted to humans through handling or consumption of meat products. Other hazards present in animals are associated with nonfood transmission routes such as aerosols and direct contact with animals or diseased tissues. Hazards of most concern in terms of severity of illness and deaths are bacterial, whereas viruses usually cause large numbers of mild gastrointestinal illness as a consequence of poor sanitation and unhygienic practices; parasites have minor involvement in meat-borne illness in developed countries (**Table 1**).

Bacterial pathogens that have been documented as transmitted through meat products include pathogenic *Bacillus* spp. (e.g., *Bacillus cereus*), *Campylobacter* spp. (thermophilic), *Clostridium perfringens*, *Clostridium botulinum*, *Escherichia coli*

Table 1 Biological hazards in meat products and their origin, products affected, type of illness, need for growth in food before consumption, and control approaches

Biological agent	*Product*	*Type of illness*	*Sources*	*Growth in food*	*Control approach*
Bacteria					
Bacillus cereus	Beef, pork, lamb, and poultry	Intoxication (emetic); toxicoinfection (diarrheal)	Soil and animals	Needed (some grow in the cold)	Inactivate spores (heat) or control growth (refrigeration)
Campylobacter spp. (thermophilic)	Beef, pork, lamb, and poultry	Invasive infection	Animals	Not needed	Inactivate (heat processing or cooking)
Clostridium botulinum	Beef, pork, lamb, and poultry	Intoxication (toxicoinfection, infants)	Soil, water, and animals	Needed	Inactivate spores (canning) or control growth (refrigeration)
Clostridium perfringens	Beef, pork, lamb, and poultry	Toxicoinfection	Soil, water, and animals	Needed	Inactivate spores (heat processing or cooking) or control growth (refrigeration)
Escherichia coli (STEC/EHEC)	Beef, pork, and lamb	Toxicoinfection	Animals	Not needed	Inactivate (pasteurization and cooking)
Listeria monocytogenes	Ready-to-eat beef, pork, and poultry	Invasive infection	Processing environment, soil, water, and animals	Needed (grows in the cold)	Inactivate (heat) or control growth (freezing, no long-term refrigerated storage)
Salmonella enterica	Poultry, beef, pork, and lamb	Invasive infection	Animals	Not needed	Control growth (refrigeration) and inactivate (pasteurization or cooking)
Staphylococcus aureus	Ready-to-eat beef, pork, lamb, and poultry	Intoxication (heat resistant toxin)	Humans, processing environment, and animals	Needed	Control growth (refrigeration)
Yersinia enterocolitica	Pork and poultry	Invasive infection	Animals, soil, and water	Needed (grows in the cold)	Control growth (freezing) and inactivate (pasteurization or cooking)
Parasites					
Cryptosporidium parvum	Beef and poultry	Invasive infection	Meat	Not needed	Freezing, salting, pasteurization, cooking, or irradiation[a]
Giardia duodenalis	Beef	Invasive infection	Meat	Not needed	Freezing, salting, pasteurization, cooking, or irradiation
Sarcocystis	Beef and pork	Invasive infection	Meat	Not needed	Freezing, salting, pasteurization, cooking, or irradiation
Taenia cysticercus	Beef and pork	Invasive infection	Meat	Not needed	Freezing, salting, pasteurization, cooking, or irradiation
Toxoplasma gondii	Beef, pork, and poultry	Invasive infection	Meat	Not needed	Freezing, salting, pasteurization, cooking, or irradiation
Trichinella spp.	Pork and game	Invasive infection	Meat	Not needed	Freezing, salting, pasteurization, cooking, or irradiation
Viruses					
Hepatitis E	Pork	Invasive infection	Animals and humans	Not needed	Sanitation[b] or cooking
Other foodborne viruses	Ready-to-eat meats and other foods	Infection	Humans	Not needed	Sanitation or cooking
Prions (encephalopathies)					
Bovine spongiform encephalopathy (BSE)	Beef	Invasive infection	Animals	Not needed	Special controls during animal growth and slaughter

[a]Irradiation is effective against all pathogens (exceptions: prions; bacterial spores and viruses need unacceptably high doses).
[b]Sanitation and hygienic conditions are crucial for control of all pathogens.

serotypes, especially shiga toxin-producing/verotoxigenic *E. coli* (STEC/VTEC) and enterohemorrhagic *E. coli* (EHEC) strains, *Listeria monocytogenes*, *Salmonella enterica* serotypes, *Staphylococcus aureus*, and *Yersinia enterocolitica*. Pathogenic bacteria considered as potentially transmitted through meat, include *Aeromonas*, *Arcobacter* (previously mesophilic *Campylobacter*), *Bacillus anthracis*, *Brucella*, *Clostridium difficile*, *Enterobacter*, *Helicobacter*, *Mycobacterium*, *Plesiomonas*, and *Shigella*.

The antimicrobial resistance exhibited by strains of some bacteria such as *Campylobacter* and *Salmonella* is also of concern. Strains may be more resistant to control procedures, survive better in their hosts, and be more virulent at lower doses. Adaptation and development of resistance by bacteria to antibiotics and potentially to traditional food preservation barriers such as low pH, heat, cold temperatures, dryness or low water activity, and chemical additives is an issue that needs further consideration and evaluation. A common sense approach for the control of antimicrobial resistance is not to overuse or abuse antibiotics in animals and humans; prudent use is recommended. Decisions on approaches for control should be based on risk analysis and examination of all issues associated with each specific type of antibiotic application and concern. Pathogen resistance issues and concerns become more important when considered in light of societal changes, including changes in consumer food preferences, lack of adequate consumer and food handler education in proper food handling, increases in number of populations at risk for microbial foodborne illness, complex meat distribution patterns that may lead to product abuses, increased international meat trade and associated risks, and better methods of testing for microbial detection.

Some microorganisms are of concern because they are responsible for spoilage and loss of eating quality in meat products. Spoilage causing microorganisms found on fresh meat include micrococci and Gram-negative rods. Common genera and groups include *Pseudomonas* spp., *Enterobacteriaceae*, *Acinetobacter* spp., *Alcaligenes* spp., *Moraxella* spp., *Flavobacterium* spp., *Aeromonas* spp., *Staphylococcus* spp., *Micrococcus* spp., *Brochothrix thermosphacta*, coryneforms, fecal streptococci, lactic acid bacteria, etc. Risks to consumers from consumption of stored meat products may also be associated with the presence of biogenic amines, such as histamine, putrescine, spermidine, and spermine, which are formed by the growth of spoilage and fermentative microorganisms.

Additional issues related to meat include the safety and quality of organic and natural products, the need for and development of improved and rapid testing and pathogen detection methodologies for laboratory and field use, regulatory inspection harmonization issues at the national and international level, establishment of risk assessment based food safety objectives, and routine implementation of the hazard analysis critical control points (HACCP) system at the production and processing level on the basis of food handler training and consumer education. Issues such as bovine spongiform encephalopathy (BSE) will continue to be of interest mostly as a target for eradication.

The issue of humane treatment and welfare of food animals deserves increased attention worldwide. Animal stressing should be avoided because it may damage meat quality and lead to higher pathogen shedding and increased contamination. In addition, ethics dictate the need for humane handling and treatment of animals.

Animal health pandemics, such as avian influenza and foot-and-mouth disease, irrespective of any impact on human health, may cause major economic losses to local, domestic, or international markets. In addition, they may develop into trade issues, and even technical, economic, political, or diplomatic challenges. National and international health authorities, through global cooperation for risk-based contingency planning, need to address such issues as effectively as possible based on early detection and diagnosis with the goal of prevention, containment, and eradication.

The ability to maintain verifiable custody of the identification of animals and their products, or traceability, from production to retail, is regarded as an important tool for the protection of animal and public health. It is increasingly accepted that traceability can play a major role in management of food safety risks and in product authentication. However, traceability of composite products, such as ground beef, is complicated and difficult, if not impossible, to apply in commerce.

Biological Hazards in Meat and Meat Products

Some pathogens may be of no major concern as meat-borne in developed world regions such as the US and the European Union. For example, *Bacillus anthracis* may cause endemic disease in Africa and Asia through direct contact with infected animals or carcasses. Extensive exposure through processing of hides and wool in enclosed facilities may result in pulmonary anthrax through inhalation of aerosolized spores. The cutaneous form of anthrax may be acquired through handling of contaminated hides or wool. Consumption of raw or undercooked meat from infected animals, showing clinical signs of the disease, may lead to gastrointestinal anthrax. *Bacillus cereus* causes intoxication (emetic form) or toxicoinfection (diarrheal form) after spore germination and multiplication in foods, including meat, but illness from consumption of other foods is more common (**Table 1**).

Spores of *Clostridium* are found in soil, dust, and water as well as in the intestines of animals. Thus, they may be present in many foods including meat products. Common species associated with food- including meat-borne transmission are *C. botulinum* and *C. perfringens*. They may become a problem when the food is temperature abused and allows growth of the pathogen. *Clostridium difficile* is an emerging animal pathogen with increased incidence and severity in nosocomial infections. Potential sources of the organism include farm (cows, pigs, and horses) and domestic (dogs and cats) animals. *Clostridium difficile* has been isolated from samples of meat and poultry products. The limited data available do not allow determination of the role, if any, of meat in the epidemiology of *C. difficile* human infections.

Bacterial hazards such as *Coxiella burnetii* are primarily transmitted to humans through aerosols, direct contact, or consumption of foods such as milk, but not meat. Similar modes of transmission exist for *Mycobacterium avium*, *M. avium* subspecies *paratuberculosis*, *Mycobacterium bovis*, and

Mycobacterium tuberculosis. Evidence for the presence of *M. bovis* in meat is limited and inconclusive, and transmission through meat consumption has not been verified. Confirmed modes of transmission include aerosols and consumption of unpasteurized milk. *Mycobacterium paratuberculosis* causes chronic enteritis in ruminants, such as cattle, named Johne's disease. Humans develop Crohn's disease, a similar chronic inflammatory condition of the intestine but any relationship of the pathogen with this disease has not been verified. The pathogen was recovered from raw and cooked meat samples containing mesenteric lymph nodes derived from carcasses of cows with advanced Johne's disease, indicating that human exposure to *M. paratuberculosis* should be avoided. *Shigella* becomes a problem only if introduced by humans in ready-to-eat products. *Staphylococcus aureus* may be present in raw meat but, because it is outcompeted by other bacteria, it may become a problem only in processed meat products where it is introduced usually by humans and, if the product is temperature abused, is able to produce heat resistant enterotoxins because competition by spoilage organisms is limited. *Yersinia enterocolitica* includes certain pathogenic serotypes, which may be transmitted with foods contaminated through water, as well as with pork products.

Most bacterial pathogens described above have been implicated in meat-borne illness. Currently, the bacterial pathogens receiving most attention by scientists, regulators, public health, and industry for their presence in fresh meat are *Campylobacter*, *E. coli* serotype O157:H7, and *Salmonella*, whereas *L. monocytogenes* is of concern in ready-to-eat meat products. Additional pathogens receiving attention presently are STEC/VTEC other than *E. coli* O157:H7, and antibiotic resistant strains such as those of *Campylobacter* and *Salmonella*.

Campylobacter

The pathogen is found in all food animals, but it is most common in poultry. Campylobacteriosis is one of the most frequently reported bacterial foodborne illnesses in the US and the European Union. Most illnesses are attributed to handling and consumption of broiler meat, whereas other meats and cross contamination are also important sources of *Campylobacter*. Its survival and growth at normal or cold conditions and in dry environments is limited, and it is sensitive to cooking temperatures.

Shiga Toxin-Producing or Verotoxigenic *E. coli*

Most serotypes of *E. coli* are harmless inhabitants of the gastrointestinal tract of humans and other warm-blooded animals. Strains of certain serotypes cause diarrheal type illness. Of the various disease causing *E. coli* groups, STEC/VTEC, including the EHEC strains are of most concern in undercooked meat products, especially nonintact meat products such as ground beef. From the gastrointestinal tract of ruminant animals, such strains contaminate animal exteriors, soil, and water, and consequently meat products and foods of plant origin. STEC/VTEC serotypes cause mild diarrhea, severe bloody diarrhea (i.e., hemorrhagic colitis) or in some cases hemolytic uremic syndrome (HUS), which is characterized by various complications including acute renal failure. Serotype O157 is involved in 80% of HUS cases in North America; approximately 6% of infected individuals develop HUS. Other foods implicated in infection are fermented meat products such as salami, unpasteurized milk and cheese, fruit juice, sprouts, lettuce, spinach, cantaloupe, and mushrooms. As the STEC/VTEC of most concern, *E. coli* O157:H7 has been declared as an adulterant for raw ground beef and other nonintact beef products in the US. Additional pathogenic STEC/VTEC serotypes (i.e., O26, O45, O103, O111, O121, and O145) are also considered for similar regulatory action in the US.

Listeria monocytogenes

This pathogen causes a severe invasive infection in sensitive individuals such as the elderly, immunocompromised, and the unborn, where it exhibits a case fatality rate of 20–30%. Invasive listeriosis is characterized by serious syndromes of the central nervous system such as meningitis and meningoencephalitis, whereas in its mild form the infection is a typical gastrointestinal foodborne illness. Although pregnant women may develop a flu-like illness, the infected fetus develops meningitis, neonatal septicemia, stillbirth, or spontaneous abortion. The incubation period of listeriosis may vary from a few days to 2–3 months. The infection is usually associated with ready-to-eat meat and poultry products and other foods, in which contamination occurs after processing and is followed by growth during prolonged storage even at refrigeration temperatures. The infectious dose should be greater than 100 cells g^{-1}; however, the possibility of lower infectious doses should not be ignored, especially for sensitive individuals. The organism is ubiquitous in the environment and may be harbored in many animals. It is of major concern because it is hardy and grows under conditions of high humidity, low temperatures, and limited nutrient levels. In meat processing environments it is found in floors, walls, drains, condensed and standing water, and food residues on equipment.

Salmonella

Strains of *S. enterica* subspecies *enterica* serotypes are causes of numerous foodborne illnesses throughout the world. Originating from animal feces, the organism is widely distributed in the environment. Thus, foods involved in human illness include animal products, as well as many other foods, including fruits, vegetables, and dry foods. Meat and poultry products are considered major sources because the main habitat of *Salmonella* is the gastrointestinal tract of food-producing animals. Salmonellosis is caused not only after ingestion of contaminated food or water but also through contact with animals or infected humans. Meat may be contaminated with *Salmonella* throughout the slaughtering, dressing, and boning processes. The United States Department of Agriculture Food Safety and Inspection Service (USDA/FSIS) has established microbiological criteria for *Salmonella* in animal carcasses and ground products as a measure of pathogen reduction since the implementation of HACCP programs. Procedures and interventions controlling STEC/VTEC should also be effective against *Salmonella* strains and similar enteric vegetative pathogens.

Other Biological Hazards and Concerns in Meat

Parasitic agents that may be transmitted with pork include *Trichinella spiralis*, *Sarcocystis* spp., and *Toxoplasma gondii*, resulting in trichinosis, sarcocystis, and toxoplasmosis, respectively (Table 1). Beef may be the source of tapeworms (*Taenia saginata*) and *Sarcocystis hominis*, and through fecally contaminated water may serve as an indirect vector for transmission of *Giardia duodenalis* and *Cryptosporidium parvum*. Poultry may transmit toxoplasmosis. Parasites, such as *Trichinella*, may also be transmitted through game meat. Parasitic hazards such as *Fasciola hepatica* and *Echinococcus granulosus* are primarily transmitted to humans through aerosols, direct contact, or consumption of foods such as milk, but not meat. Inactivation of parasites in foods is achieved through proper cooking, freezing, salting, chemical treatments, and ionizing radiation.

Common viral agents in meat products include norovirus, hepatitis A virus, and enteroviruses. Viruses are usually associated with the highest number of foodborne illness cases. Similar to parasites, viruses are unable to grow in foods and are generally sensitive to cooking. Their control in ready-to-eat foods should be through proper sanitation and hygienic practices of food service workers.

Prion diseases, and especially BSE, emerged as a major animal health problem in the 1990s. The concern was high because of the potential association with human transmissible spongiform encephalopathies such as the new variant Creutzfeldt–Jakob Disease. Preventive controls, including feed bans and control of 'specified risk materials' (brain, skull, eyes, spinal cord, small intestines, etc.) during slaughter of all cattle (small intestines) or those exceeding 30 months of age; increasing process controls for material obtained with 'advanced meat recovery' systems; banning the use of 'mechanically separated meat' in food products; and, banning the use of the above materials in dietary supplements and cosmetics, have resulted in control of BSE. Control programs should continue being implemented worldwide through international collaboration and coordination for potential eradication and prevention of reemergence.

Meat-Borne Illness Episodes

Meat and meat products are important vehicles in the transfer of foodborne hazards to humans. However, considering their high potential to be contaminated and the great quantities of products consumed on a daily basis in terms of servings, their safety record is considered, overall, as high. Nevertheless, any amount of products found potentially contaminated and recalled from the marketplace, as well as any illness, and especially death, through consumption of food, including meat, is unacceptable. Indicative data and reasons for product recalls in the US are presented in Table 2. Data in Table 3 show

Table 2 United States recalls of meat and poultry products in 2011 as reported by USDA/FSIS

Agent or product	*Number of recalls*	*Amount of product recalled (kg)*
Escherichia coli O157:H7	13	454 939
Salmonella	10	16 448 383
Listeria monocytogenes	11	238 589
Undeclared allergen	40	582 353

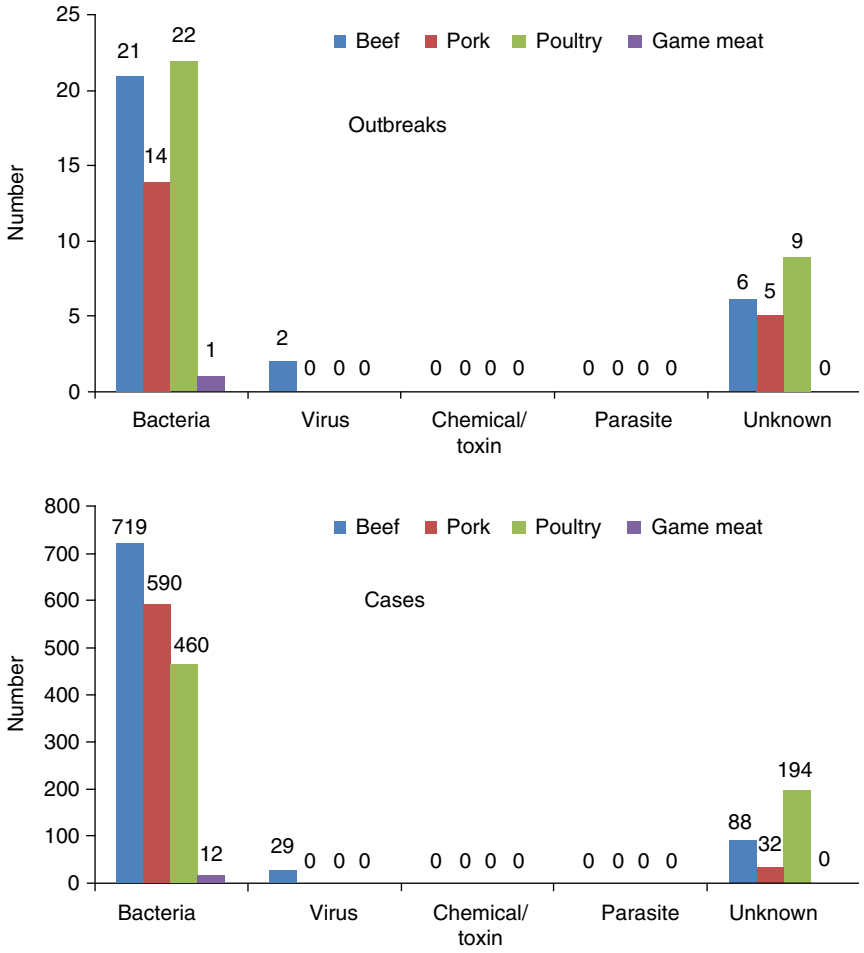

Figure 1 Numbers of confirmed outbreaks and cases due to various agents and meat products in the US (2008).

numbers of confirmed foodborne outbreaks in the European Union in 2008 and 2009, indicating that all meat products combined were responsible for 10–17% of the total outbreaks, compared to 19–25% and 8–9% for fruits and vegetables and fish and seafood, respectively. Data showing numbers of outbreaks and cases of illness associated with pork and broiler consumption in the European Union are shown in Tables 4 and 5, respectively. Figures 1 and 2 present numbers of outbreaks and cases of illness caused by various hazards and associated with consumption of meat products in the US. The data of Table 6 show the locations and settings associated with transmission of the pathogens for foodborne illness of confirmed outbreaks during 2008 and 2009 in the European Union. It is noteworthy that 21–23% and 36–38% of the outbreaks were associated with restaurant and household settings, respectively. The following are examples of outbreaks demonstrating the diversity of causes and reasons for their occurrence:

- In 1988, the first documented incidence of listeriosis due to a meat product was confirmed in the US. It afflicted a female cancer patient, who, on a daily basis, ate turkey frankfurters of the same brand, heated in a microwave oven. *Listeria monocytogenes* was isolated from an open package of product in the woman's home, from unopened product packages obtained from a local store, and from other opened foods in the woman's refrigerator suggesting the occurrence of cross contamination.
- Consumption of undercooked hamburgers from 73 Jack in the Box fast food restaurants in the Pacific Northwest of the US killed four children and sickened 700 others (171 hospitalizations) due to *E. coli* O157:H7 contamination in 1993. The extensive publicity associated with this unfortunate event resulted in political pressure that led to new USDA/FSIS meat inspection regulations.
- In 1994, one person was placed under mechanical ventilation after eating homemade beef stew. The stew was cooked and left on the stove for 3 days before eating without reheating. Botulism toxin type A was detected in the stew.
- An outbreak of *E. coli* O157:H7 occurred in Central Scotland in 1996. It involved a total of 496 cases and 21 deaths of elderly persons. The outbreak was traced to cross contamination between raw and cooked meat at a butcher shop operating under very poor hygiene.
- In 1998, a deadly listeriosis outbreak was linked to consumption of hot dogs and delicatessen meats in 24 states of the US, leading to at least 14 deaths and 4 miscarriages or

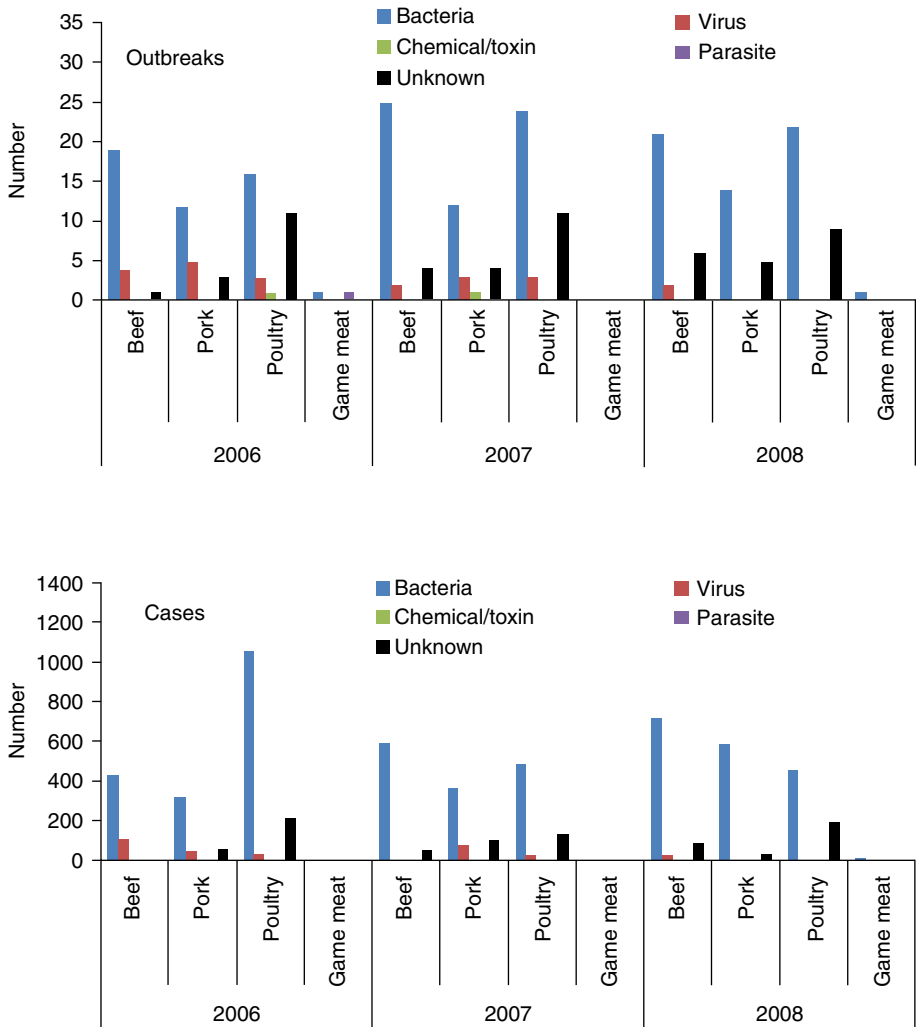

Figure 2 Numbers of confirmed outbreaks and cases associated with different hazards and various meat products in the US (2006–08).

Table 6 Settings involved in foodborne outbreaks (%) in the European Union (2008 and 2009)

Setting	*2008 (N=890)*	*2009 (N=977)*
Household	38.0	36.4
Restaurant, café, pub, bar, or hotel	23.1	20.6
Take away or fast food	2.7	–
Canteen or workplace catering	4.3	4.9

Other setting	10.8	9.9
Unknown	13.3	15.0

stillbirths. Illness onsets occurred from January 1998 to February 1999. Product contamination was attributed to demolition of a refrigeration unit, which increased environmental contamination in the production environment.

- *Staphylococcus aureus* intoxication occurred at a company picnic in an amusement park in GA, USA, in 2000. The illness was attributed to consumption of pork barbeque, which was kept in a cooler at high temperature.
- In 2002, processed chicken products contaminated with *L. monocytogenes* led to the death of seven and three miscarriages, whereas 12 250 000 kg of product were recalled.
- Trichinellosis, without deaths, occurred in Laos in 2005. It was associated with consumption of uncooked or fermented boar meat at funeral and wedding ceremonies.
- In 2006, two people became ill from *Campylobacter jejuni* and *Salmonella* Enteritidis after eating baked turkey in a private home in WI, USA.
- An outbreak of *Staphylococcus aureus* involved consumers of ham at a private home in NY, USA in 2008.
- An outbreak of *Bacillus cereus* and *Staphylococcus aureus* occurred in 2008 affecting people who ate prime rib beef at a banquet facility in AZ, USA.
- In 2009, an outbreak of Norovirus was attributed to eating chicken dishes, fruit, or vegetables at a restaurant in CO, USA.

- An outbreak due to *Bacillus cereus*, *Enterobacter*, and *Staphylococcus aureus* afflicted people who ate catered pork in Puerto Rico, in 2009.
- *E. coli* O157:H7 linked to a farm visit in Redhill, Surrey, England, in 2009, resulted in the hospitalization of 13 children.
- A total of 132 cases of salmonellosis occurred between August 5, 2010 and September 26, 2011 in 18 states of the US affecting people between 1 and 75 years of age. No deaths were reported and the source was attributed to handling turtles.
- In 2011, an outbreak of *E. coli* O157:H7 occurred among children visitors to an animal farm in WA, USA involving five laboratory confirmed, one probable case, and one hospitalization, but no deaths. Two calves were positive for the pathogen.
- *Clostridium perfringens* caused an outbreak, in 2011, at a business luncheon served by an unlicensed caterer, potentially due to improper reheating and hot holding of food.

Control of Biological Hazards in Meat Products

General

Meat products are rich in nutrients and provide a suitable environment for rapid microbial proliferation making them highly perishable foods. Therefore, microbial contamination of meat products needs to be adequately controlled in order for them to be preserved for maintenance of quality, delay of spoilage, and assurance of safety. A comprehensive and effective strategy for foodborne pathogen control should be based on an integrated approach from farm-to-table, and thus, it should be a shared responsibility of all involved in the meat production sector; producers, packers, processors, distributors, retailers, food service operators, and consumers. Control should be based on good production practices at the farm, slaughtering of animals that are disease free, processing of carcasses under sanitary and hygienic conditions, use of decontamination intervention strategies to reduce microbial levels, thermal or other (e.g., high pressure and irradiation) processing, drying, fermentation, acidification, prudent use of antimicrobials, maintenance of the cold chain during distribution, and proper storage and preparation procedures by food service and consumers.

The target of pathogen control at the preharvest level should be to minimize sources, levels, access, and transfer of contamination to the animal. Activities during slaughter and processing should be designed to minimize transfer and introduction of contamination on carcasses and meat, and to reduce existing contamination levels through implementation of decontamination or sanitization interventions, processing treatments for complete or partial destruction of contamination, or antimicrobial procedures for inhibition or retardation of microbial growth. The goal of pathogen control during storage and distribution, and at retail, food service and consumer level should be to prevent introduction of additional contamination, recontamination or cross contamination, and to inactivate or inhibit existing contamination. Discussion of microbial control in meat products is presented here in the context of control of contamination levels through sanitation, hygiene and decontamination; inactivation of contamination through sterilization (canning), pasteurization, and cooking; and, control of microbial growth through single or multiple antimicrobial hurdles. Successful implementation of pathogen control interventions should include adequate and effective education of food handlers and consumers, and should be managed based on the principles and spirit of the HACCP system.

Control of Microbial Contamination Levels

The first goal in microbial control is to maintain initial levels of contamination as low as possible because the amount of initial contamination influences the efficacy of all other antimicrobial interventions, and some agents are infectious at very low levels. Concentrations of contamination are reduced by procedures that restrict the sources, access, and transfer of microorganisms, including cleaning, sanitation, and hygienic practices, as well as packaging technologies such as aseptic packaging of thermally processed products. In addition, microbial levels on meat are reduced by decontamination technologies such as washing, application of hot water, steam, acids or other chemicals, and their combinations. Low levels of contamination ensure that acceptable intensities of subsequent antimicrobial interventions will be adequate to control contaminants and thus assure meat safety. In general, low contamination levels in meat assure that, even if the product is intentionally or unintentionally undercooked, the probability of illness will be lower.

Controlling animal contamination at the farm level (preharvest) may contribute to lower microbial loads reaching the abattoirs and the meat processing environment, and consequently contaminating carcasses and meat. Further, it reduces transmission of pathogens, through animal manure, to the soil and water, thus reducing the potential for contamination of foods of plant origin with enteric pathogens, as well as direct animal-to-human transmission of pathogens.

Antimicrobial interventions considered, or explored, for use to control contamination at the farm level include animal diet modifications, use of feed additives or supplements, antibiotic treatments, vaccination, bacteriophage therapy, competitive exclusion, prebiotics or probiotics, and good animal production management practices such as animal pen management, clean feed, water chlorination, clean and unstressful transportation of animals to slaughter, and clean animal holding environment before slaughter.

With the exception of good production management practices, and to some extent feeding of probiotics, the other approaches are still in the experimental stage or of limited use. Some countries (e.g., Scandinavian) have implemented some apparently successful preharvest pathogen control programs for certain animal types. Nevertheless, overall, preharvest pathogen control is still difficult due to limitations in existing relevant scientific knowledge related to sources and reservoirs for certain pathogens, existence of numerous and complicating variables, animal carriers being asymptomatic for

important pathogens such as *E. coli* O157:H7, pathogen shedding often being sporadic or of low prevalence and cell numbers, large levels of interfering total microbial contamination, lack of effective pathogen detection methodologies for use in the field, ubiquitous presence of some pathogens, lack of proven and approved pathogen control interventions, and economic considerations.

When at slaughter, animals are inspected antemortem and carcasses postmortem for animal health problems, and for the presence of parasitic agents and some animal pathogenic bacteria that also cause human illness (e.g., *M. tuberculosis*). These procedures, however, although necessary for verification of animal health and welfare, are not designed to determine the presence of enteric bacterial pathogens that contaminate meat and result in foodborne illness if not properly controlled.

In response to a major *E. coli* O157:H7 outbreak associated with consumption of undercooked ground beef in 1992–93, the USDA/FSIS established additional inspection requirements in 1996. These require meat and poultry processors to meet established performance criteria for biotype I *E. coli* contamination as a verification that HACCP-based process controls are adequate in preventing and removing fecal contamination. Another requirement is testing of carcasses or raw ground products in order to evaluate pathogen reduction performance standards for *Salmonella*. In addition to the US, microbiological performance criteria for meat have been established in the European Union, Australia, New Zealand, and other countries. In the US, processors and USDA/FSIS also test ground beef and raw materials destined for ground beef production for *E. coli* O157:H7, which is considered an adulterant in these products. To provide safer products and to meet regulatory requirements, as well as contractual specifications with major users of raw beef, the meat animal processing industry in the US and some other countries has employed extensive microbial pathogen reduction interventions as decontamination treatments for carcasses or meat cuts.

Decontamination interventions applied include animal washing, cleaning or partial hair clipping before slaughter, spot cleaning of visible soil on carcasses before evisceration by knife trimming or steam and vacuum, carcass water washing after visual inspection for absence ('zero tolerance') of physical contamination (e.g., feces, hair, etc.), and spraying, rinsing or deluging of carcasses before evisceration and/or before and after chilling with hot water or steam and with approved antimicrobial chemical solutions. Approved and used chemical agents include mostly organic acids (e.g., lactic-, acetic-, and citric acids), as well as acidified sodium chlorite, peroxyacetic acid-based preparations, etc. Frequently, these decontamination treatments are applied as multiple or combined, sequential or simultaneous interventions (multiple hurdles). Decontamination interventions reduce pathogen prevalence and contamination levels by 1–3 log units without eliminating it because they are mostly instantaneous or of short duration and of mild intensity. Their application should be optimized to avoid cell transfer, spreading, cross contamination, penetration, and biofilm formation in meat. In addition it is useful to examine whether they cause cell inactivation, injury, antimicrobial resistance, selection/adaptation/cross protection, or alteration of the natural microbiota of meat and the metabolic activity of survivors.

Pathogen Inactivation

Common processes that destroy microorganisms in foods include the thermal treatments of canning, pasteurization, and cooking. Additional inactivation processes include ionizing radiation and high pressure processing. Irradiation was approved in the US for use in fresh and frozen poultry meat in 1992 and fresh red meat in 1997, but it has found only limited application. Reasons for this may include consumer resistance and conflicting reports indicating potential negative effects of irradiation on meat color and undesirable odors. Ultra-high atmospheric pressure processing for pathogen control has found recent application in certain meat products, such as ready-to-eat ham, for the control of *L. monocytogenes* in the US. At the intensities applied, these processes are able to inactivate vegetative microorganisms, including pathogens, but not bacterial spores. Effectiveness may be increased if nonthermal and thermal technologies are used in milder combinations according to the multiple hurdle approach.

Inhibition of Microbial Growth

Microbial growth on meat products, as well as other foods, is affected, not only by the type and level of initial contamination but also by various factors associated with the product (intrinsic) or its environment (extrinsic). Approaches aiming to inhibit microbial growth are mostly based on manipulation or changes in these factors. These include storage at low temperatures, drying (evaporation) or reduction by binding of water levels (salting and sugaring) available for microbial growth (water activity), addition of acids (low pH), fermentation (low pH and production of antimicrobials), packaging under modified atmospheres such as vacuum, and use of chemical antimicrobials. Combinations of antimicrobial technologies, applied individually at sublethal levels (hurdle technology), are frequently used in many meat products as they result in microbiologically stable and safe products of desirable eating quality. It is important to properly select and apply sublethal hurdle combinations with the objective of pathogen control without stress adaptation or selection of resistant pathogens.

Management of Food Safety

Regulatory inspection authorities, in addition to microbiological performance criteria, have established requirements for the industry to implement sanitation standard operating procedures (SSOP) and HACCP programs for management of pathogen control interventions. Complete and routine implementation of validated and verified HACCP plans should be based on a solid foundation consisting of effective overall prerequisite programs, including proper and sanitary building and equipment designs, good manufacturing practices and good hygiene practices, and proper employee education and training. Employee education and training should be accomplished through development and implementation of specific standard operating procedures or job instructions for each activity. The management of the operations should also be educated to understand meat safety hazards and risks as well as the importance and function of HACCP because it provides

funding for materials, equipment, and adequate time for training and education of employees.

Microbial Testing

The development and widespread adoption and implementation of HACCP principles were based on the realization that traditional end-product microbiological testing is inadequate to assure meat safety. It is important to note that microbiological testing is essential for determination of hazards and risks, and for development, establishment, implementation, validation, maintenance, and verification of HACCP and other safety assurance systems. Limitations associated with finished product testing, as means of meat safety assurance, include the fact that foodborne pathogens are distributed sporadically and unpredictably, and/or occur at a low incidence within the product. Therefore, the number of samples that needs to be tested from a specific lot is unrealistically high if it is to provide meaningful information, and furthermore, the results obtained may provide a false sense of security. Thus, control of the microbiological safety of products should be based on the proper implementation of validated process management systems based on hazard prevention rather than end-product testing, which should be relied on for validation and verification of activities.

Conclusions

By nature, raw meat becomes contaminated with microorganisms, including some that are pathogenic to humans. Contamination is introduced during production in the field, harvesting, storage, distribution, further processing, retailing, preparation, and consumption, and it originates from soil, decaying material, and animal fecal waste, which contaminate water, air, animals, plants, processing facilities, equipment, and humans; leading to a complete contamination cycle. Pathogens present on meat may cause illness ranging from mild gastrointestinal discomfort to severe acute or chronic syndromes or death. Extent, prevalence, and type of contamination are controlled under sanitary and hygienic conditions during animal production, processing, and handling of the products at all stages of the chain. Control of pathogens and management of food safety risks should be based on an integrated effort and approach by all sectors involved, from the producer through the processor, distributor, packer, retailer, food service worker, and consumer. Interventions applied during processing include proper and adequate cleaning, effective sanitation, decontamination, heating, chilling, freezing, drying, fermentation, use of chemicals as acidulants or antimicrobials, packaging, proper storage and distribution, and appropriate handling. Proper application of control processes yields products that should be safe for consumption following proper cooking and serving. Consumers should be advised to handle and prepare all foods, including those of animal origin, properly, and to follow labeling instructions. They should store and handle foods under conditions that avoid cross contamination (clean and sanitary environment), and they should cook them properly (e.g., ground beef to 71 °C), and store or hold them at the correct temperatures (cold: under 4 °C; hot: above 60 °C) within the indicated length of time (<2 h). At-risk persons should be instructed to avoid or cook risky foods before consumption, and to avoid raw or unpasteurized products.

SAFETY OF FOOD AND BEVERAGES

Poultry and Eggs

F Hilbert, P Paulsen, and FJM Smulders, University of Veterinary Medicine Vienna, Vienna, Austria

Glossary

Logistic slaughter Flocks or animals with known or assumed low risk of microbial contamination are slaughtered before flocks or animals with known or assumed high risk of microbial contamination.

Microbial decontamination of foods Methods aiming at removal or inactivation of contaminant bacteria present in or on foods. These methods include physical, chemical, thermal treatments and other methods.

New York dressed poultry Poultry carcasses which are placed on the market in defeathered, but not eviscerated condition.

Organic food production Food production with intention to minimize the human impact on the environment; this includes, for example, restrictions in the use of synthetic pesticides in farming and pharmaceuticals in animal breeding, raising animals in open-air systems, a ban of genetically engineered organisms.

Introduction

Food of animal origin, its production, processing, transport, and preparation, has always been of concern for public health. This thematic issue remains topical through recent outbreaks of new zoonotic diseases, for example, influenza virus H5N1 or prion disease bovine spongiform encephalopathy and the possible transfer of such diseases to consumers. Nowadays, foodborne pathogens tend to spread more readily because of an increased worldwide trade in livestock and the foods of animal origin they produce: Especially globalization may make a primarily local foodborne disease a global issue.

In contrast to beef or pork, poultry meat is in demand by an increasing human population not only because it is considered to be healthy and its consumption is not prohibited by any religious codices, but also because it can be produced at lower cost and is therefore cheaper. Worldwide, poultry meat production amounts to approximately 95 million tons per annum (2010 data), second only to pork (approximately 108 million tons) and is steadily increasing, generally in farms producing under conventional conditions, which mode of production saw the highest increase in all food production systems over the past decade. This results in a high throughput of animals of similar genotypes, separation of breeding, fattening, feed production, and meat (egg) processing. At the same time, to be successful, all these facilities have to operate in an integrated way, i.e., in highly controlled, logistically and technically mature production units. Especially in Europe, the demand for organically produced poultry meat and eggs is increasing, for which specified protocols have been set up by the European community. These are stipulated by regulations including issues such as welfare, feeding, medical treatment, and environmental considerations. The access of production animals to outdoor facilities is probably the most important demand of organic meat and egg production. This bears the risk of disease transmission from wildlife to production livestock as well as the carry-over of epidemic diseases to (endangered) wildlife species. In this short overview, the authors focus on different poultry production systems and their implications for public health, on control measures already set in place, and on future mitigation strategies to minimize the consumers' risks for foodborne infections.

To this end, both conventional and organic poultry production are addressed.

Poultry Meat: Conventional Production

In conventional production, only a narrow selection of breeds are available for producers. Commonly used breeds include Ross, Cobb, Sasso, Hubbard, and Arbor, all of which gain a reasonable slaughter weight within 6 weeks under low feed conversion. The weight gain ranges from 35 to 62 g day^{-1}. The broilers leave the hatcheries and are delivered at the farm 1 day after hatching. Both stables with and without natural light prevail (scientific results on the benefits of natural light are still controversial). Many poultry farms have more than one stable house each of it giving room for up to 40 000 broiler chickens. Important factors include ventilation, temperature, lighting, and litter conditions. Different kinds of stable bedding can be used from straw to wood or corn shaving as well as sand or recycling paper. These broiler litters differ in chemical composition like pH and inorganic components. Thus, there are different advantages like moisture holding, dust reduction, or soil stability and soil biology for one or the other bedding. Also, bedding material influences the efficacy of insect and rodent control and thus the degree of colonization with foodborne pathogens such as *Campylobacter*. Good management practices (GMPs) include an effective ventilation to keep the moisture as low as 30% and the ammonia level in the air lower than

 doi:10.1016/B978-0-12-378612-8.00284-5

25 ppm. Wet litter may not only cause pododermatitis and breast blisters, but is also known to adversely affect the respiratory system of chickens, which may lead to various bacterial or viral infections that need to be treated with antimicrobial substances. Temperature in poultry houses need to be such that chickens are able to maintain their body temperature between 40.6 and 42 °C. The birds' so-called thermo-neutral zone is between 18 and 24 °C and any lower temperature is associated with a higher feed conversion. Higher temperatures cause chickens to drink more and it leads to less feed uptake and ultimately higher humidity. This heat stress is a main problem in fast-growing breeds and can lead to high losses and an increased susceptibility to infectious diseases. In cold months heating is less of a problem for most poultry producers. Nevertheless, in recent years high prices for energy and feed have caused the increase in poultry production worldwide to stagnate. Great discrepancy exists regarding light management. Birds are very sensitive to light. It stimulates food intake and hormone regulation. But the day–night cycle is also important for developing good immunity. Thus, a dark period of at least 6 h is required for good health. Long light periods used in conventional poultry industry promote feed consumption and, consequently weight gain. With alternate dark and light periods birds are more active during the light period. Higher light intensity can induce activity but reduce weight gain. Whereas major zoonotic pathogens (*Campylobacter*, *Salmonella*) can colonize chickens, pathological signs like liver or myocardial necrosis are observed after infection with *Salmonella*. Finally, cellulitis or enterocolitis may be caused by toxin-producing *Escherichia coli* with a zoonotic potential.

Poultry Meat: Organic Production

Over eight million laying hens and over nine million broilers are kept under organic production in all of Europe, and still represent a rather modest part of the total production (e.g., in Austria, 3.5% in the case of broilers).

Organic broiler production is regulated in the European Union (EU) in Reg. (EG) 834/2007 which stipulates access to pasture, a minimum of 12 weeks of age before slaughter, feeding on organic feed produced mainly on the farm of the broiler production, more space per chicken weight, and the restrictive use of chemically synthesized allopathic veterinary medication (e.g., antimicrobial substances). Natural light and longer dark periods lead to less weight gain and higher activity. In most cases, organic poultry production is small scale (i.e., not more than 4500 chickens per flock). Good welfare indoors and the implementation of GMPs as regards temperature, ventilation, feed, water supply, and litter, are required to avoid disease contraction. Organic poultry production is important for protecting the environment, allowing sustainable agriculture and focusing on consumer interests. Most studies comparing conventional and organic poultry production have not found significant differences in colonization with zoonotic agents. Some studies report a reduced rate of antimicrobial resistance in bacterial isolates in poultry raised organically. The use of chemically synthesized allopathic veterinary medicinal products and antibiotics is prohibited for preventive treatment and can only be applied once in the case of disease.

Poultry Meat Processing: Transport, Stunning, Bleeding, Scalding, Plucking, Evisceration, Meat Inspection, Cooling Technology, and Packaging

Highly automated poultry meat processing systems have been developed over time. Both their efficiency and hygienic design have influence on slaughter hygiene and the degree of contamination of chicken meat with zoonotic agents. The observed differences in slaughter hygiene primarily depend on the age of birds at slaughter and cooling and packaging technologies, rather than on the region where they were produced. Nevertheless, consumer preferences on how to purchase and prepare chicken meat (e.g., with or without skin, fresh or frozen, breast meat or New York-dressed poultry) have an impact on processing technology, handling, and preparation. Provided good hygiene practices are applied, carcass contamination can be minimized as illustrated by the scalding process. For instance, washing carcasses pre-scald, the use of high scald temperatures approximately 60 °C, clean scald water, and water sprays instead of immersion will effectively reduce microbial loads on carcasses; however, 'hard' scald results in more crevices and porous structures in the skin, which will retain more water, and thus facilitate entrapment of contaminant bacteria in subsequent processing steps. The scalding process is important as it influences the degree of *Campylobacter* and *Salmonella* carcass cross-contamination. Other important operations for possible cross-contamination at poultry slaughter are defeathering and evisceration. Cleaning, disinfection, and removal of porous pluck fingers are major factors influencing the amount of microbial contamination. In particular, organic matter remaining on (porous) rubber pluck fingers, and the warm and moist environment allow accumulation and even multiplication of *Staphylococcus aureus* originally derived from poultry skin. An improved hygienic design should make such equipment more suitable for cleaning and disinfection. Evisceration technology has a high influence on fecal contamination and thus on contamination with zoonotic enteric bacteria like *Salmonella*, *Campylobacter*, *E. coli*, or clostridia. New systems with automatic cleaning and disinfection of knifes between each carcass evisceration reduce fecal contamination. Heterogeneity in broiler carcass sizes bears the higher risk of gut rupture and thus of fecal contamination. A possible new technology based on laser distance measurements followed by an automatic adjustment of the evisceration cutter to the carcass shape, may reduce or prevent gut rupture. Measures for reduction of microbiological loads on carcasses include cooling, decontamination, crust freezing, steam or hot water spray, and irradiation. Not all of these technologies are accepted in Europe or other parts of the world and they have diverse effects on the reduction or elimination of major zoonotic pathogens. Cutting and further processing of carcasses pose similar problems as known for other meats. In addition to the bacteria mentioned above, post-processing contamination by *Listeria monocytogenes* has been reported.

Egg Production: Laying Hens

Laying hens can be kept in cages, in so-called enriched cages, in floor pens, or free range (organic or conventional). Different breeds seem to behave differently under each of these conditions. Although the use of cages has been banned in Europe since 2012, not all European countries have implemented this regulation till today. Animal welfare and consumer preferences have – at the cost of economic disadvantages – been considered in this decision. The influence of housing systems on *Salmonella* infections has been seen as controversial. Some studies show an increase in transmission between birds in non-cage housing, whereas others demonstrate that *Salmonella* infections are seen significantly more often on farms keeping hens in cages. This has also been discussed by European Food Safety Authority (EFSA) in 2007 in their scientific opinion on a possible European ban of keeping laying hens in cages. Optimal biosecurity, cleaning, and disinfection have been characterized as protective against *Salmonella* in laying hens in existing housing system.

Eggs and Egg Processing

Eggs have arguably the most complex structure among the foods of animal origin. From the surface to the core, a thin layer (cuticle) is covering the porous shell, then two internal layers follow. In the center of the white egg (albumen), the egg yolk is situated. Microbial contamination can occur (1) in the ovarium, i.e., the egg yolk is contaminated, before formation of the albumen layer and egg shell or (2) in the cloaca, i.e., on the egg shell surface, or during/after laying when the egg comes into contact with litter, feces, etc. Generally, the cuticle and the inner membranes provide some protection against migration of bacteria in deeper structures, whereas the egg white has antibacterial properties due to lysozyme, high pH, and chelating compounds. Generally, eggs with damaged shells and protruding egg white are not considered fit for human consumption. In some countries, additional requirements apply to table eggs. Both eggs of best quality as well as eggs with damaged shell may be processed into egg products. Those basic products are whole eggs, yolks, whites, and blends including those with nonegg ingredients. Pasteurized egg products are available in a liquid or dried state, and (also unpasteurized) in a frozen state. Food industry and foodservice will predominantly use such products for bakeries, pasta, omlettes, and other dishes not only because of its convenience in storage and handling, but also because pasteurization will inactivate the common egg-borne pathogenic bacteria. Nevertheless, the egg-processing plants have to adhere to good manufacturing practices and implement hazard analysis critical control point (HACCP) to ensure overall microbiological quality and safety. The processing steps include transportation of eggs from primary production, breaking eggs, filtering, mixing, stabilizing, blending, pasteurizing, cooling, and possibly drying, freezing, and packaging. All of these processing steps are highly automated. Eggs are transported from hen stables in racks or pallets to the production facilities. Eggs as well as transport pens may carry microorganisms including pathogens that exist on the farm, for example, *Salmonella* and *Campylobacter*. To calculate the risk of a possible transfer from the primary production, it is relevant to distinguish between the various production systems, for example, conventional cage or free range. Thus, cleaning and disinfection of all racks and pallets is most important to prevent entry of pathogens from primary production into the processing facilities. Shell eggs are washed and sanitized before breaking to reduce the aforementioned risk. After separation of yolks and whites, the liquid egg is filtered and chilled before pasteurization. Pasteurization is an important critical control point to assure safety particularly against *Salmonella* spp. The processed egg should stay as close as possible to the primary product in flavor, color, or usability. The processing plant must adopt a sanitation concept particularly to avoid recontamination after the pasteurization process. A rodent and insect control is as important as the separation of the cooling, packaging facilities after pasteurization to guarantee a safe and proper way to use the product.

Risk and Control Measures

Although a variety of foodborne biological hazards are associated with poultry and eggs (Table 1), *Campylobacter* and *Salmonella* are the major pathogens implicated in foodborne diseases. In the EU, it is estimated that 44–68% of human foodborne cases of salmonellosis are attributable to the handling, preparation, and consumption of eggs, whereas a mere 4–7% is attributable to broiler and turkey meat. In contrast, 20–30% of human foodborne campylobacteriosis cases are attributable to handling, preparation, and consumption of

Table 1 Biological and chemical hazards transmissible to humans via poultry, meat, and egg (products) consumption or food preparation

Biological hazards	
Bacteria and their toxins	*Bacillus cereus* toxins
	(thermophilic) *Campylobacter* spp.
	Clostridium botulinum toxin
	Clostridium difficile
	Clostridium perfringens toxin
	E. coli, toxicoinfectious strains including verotoxin-forming *Escherichia coli* (VTEC)
	Extended-spectrum-β-lactamase/AmpC *E. coli* and *Salmonella*
	Listeria monocytogenes
	Salmonella sp., non-Typhi
	Staphylococcus aureus toxins
	Yersinia enterocolitica
Protozoa	*Toxoplasma gondii*
Helminths	Various trematodes
Chemical hazards	
Contaminants	Dioxins and dioxin-like polychlorinated biphenyls
Residues	Antimicrobials: chloramphenicol, nitrofurans, nitroimidazoles
Physical hazards	As in other meat species or foodstuff

broiler and turkey meat (or 60–80%, when cross-contamination pathways occurring in the kitchen are considered).

Measures to control *Salmonella* in the poultry meat and egg chain start with the provision of *Salmonella*-free eggs for breeding layers or broilers, considering both intra-ovarian as well as shell-surface contamination. Preventing the introduction of the pathogen in flocks is a task of biosecurity measures, including feed and water. In addition, animal transport, slaughter, and further processing must be under control in the meat chain, while the cleanliness of the egg shell, integrity of the cuticle, and avoidance of temperature shifts are crucial for the safety of table eggs. From a regulatory view, the establishment of target prevalences is a key step that allows to assess if control measures have been effective. Safe handling and processing techniques must not only be implemented into good hygiene practice (GHP) systems of the food business operators, but also be communicated to the consumers. At farm level, vaccination of poultry as well as stamping out of positive flocks have been established as preventive or reactive measures. Intervention measures at slaughter may either be improvements in the common slaughter steps (scalding, defeathering, evisceration, chilling), or be separate measures ('microbial decontamination') aimed at removing bacteria from carcass surfaces (cold/hot water washes, or steam treatment), or to inactivate them (irradiation; dips, sprays, or rinses with organic acids or oxidizing compounds). Such inactivation treatments are not allowed in all countries and should be implemented only when GHP and HACCP is well established and functional. Temperature abuse may result in the multiplication of this pathogen, and breaching of other GHP principles may result in cross-contamination. It must be noted that also direct contact with live poultry has caused outbreaks of human salmonellosis, for example, in the USA in 2012.

As regards *Campylobacter*, there are few single measures that would substantially reduce the prevalence or concentration on poultry meat. The bacterium is sensitive to oxygen, dryness, and will not multiply under temperature conditions common in the meat chain. However, the structure of poultry skin and coexistence with oxygen-consuming *Pseudomonas* will allow *Campylobacter* to prevail in a viable state, albeit occasionally not culturable on selective media. Dry air chilling of eviscerated carcasses as well as retailing deep-frozen instead of chilled carcasses has an effect on the numbers of culturable *Campylobacter*. Whereas the latter approach was successful in Iceland, New Zealand fruitfully pursued a multistage approach. Slaughter of *Campylobacter*-negative flocks before positive ones (logistic slaughter) will have only limited effect

Table 2 Process criteria to ensure stop of growth or inactivation of selected biological hazards

	Freezing	*Heat treatment*	*Irradiation*	*Other*
Bacteria and their toxins				
(Thermophilic) *Campylobacter* spp.	n/a	50–57 °C for 0.8–13.3 min (D)	0.08–0.29 kGy (D)	Preservatives
Listeria monocytogenes	n/a	70 °C for 0.14–0.27 min (D)	0.34–1 kGy (D)	Preservatives, UV irradiation
Salmonella sp., non-Typhi	n/a	75 °C in the core of the food	0.2–11 kGy (D) dependent on Serovar and food medium	Preservatives
Staphylococcus aureus toxins	n/a	104–121 °C for 20–100 min, thus highly stable	n/a	Preservatives; more research is needed for conclusive results
Parasites				
Toxoplasma gondii (tissue cysts)	−20 °C, 11 days	58 °C, 9.5 min	0.4–0.7 kGy (D)	2% NaCl at 4 °C, 7 days

Abbreviations: D, time to reduce numbers of viable organisms to 1/10; n/a, not applicable; UV, ultraviolet.

Table 3 Selected major product recalls or foodborne disease outbreaks attributed to poultry meat and eggs

Year	*Region*	*Disease outbreak, recall, ban*	*Food type*	*Source/reason*
1994	USA	Disease (established 22 400 cases), recall	Ice cream	Ice cream premix transported in a tank that had contained raw egg contaminated with *Salmonella*
1999	Belgium/Europe	*Post hoc*	Poultry and eggs	Feedstuff contaminated with dioxins/polychlorinated biphenyls (PCBs) in transformer oil
2011	Germany/Europe	Recall, ban	Poultry and eggs	Fat contaminated with dioxins/PCBs
2011	USA	Disease (136 cases), recall	Ground turkey	Undercooking
2011	USA	Disease (>30 cases), recall	Broiled chicken liver	Undercooking
2012	Germany/Europe	Recall	Eggs	Feedstuff contaminated with dioxins

on the overall carcass prevalence, as long as the flock prevalence is high; also, within the period from sampling of flocks to obtaining results and arranging the order of slaughter, conversion of previously negative flocks can occur. Although a number of intervention measures starting from the phase of microbial colonization of chicks have been proposed and studied and mathematical models have been set up to quantitatively describe the *Campylobacter* load along the poultry meat chain, the major players in poultry meat production and consumption still have to elaborate more harmonized risk control approaches to control this foodborne pathogen. A number of studies indicate that cross-contamination during food handling and processing contribute more to human foodborne campylobacteriosis than underheating of poultry meat.

Some process criteria for freezing and heating, as well as other treatments are given in **Table 2**; likewise, some major food recalls and foodborne disease outbreaks attributed to poultry meat and eggs are listed in **Table 3**.

Existence of commensal or pathogenic bacteria carrying resistance against a number of diverse antibiotics (multiresistance) or against an entire group of antimicrobial (e.g., due to extended spectrum β-lactamase production) is not unique in poultry and egg production, and the reader is referred to the pertaining articles of the Encyclopedia. Also, chemical hazards, in particular dioxine introduced via feedstuff or others introduced via litter, are dealt with in another article of this encyclopedia.

Y Motarjemi, Food Safety and Risk Management Consultant, Switzerland

Glossary

Acquired immunodeficiency syndrome (AIDS) A disease of the human immune system caused by infection with the human immunodeficiency virus (HIV).
Biogenic amines Low molecular weight organic bases such as histamine, tyramine, cadaverine etc. formed in food by the microbial decarboxylation of amino acids that can result in consumers suffering allergic reactions.
Bovine somatotropin (BST) A metabolic protein hormone used to increase milk production in dairy cows.
Epitopes Allergenic segments or polypeptides of proteins capable of eliciting an immune response
Glycation The result of non-enzymatic covalent bonding of a protein or lipid molecule with a reducing sugar molecule, such as fructose or glucose.
Hemolytic uremic syndrome (HUS) A disorder that usually occurs when an infection in the digestive system produces toxic substances that destroy red blood cells, causing kidney injury.
Mastitis An inflammation of the mammary glands.
Milk Defined as the normal mammary secretion of lactating animals obtained from one or more milkings without either addition to or removal from it; intended for consumption as liquid milk or for further processing.
Milk products Also known as dairy products, are foodstuffs made from mammalian milk by processes such as homogenization, pasteurization, freezing, fermentation, evaporation and drying etc. Additional ingredients may be added.
Q-fever A global disease with acute and chronic stages caused by the rickettsial microorganism *Coxiella burnetii*. Cattle, sheep, and goats are the primary reservoirs.

Introduction

Potential foodborne hazards are undesirable substances or organisms in food that may constitute a health risk to the consumer. Three classes of such hazards in milk and dairy products are considered in the present article and include: (1) biological hazards, such as viruses, bacteria, and other microbial pathogens; (2) chemical hazards such as mycotoxins, residues of veterinary drugs used in lactating animals, pesticide residues, and a variety of industrial and environmental contaminants that might contaminate the feed of lactating animals; and (3) physical hazards such as metal, wood or glass, and any other foreign object that may have found its way into milk and dairy products, for example, hair, stones, and jewelry.

It is ironic that at a period in time when food is arguably safer than ever before, sporadic food safety incidents continue to undermine consumer confidence in the safety of the food supply. The illegal addition of melamine to milk in China is one of the more recent examples. Many of the potential health risks posed by contaminants in milk have been known for well over a century. Since that time, considerable efforts by both the public and private sectors have significantly reduced the prevalence of milkborne diseases. It is now common practice, at least in industrialized countries, that the production of safe and wholesome milk and dairy products includes control over all the factors that may impact on the safety of the final product at each step of the production chain. This procedure is often referred to as 'Integrated Chain Control for Food Safety.' This shared responsibility for food safety by all players along the production chain is recognized as the best means for assuring safe and wholesome milk and milk products. However, this approach first requires the identification of potential hazards and means for their control. These are discussed in the following sections.

Pathogens of Special Relevance

Milk is the ideal medium for the growth of both pathogenic and spoilage microorganisms. The fact that dairy products are consumed safely on a daily basis by most individuals in the world is a tribute to the efforts of all involved in ensuring the safety of dairy foods. Recent studies have indicated that dairy products account for a very small percentage of all foodborne illness. Although milk and milk products are among the safest foods worldwide, they have an inherent potential for causing illness as they are potentially the source of a very broad range of microbial, chemical, and physical

Table 1 Potential hazards and foreign bodies in milk and dairy products

Biological hazards	*Chemical hazards*	*Physical hazards*
● *Bacillus cereus* ● *Brucella* spp. ● *Campylobacter jejuni* ● *Coxiella burnetii* ● *Cronobacter sakazakii* ● *Cryptosporidium parvum* ● Pathogenic *Escherichia coli* ● Enterohaemorrhagic *E. coli* ● *Listeria monocytogenes* ● *Leptospira* ● *Mycobacterium bovis* ● *Mycobacetrium paratbuberculosis* ● *Salmonella* (non-typhi) ● *Shigella* spp. ● *Staphylococcus aureus* (enterotoxins) ● *Yersinia enterocolitica* ● Fecal-orally transmitted pathogens such as hepatitis A, *Salmonella* typhi and paratyphi, pathogenic *E. coli*	● Residues of antibiotics ● Antibiotics ● Pesticides ● Hormones ● Dioxin ● Aflatoxin M_1 ● Heavy metals ● Radionuclides Processing contaminants ● Packaging contaminants (bisphenol A) ● Melamine and other adulterants	● Metal fragments screws and rivets ● Machine filings ● Glass pieces ● Jewelry ● Stones ● Insulation/paint ● Plastic material fragments ● Personal effects such as jewelry, buttons, nail fragments, nail varnish, and dressings ● Hair, dust, and dirt insect parts/fragments

hazards. As such these hazards are a major concern to producers, processors, regulators, and consumers.

Normally milk is collected from a lactating animal (most commonly a dairy cow). Such milk can harbor a variety of microorganisms, many of which are pathogenic to humans. Principal sources of microbial contamination are endogenous, such as the cow itself, or exogenous, such as the environment (soil, water, manure, and domestic and wild animals). Unsanitary milking and/or processing equipment and contact by farmers or workers on the farm or in the factory are also considered exogenous sources. In general, milkborne diseases can be caused by bacteria, protozoa, or viruses. These are presented in Table 1.

Some of these infections cause disease in the dairy animal, whereas others do not. Obviously, asymptomatic animals make identification and control more difficult. Some of the microorganisms in Table 1 have highly specific symptoms in infected humans such as hemolytic uremic syndrome (HUS) caused by the enterohaemorrhagic *Escherichia coli* O157, Q-fever caused by *Coxiella burnetti* and tuberculosis caused by *Mycobacterium bovis*. Although most of the organisms cause self-limiting gastrointestinal disorders, some infections are associated with long-term sequelae. Persons falling in the so-called the Young, the Old, the Pregnant, and the Immunocompromised ('YOPI' group) are at greater risk of more severe and often lethal infections by some agents, such as *Listeria*.

Most milk is pasteurized or treated in some manner, thereby eliminating foodborne pathogens that may be present. In some countries, the practice of consuming untreated raw product has been increasing because of purported health benefits. Unpasteurized milk is often consumed directly by dairy producers, farm employees and their families, neighbors in the region, and raw milk advocates. It is also consumed directly by segments of the population in certain regions of the world through the consumption of raw-milk cheeses. However, the direct consumption of raw or unpasteurized milk has been unequivocally traced to outbreaks of disease in humans. In the ensuing Sections: Viruses, Rickettsiae, Protozoa, and Bacteria, these milkborne biological agents that can be eliminated by pasteurization or other treatment will be discussed. Prions, the agents of transmissible spongiform encephalopathies, will not be discussed because, except for the hypothetical case of bovine spongiform encephalopathy in small ruminants, presently there is no scientific evidence to suggest that milk and dairy products can present any risk.

Viruses

Viruses have emerged as significant causes of food- and waterborne diseases in recent years. In the US, the Centers for Disease Control and Prevention (CDC) reported on the ranking of various foodborne pathogens that were acquired domestically in 2011. Of these, norovirus was by far the leading cause of the estimated 47.8 million foodborne diseases that occurred that year. It was the second leading cause of the estimated 127 839 hospitalizations and the fourth leading cause of the estimated 3037 deaths. Foodborne hepatitis A virus is also important and was responsible for one of the biggest outbreaks ever documented when contaminated 'hairy' clams caused over 300 000 cases in China in 1988. Calicivirus, rotaviruses, and poliovirus are also important, particularly in developing countries.

Virtually all foodborne viruses are transmitted via the fecal–oral route and can be transmitted by raw- and improperly pasteurized milk that is directly or indirectly contaminated by fecal matter. Experiments have been conducted where various dairy products and pasteurized milk were artificially inoculated with a variety of viruses to assess their survival in these products. In inoculated pasteurized and boiled milk, poliovirus and coxsackievirus B5 could survive for at least 90 days at 4 °C and for up to 30 days at 25 °C. Yoghurt stored at 4 °C, supported the survival of poliovirus and coxsackievirus B5 for 90 days. However, pasteurization has been demonstrated to be an

adequate treatment to control any viruses that may have contaminated raw milk.

Regarding milkborne outbreaks, the first enteric virus associated with such an incident was the poliovirus in the period before the Second World War. The virus was transmitted through water and unpasteurized milk. Poliovirus is host-restricted to humans and therefore cannot infect cows, but inadequate milk handling practices by infected workers and lack of pasteurization sometimes allows outbreaks to occur.

In 1993, seven people were infected with the tick-borne encephalitis (TBE) virus after drinking unboiled goat's milk. Previous cases of alimentary TBE were recorded in 1984 (4 cases) and in 1989 (2 cases). Both of the latter outbreaks were associated with the consumption of unpasteurized goat's milk. TBE belongs to the flavivirus family and is the only enveloped virus known to be associated with foodborne infections. The virus infects dairy animals via the tick vector and infected animals shed the virus in their milk, which if ingested without pasteurization, may infect humans.

Protozoa

Over recent decades, parasitic protozoa have been recognized as having great potential to cause food- and waterborne diseases. The organisms of greatest concern in food production worldwide are *Cryptosporidium*, *Giardia*, *Cyclospora*, and *Toxoplasma*. Although other parasitic protozoa can be spread by food or water, current epidemiological evidence suggests that these four present the largest risks. Very little documented evidence is available in which milk or dairy products are implicated in cases of foodborne disease caused by these organisms. Of the four genera referred to above, *Cryptosporidium* appears to be the most significant in terms of milk and dairy products. Even in the case of *Cryptosporidium*, however, the public health risk of foodborne spread from the point of view of milk and dairy products (such as butter, cheese, and yoghurt), appears to be negligible. Consequently only *Cryptosporidium* will be discussed in more detail in this section.

It nevertheless remains important to prevent protozoan parasites from entering the food (and also the milk production) chain. Three main routes by which these parasites enter the food production process are:

- Contamination of food ingredients or raw materials on the farm;
- contaminated water use in the final product or resulting from processing, washing, or cleaning; and,
- transfer from infected food handlers in production, food service, or domestic settings.

Prevention and control methods should, therefore, be devised to cover these three routes whenever they could be of significance to the final product consumed. It is also important that analytical laboratories tasked with examining outbreaks of infectious intestinal disease should have the capability and expertise to diagnose the presence of parasitic protozoa in patients.

Cryptosporidium

Human cryptosporidiosis emerged as an important gastrointestinal infection in the 1990s, because of the ingestion of contaminated water and foodstuffs containing the protozoan parasite, *Cryptosporidium parvum*. When ingested, it is capable of causing a high degree of morbidity in healthy populations. It also can result in mortality in vulnerable populations such as immunocompromised persons infected with human immunodeficiency virus (HIV)/aquired immunodeficiency syndrome (AIDS) or cancer patients receiving chemotherapy.

There is no effective antimicrobial treatment to eradicate this agent from the gastrointestinal tract. Generally, cryptosporidiosis is a self-limiting disease presenting with various symptoms, including diarrhea, dehydration, abdominal cramps, vomiting, weight loss, and electrolyte imbalance. Cryptosporidial infections can, however, persist in persons infected with human immunodeficiency virus (HIV)/aquired immunodeficiency syndrome (AIDS) to the point of being life threatening. Although there are 10 recognized species of *Cryptosporidium*, human infection is mainly caused by *C. parvum*, which is an obligate intracellular parasite that infects the microvillus border of the epithelium in the gastrointestinal tract of humans and various animal hosts. Water has been found to be the most important source of *C. parvum* and because of its chlorine resistance, this organism has been a particular threat to otherwise safe drinking water supplies.

Cryptosporidium oocysts have been isolated from several foodstuffs, including fruit, vegetables, and shellfish. Several outbreaks of cryptosporidiosis have been associated with milk. In 1985, an outbreak of 22 cases of cryptosporidiosis occurred in Mexico in which contaminated milk was suspected. In 1995 50 cases of cryptosporidiosis were confirmed in the United Kingdom. Junior-level school children were infected after drinking milk that was distributed to the school by a small-scale local producer. The on-farm pasteurizer was found to be faulty and hence, the milk was not adequately pasteurized. In 1984, a mother and her 1-year old child were infected with *Cryptosporidium* after drinking unpasteurized goat's milk that had been purchased locally in Australia.

Cryptosporidium parvum cannot survive pasteurization of milk and 100% inactivation was achieved by heating milk to 71.7 °C for 5 s. *Cryptosporidium parvum* showed 0–5% viability after 48 h in ice cream stored at − 20 °C. However, prolonged storage of contaminated yoghurt for up to 240 h was not sufficient to destroy *C. parvum*. A decrease in viability of the organisms from 83% at time 0, to 61% after 240 h was noted.

Bacteria

Rickettsiae

Coxiella burnetti

Coxiella burnetti, the causative agent of Q-fever, is an organism that may infect the udder, probably by the hematogenous route. Consumption of, or contact with, the infected milk can also lead to human infection. This organism was found to be more heat resistant than *Mycobacterium tuberculosis* and in 1956, the recommended vat pasteurization temperature was raised from 61.7 to 63 °C (holding time 30 min) to ensure destruction of the organism. The current high temperature short time (HTST) pasteurization temperature of 72° for 15 s is also effective in this regard. Milk alkaline phosphatase, which serves as an indicator of pasteurization efficacy for

bovine milk, is more heat resistant than *C. burnetti* and is destroyed by the above pasteurization treatments.

Brucella

Brucella abortus and *Brucella melitensis* are zoonoses that can cause milkborne disease outbreaks in humans and are the causative agents of brucellosis in cattle. Brucellosis eradication programs in many countries have resulted in a decrease of outbreaks. In many parts of the world this eradication has been so successful that the organism no longer poses a hazard to human health. Where the disease still occurs, pasteurization of milk has minimized the number of human outbreaks by these microorganisms.

Mycobacterium

Mycobacterium bovis is a microorganism of concern to the dairy industry because it causes tuberculosis in cattle. It can also result in milkborne *M. bovis* infections of humans. Cattle immunization and pasteurization of the milk has limited the number of tuberculosis cases associated with the consumption of milk or dairy products.

Another *Mycobacterium* sp. that has generated increasing interest in recent times is *Mycobacterium avium* spp. *paratuberculosis* (MAP). This organism is the etiological agent of paratuberculosis (also known as Johne's disease), which is a global disease of ruminants that was first described in 1895. The disease itself is a slow developing colitis in which the intestinal macrophages are infected. In the process inflammatory reactions are induced in the host gut. This affects the ability of the gut to absorb protein from the diet resulting in clinical features that include diarrhea and chronic weight loss.

Although there are similarities between paratuberculosis in cattle and Crohn's disease in humans, the homology of the two diseases is still in dispute. However, sufficient evidence exists to indicate that MAP should be prevented from entering the human food supply. Milk may be contaminated by the natural shedding of infected macrophages or by fecal contamination. Although the infectious dose is reported to be as low as 1000 organisms, clinically affected animals may shed up to 5×10^{12} mycobacterial cells per day. Occurrence of the pathogen in milk producing animals is consequently a challenge to animal health, milk quality, and the safety of the milk supply. As Johne's disease in cattle is itself devastating for the animals and a cause of reduced milk productivity, the most efficient control measure is the eradication of the illness in cattle and the sourcing of milk from healthy animals.

Enterobacteriaceae

The presence of any member of the Enterobacteriaceae family is undesirable in pasteurized milk and dairy products. This is because of: (1) the inherent spoilage capacity of many genera in this family, (2) the fact that the presence of certain genera in water and food may be indicative of fecal contamination, and (3) the serious food safety implications that the presence in food or water of the many pathogens in this family may have.

Salmonella

The gastroenteritic form of nontyphoid salmonellosis was not clearly linked to raw milk consumption until the mid-1940s. Interest in milkborne salmonellosis has peaked twice since then. In 1966 several large outbreaks were traced to nonfat milk powder and again in 1985 one of the largest recorded outbreaks of foodborne salmonellosis involving more than 180 000 cases was traced to consumption of a particular brand of pasteurized milk in the Chicago area. The incident was caused by the postprocess contamination of pasteurized milk because of an error in equipment design allowing cross connection between raw and pasteurized milk lines. This outbreak also led to the discovery that reactive arthritis ('Reiter's syndrome') is a sequelae of salmonellosis, occurring in approximately 3% of patients. Today *Salmonella* and *Campylobacter* are generally recognized as the two leading causes of dairy-related foodborne illness in the US and Western Europe with rates of infection being particularly high in regions where raw milk is neither pasteurized nor boiled before consumption.

Raw milk can be a source of salmonellae and 32 of 678 raw bulk milk samples were reported to test positive in the US in 2003. Standard pasteurization destroys expected levels of salmonellae (i.e., < 100 cfu ml^{-1}), with a wide margin of safety. Inadequate pasteurization and postprocess contamination have occasionally resulted in milk and cream that test positive for *Salmonella* as evidenced by the reported outbreaks. *Salmonella* is not particularly tolerant of heat, refrigeration or salt, so the typical hurdles used in the dairy industry are effective in controlling this organism.

Escherichia coli

Escherichia coli is currently the best known indicator of fecal contamination, primarily, not only of water but also of raw food products. Its recovery from fresh dairy products consequently suggests that other organisms of fecal origin, including pathogens, may be present. *Escherichia coli* strains are commonly associated with the normal facultative anaerobic microflora of the intestinal tracts of humans and animals. Although many of these strains are harmless commensals, various *E. coli* strains have acquired genetic determinants (virulence genes) rendering them pathogenic for both humans and animals. These pathogens are responsible for three main clinical syndromes, namely enteric and diarrheal diseases, urinary tract infections, and sepsis/meningitis. On the basis of their distinct virulence properties and the clinical symptoms of the host, pathogenic *E. coli* strains can be divided into numerous categories or pathotypes. The extraintestinal infections are caused by three separate *E. coli* pathotypes, namely uropathogenic strains, neonatal meningitis strains and strains that cause septicemia in humans and animals. The diarrheagenic *E. coli* strains include enteroaggregative *E. coli*, enteroinvasive *E. coli*, enteropathogenic *E. coli* and enterotoxigenic *E. coli* (ETEC). Members of the latter group adhere to the mucosa of the small intestine and produce heat labile and/or heat stable enterotoxins. A group of ETEC strains produce cytotoxins called verotoxins or shiga-toxins and hence the acronyms VTEC or STEC. These colonize the intestinal tract of healthy domestic animals, chiefly cattle. The STEC serogroups, 0157, 026, and 0111, are also designated enterohaemorrhagic *E. coli* (EHEC). Only this latter group of organisms will be the subject of further discussion in the present article.

Several outbreaks of *E. coli* gastroenteritis have been traced to raw milk and dairy products. Infections with EHEC of the

serotype O157:H7 were first described in 1982. *Escherichia coli* O157:H7 has become a pathogen of major concern for the food and dairy industries because of its ability to cause severe ailments such as hemorrhagic colitis (HC), HUS, and thrombocytopenic purpura. These ailments affect all human age groups and the pathogen is exceptional in the severe consequences of infection, its low infectious dose and unusual acid resistance. Cattle are the main reservoir of *E. coli* O157:H7, although the most likely mode of transmission in foods is through fecal contamination. The organism has an oral infectious dose within the range of 10–100 cells, or even lower in the case of susceptible groups.

Its survival in acidic foods such as yoghurt and its survival in fermented as well as fermenting dairy foods for long periods of time make its hardy nature apparent. During the manufacture of cottage cheese (the most well-known and popular acid–curd cheese), low pH of the product did not halt the growth of *E. coli* O157:H7.

Prompt action taken in response to recent HC outbreaks associated with acidic foods has resulted in a large number of validation studies in many countries. In particular, the US mandates that food processors should guarantee a 5-log reduction of *E. coli* O157:H7 during processing of fermented sausages and fruit juices, but has not yet extended this to fermented milk products.

The behavior of *E. coli* O157:H7 was studied during the manufacture and ripening of raw goat milk lactic cheeses. When cheese was manufactured from raw milk in the laboratory and inoculated with *E. coli* O157:H7 to a final concentration of 10, 100, and 1000 cfu ml^{-1}, counts decreased to less than 1 $\log_{10} g^{-1}$ in curds just before molding. However, viable *E. coli* O157:H7 were found in cheeses throughout processing and even after 42 days of ripening. This implies that the presence of low numbers of *E. coli* O157:H7 in milk destined for the production of raw milk lactic cheeses can constitute a threat to the consumer. Consequently, it is imperative to ensure that milk used in the manufacture of such cheeses is of the highest microbiological quality.

Given the potential for contamination of milk by *E. coli* during milking, consumption of raw milk should be avoided. *Escherichia coli* O157:H7 is not heat resistant and, like most *E. coli* strains, is readily destroyed by the pasteurization process. If good manufacturing practices are followed, consumption of pasteurized milk poses little or no risk of contracting this microorganism. Although the organism is unable to grow at less than 10 °C, substantial growth can occur in temperature abused milk.

Yersinia

Yersinia enterocolitica and other yersiniae falling within the family Enterobacteriaceae, are often referred to as 'environmental strains.' *Yersinia enterocolitica* is, nevertheless, a well-established pathogen of humans, causing acute gastroenteritis, enterocolitis, and mesenteric lymphadenitis, as well as a variety of extraintestinal disorders. The symptoms of these ailments may be especially severe in children and individuals with underlying disease.

Yersinia enterocolitica is regarded as an unusual cause of milkborne illness because of the low incidence of human pathogenic strains in the raw milk supply and high susceptibility of the organism to pasteurization. Yersiniae contamination of raw milk is thought to occur through contact with feces or polluted water. Raw milk and inadequately pasteurized milk and dairy products have, nevertheless, been implicated in the transmission of *Y. enterocolitica* infections to humans. In 2005, the first recorded food-associated outbreak of yersiniosis occurred in New York, NY, USA where more than 220 individuals were stricken with acute intestinal illness after consumption of contaminated milk. In addition epidemiological studies have revealed that refrigerated food stored over prolonged periods of time pose an additional risk since *Y. enterocolitica*, as a psychrotrophic microbe, is able to grow at temperatures as low as 0 °C. *Yersinia enterocolitica* and atypical *Yersinia* spp. were also isolated from cheese samples in Turkey and results indicated that *Yersinia* spp. are more likely to be isolated from foods with a high level of coliforms than from foods with low coliform counts. This lends support to the hypothesis that *Yersinia* contamination of raw milk is of fecal origin.

Cronobacter sakazakii (previously *Enterobacter sakazakii*)

This is an opportunistic pathogen affecting infants and neonates causing sepsis, necrotic enterocolitis, and meningitis. It is ubiquitous in environment, but has particularly been associated with powdered infant formula. The organism is heat sensitive and is destroyed by heat treatment of milk. The major source of contamination is believed to be postprocess contamination, or contaminated ingredients in dry mix processes.

Campylobacter jejuni

Campylobacter jejuni has been recognized since 1909 as an important cause of abortion in cattle and sheep. Improved isolation strategies have also implicated this organism as a causative agent of human diarrhea. For the year 2011, CDC reported that *Campylobacter* spp. were the fourth leading cause of domestically acquired foodborne illness with 845 024 cases. They were also the third leading cause of hospitalizations and fifth leading cause of death. Although CDC is only beginning to compile food attribution data, a previous study indicated that many outbreaks of campylobacteriosis involved ingestion of raw milk. Similar reports linking raw- and inadequately pasteurized milk to 13 outbreaks in Great Britain from 1978 to 1980 helped to further substantiate *C. jejuni* as an important milkborne pathogen that has come to rival or even surpass *Salmonella* as an etiological agent of human gastroenteritis worldwide.

Campylobacter jejuni can be isolated from the feces of cattle infected or colonized with the organism and has been shown to cause asymptomatic bovine mastitis in which the organism is excreted directly into the milk by an infected cow. In most outbreaks, however, *Campylobacter* could not be isolated from milk after an outbreak. Nevertheless, a survey done in England in 1988 showed that 5.9% of milk samples tested were positive for *C. jejuni*. It was also found, in the latter survey, that there was a significant association between the presence of *E. coli* in milk and that of *C. jejuni*.

Campylobacter jejuni infections have been shown to be hyperendemic in developing countries, including South Africa, with an age-related decrease in the incidence of infections in humans. Acquired immunity could be important in preventing infection

or preventing illness after infection. Nevertheless, immunocompromised people are at risk of contracting the infection.

Campylobacter jejuni is killed by proper pasteurization, but outbreaks involving inadequately pasteurized milk have been described in England. Failure in the public electricity supply and a faulty pasteurizer were identified as the causes of the problem. *Campylobacter* is also acid sensitive and this suggests that the genus will not survive a normal fermentation in a product such as yoghurt.

Staphylococcus aureus

Staphylococcus aureus is a significant cause of mastitis in dairy cows throughout the world. The bovine mammary gland can be a significant source of enterotoxigenic strains of *S. aureus*. Enterotoxins produced by enterotoxigenic strains of this organism are classified according to serotypes into A–H groups and the presence of the so-called 'toxic shock syndrome toxin' (TSST). TSST was detected in *S. aureus* strains in milk from cows with clinical and subclinical mastitis and also from farm bulk tank milk. Various other studies also implicated bulk tank milk as a potential source of enterotoxigenic *S. aureus* in milk and milk products. Consumption of raw milk generally increases the chances of direct contact with food pathogens such as *S. aureus* and its toxins.

Workers involved in processing the milk and manufacturing dairy products can also be a source of *S. aureus* in the product. Various surveys that have demonstrated that from 4% to 60% of humans are nasal carriers of *S. aureus* and that between 5% and 20% of people carry the organism as part of the normal skin microflora.

Staphylococcus aureus was found to be the most frequent pathogen associated with cheeses from raw or 'unspecified' milk in toxi-infections alimentaires collectives (TIAC) reports in France. For TIAC, an outbreak is defined as the occurrence of two or more cases of a similar illness, usually gastroenteritis, caused by the same food. Although the majority of patients from the various outbreaks were hospitalized, no fatalities were reported. Other outbreaks of *S. aureus* enterotoxicoses have occurred. In 1985, 860 children were affected by drinking chocolate milk in Kentucky, USA. More than 14 000 people in Osaka, Japan, were affected by drinking contaminated pasteurized milk in 2000. The latter mentioned incident was because of the lack of cold storage as a result of an electricity failure.

Staphylococcal enterotoxin production can be prevented by keeping the raw milk refrigerated until the milk can be effectively pasteurized. Although pasteurization procedures will kill the cells of *S. aureus* in the milk, they will not destroy enterotoxin already present. Therefore, care should be taken to prevent postprocess contamination and maintaining the cold chain.

Listeria monocytogenes

Listeria monocytogenes has emerged in recent decades as a serious foodborne pathogen that can cause abortion and death in pregnant women and meningitis, encephalitis, and septicemia in newborn infants and the immunocompromised. Although the disease is rare resulting in 2.8 cases per 1 000 000 people per year in the USA in 2011 and accounts for only approximately 0.02% of all cases of foodborne illness, listeriosis is estimated to account for approximately 19% of the deaths resulting from foodborne illness in the USA. This severe mortality rate emphasizes the necessity to minimize the exposure of high risk individuals referred to above.

The variability in virulence of *L. monocytogenes* strains is gaining recognition and acceptance. Throughout the world, three serotypes (i.e., 4b, 1/2a, and 1/2b) account for 89–96% of cases of human listeriosis, providing additional evidence that certain strains are more likely to cause illness. Serovar 4b, for example, has caused several major outbreaks. One outbreak in Switzerland originated from soft cheese and involved 122 cases, resulting in 34 deaths during the period 1985–87.

It has been suggested that the infective dose of a virulent strain of *L. monocytogenes*, is in the order of 100–1000 cells. In general, foods that have been implicated in listeriosis have contained >1000 cfu ml^{-1} or per g. The most important property of *L. monocytogenes* is its ability to multiply in foods at refrigeration temperatures and most foods incriminated in listeriosis have been held under refrigeration. Any ready-to-eat food contaminated with *L. monocytogenes* that is kept refrigerated, may consequently yield population numbers that can present a threat to susceptible consumers. Milk and dairy products have been found to be sources of foodborne listeriosis and after outbreaks involving a large number of cases, *L. monocytogenes* has become a pathogen of great concern to the dairy industry.

Listeria monocytogenes is commonly encountered in the dairy farm environment. The most likely sources of the organisms in raw bulk-tank milk are, therefore, environmental in nature with fecal sources and manure playing major roles. Contamination from within the udder as a result of shedding because of bovine listeriosis or listerial mastitis is likely to be rare. The organism can be transmitted to cows via feeds such as improperly fermented silage and other feedstuffs, causing infection in the animal. Incidences of *L. monocytogenes* of 4.2%, 2.2%, and 2.6% have been reported in farm milk samples of bovine, ovine, and caprine origin, respectively.

Listeria has been isolated from many dairy products, including ice cream and various types of cheese. In soft ripened cheese, contamination is limited to the first few millimeters under the rind. Hard cheese such as Parmesan does not favor growth and other cheeses such as Colby, Swiss, Provolone, Munster, Feta, and Limburger show gradual die-off of the bacteria. In Mozzarella, the bacteria will survive the manufacturing process, but not the stretching temperatures. *Listeria monocytogenes* will not grow in cottage cheese, but can survive. Although the organism has been found to gain access to yoghurt as a postpasteurization contaminant, it will not survive at pH levels of less than 4.6.

Listeria monocytogenes is quite well adapted to dairy factory environments. It is generally more common in factories where conditions tend to be wet and cool with areas of pooled water or liquid. High organic load on the floors and in the drains can also contribute to the growth and survival of *Listeria*. The primary source of *Listeria* spp. in processing plants is probably floors and floor drains, especially areas around coolers or places subject to outside contamination. Because of the ubiquitous nature of the organism, all raw materials carried into the packaging area must be suspect. Cooling waters should also be considered as a possible source of contamination.

Work practices of factory personnel and the dispersal of the organisms in water sprays and aerosols have also been identified as significant sources of the organism throughout the factory.

Many researchers have demonstrated that once strains of *L. monocytogenes* become established in a food-processing facility, they can remain members of the resident microbial flora for many years. Examples of niches in which the organisms can become established are hollow rollers on conveyors, cracked tubular support rods on equipment, the space between close-fitting metal-to-metal or metal-to-plastic parts, worn or cracked rubber seals around doors, on–off valves, and switches for equipment as well as saturated insulation material.

Listeria monocytogenes can become established on steel and rubber surfaces in the form of biofilms. The organism was found to survive for prolonged periods on stainless steel and buna-*n* (acrylonitrile butadiene) rubber. Under favorable conditions, it can even multiply on stainless steel. Temperature, relative humidity, soiling, and the surface type affected the behavior of surface-associated *L. monocytogenes.* In addition, the attachment surface affected the efficacy of sanitizers.

In terms of prevention or control procedures, *Listeria* spp. can contaminate raw milk from many environmental sources and it is difficult to entirely prevent the presence of *Listeria* in raw milk. In most cases control of raw milk contamination should, however, be readily achieved by good sanitation and milking practices.

In controlling the presence of *L. monocytogenes* in the processing area and product itself, the following strategies can be followed:

- In the first place, steps should be taken to prevent entry of *L. monocytogenes* into plant areas: These steps basically include the isolation of the milk receiving area and associated personnel, from the processing and packaging area and prevention of any raw product from entering the processing area. Any product and container returns should similarly not be permitted back into the manufacturing or packaging area. There should be no unsealed openings to the manufacturing area from other areas.
- *Listeria* should be prevented from establishing and growing in niches or other sites that can lead to contamination of the processed food. This should include a thorough check of water and glycol cooling systems, cracks and crevices in storage tanks and other equipment components, and effective cleaning and sanitising. All drains must be properly constructed, cleaned, and sanitized each day. Floor drains should not be located under or near filling and packaging equipment.
- Effective pasteurization is the key step to control *Listeria* in processing. In the case of HTST pasteurization of milk, a minimum of 72 °C for 15 s is essential. Products containing higher fat or sugar levels require higher temperatures to ensure effective destruction of *Listeria* spp., such as 75 °C for 15 s to be safe.
- Cleaning and sanitizing programs are vital in ensuring that postpasteurization contamination does not occur. Absorbent items such as rags and sponges should be eliminated to reduce potential harborage and spread of the organisms. Separate brushes should be used for product contact and nonproduct contact surfaces.
- A sampling program should be implemented that can assess in a timely manner whether the food processing environment is under control. There should be a rapid and effective response to each positive sample obtained. Finally there should be verification by follow-up sampling that the source has been detected and corrected.

Bacillus cereus

Bacillus cereus is a well-known pathogen that may cause illness through the production of either an emetic (vomit-inducing) toxin or at least three diarrheal toxins or enterotoxins. Raw milk appears to be the major source of *B. cereus* in the pasteurized milk. Postpasteurization contamination along the milk processing line is possibly only a minor source. Nevertheless, *B. cereus* cells can attach to stainless steel surfaces and are capable of forming biofilms, a situation that can present a major problem for the food industry.

Spore formers such as *Bacillus* spp. which have survived the pasteurization process can cause a variety of spoilage problems in dairy products and *B. cereus* has been detected in ice creams, milk powders, fermented milks, and pasteurized milks. Although *B. cereus* is able to grow at low temperatures, pH is a definite hurdle with pH 5 being critical for its growth. It is expected, therefore, that growth in fermented dairy products with a pH lower than 5 will be minimal. Even where population levels of a toxigenic *B. cereus* strain in milk did attain levels of up to 9×10^7 cfu g^{-1}, the emetic toxin (cereulide) production was very low. Milk and milk products are consequently not likely to be sources of intoxication caused by emetic toxin-producing *B. cereus* strains.

Clostridia

Clostridia spp., for example, *Clostridium botulinum*, *Clostridium perfringens*, are widely distributed in soil, dust, water, sediments, sewage, and vegetation. Feeds and especially silage, can also be contaminated; under favorable conditions of water activity (aw), pH, and temperature, they can grow and contribute to the spread of spores. Raw milk can become contaminated during the milking process. Numbers of *Cl. botulinum* spores in raw milk are generally very low; in cheese production, during centrifugation and filtration steps, they can increase to 10 or more per gram of cheese. However, in favorable conditions of growth even low numbers of *Cl. botulinum* spores can be dangerous. Most outbreaks of *Cl. botulinum* intoxication are associated with proteolytic strains as they are more heat- and acid resistant than the nonproteolyitc ones. Outbreaks are often associated with pasteurized and heat-treated milk where competitive flora are killed. Outbreaks have been reported with cheese and yoghurt because of the addition of a contaminated ingredient. Contamination of infant formula with *Cl. botulinum B* spores has also been suspected to be a cause of infant botulism. Another potential concern is the consumption of milk derived from cattle or other animals affected by botulism.

Chemical Hazards

Mycotoxins

Mycotoxins are secondary metabolites produced by fungi of various genera when growing on agricultural products before or after harvest or during transportation or storage. Contamination by such fungi can occur at many stages during feed production, for example, during plant growth, harvesting, storage, and processing. Mycotoxins are found mostly on feed ingredients such as maize, sorghum, wheat, and groundnuts. Mycotoxins pose a risk to both animal and human health and depending on the chemical structure of the mycotoxin, pathology may result because of the carcinogenic, estrogenic, neurotoxic, dermonecrotic, or immunosuppressive activity of the toxin.

Fungal species of greatest concern in the dairy industry are *Aspergillus flavus*, *Aspergillus parasiticus*, and *Aspergillus nomius.* These species produce aflatoxin B_1 and related toxins under favorable conditions of temperature, water activity, and nutrient availability often found in subtropical climates. In recent years, concern has been expressed about the presence of aflatoxin M_1 in milk and milk products, which is an animal metabolite of aflatoxin B1.

The exposure of humans to aflatoxins has resulted in liver damage and cancer. Aflatoxin M_1 levels in dairy products are regulated in many countries. Codex has adopted a maximum limit of 0.5 $\mu g\,kg^{-1}$ of liquid milk, but has not set a level for animal feed. The European Union (EU) maximum limits (MLs) for different feed commodities vary between 0.05 and 0.005 $mg\,kg^{-1}$. Provided that these MLs for Aflatoxin B1 (and other mycotoxins) in feeds are observed, there should be no problems with harmful residues in milk.

Mycotoxins produced by fungal species other than *Aspergillus* and possibly *Penicillium* are of minor concern for dairy products. Nevertheless contamination of feed and forage with zearalenone (a *Fusarium* spp. mycotoxin) has been shown to result in residues of zeranol in forage fed cattle. Zeranol, approved in some countries as a hormonal growth promoter, is specifically prohibited from use in food animals in the EU. Hydrogenation of alfa-zearelenol, probably in the rumen, is responsible for the formation of zeranol. This finding of a 'natural' zeranol in cattle has complicated control measures. This makes it necessary to differentiate zeranol arising from feed and forage contamination from deliberate growth promoter abuse.

Once the feed has been contaminated, processing the feed by means of heat treatment has little effect in eliminating most mycotoxins. Continuous monitoring of levels needs to take place to ensure that contamination does not exceed acceptable tolerance levels. Preventing contamination at source is one of the most effective methods of reducing the risk of mycotoxin contamination. Suitable measures need to be applied during crop production, handling, storage, and processing. Proper drying is particularly important.

Antimicrobials

The most frequently and commonly used veterinary drugs associated with milk are antibiotics, employed to combat mastitis-causing pathogens in the dairy cow. National surveys in developed countries show that between 0.1% and 0.5% of tanker milk samples test positive for antibiotic residues. The occurrence of antibiotic residues in milk may have economic, technological, and even human health implications. In the first place, such residues can lead to partial or complete inhibition of acid production by cheese starter cultures. This can lead to inadequate ripening and maturation of the cheese, resulting in flavor or texture defects and substantial financial loss for the dairy industry. There has also been increasing public concern over the possible links between veterinary drug residues in milk and the transfer of antibiotic resistant organisms to humans as a result of veterinary and zootechnical use of antibiotics in food animals. A third concern raised was that sensitive individuals could exhibit allergic reactions to drug residues or their metabolites, especially in the case of β-lactam antibiotics.

As from 1990, maximum residue limits (MRLs) have been set in Europe for veterinary drugs in foodstuffs of animal origin like milk. Most dairy companies also use rapid tests to monitor all incoming milk for the presence of β-lactam antibiotics. Some of these companies are claiming compensation for the costs of disposing of the milk of a contaminated tanker load from the responsible farmer.

The solution to the problem of drug residues in milk lies in the application of the general principles of 'good farming practice.' These include the following principles:

- Good farm management should in the first place be directed toward the prevention of infectious diseases, such as (sub)clinical mastitis, in order to limit the use of veterinary drugs;
- in the process the farmer must keep his animals in sound physical condition by ensuring hygiene and good housekeeping practices and implementing sound farm management;
- in preventing mastitis, the use of properly functioning milking machines is of primary importance. The use of veterinary drugs, nevertheless, remains necessary, but this option should only be exercised after a correct diagnosis by a veterinarian. Only registered pharmaceutical products with known depletion patterns should be used;
- correctly administering the drugs is also very important in terms of prescribed dose, frequency, and route of administration;
- the keeping of reliable records of such drug use is also essential. It remains the responsibility of the milk producer to respect the prescribed withdrawal period. In the process, the treated animals need to be marked clearly to allow for correct identification (e.g., by taping a hind leg);
- treated cows need to be milked last and during the withholding period, the milk must be discarded in the proper way. The milking equipment should also be cleaned properly after contact with the contaminated milk;
- special care should be taken with the milk of cows that have been treated with long-acting dry cow products or with milk from cows that have been recently purchased; and
- good communication is also important. Everyone on the dairy farm should be informed of any treatment, although the number of people authorized to administer antibiotic

drugs should be limited. If in any doubt, the milk should be tested.

Other Veterinary Drugs

Many human drugs are contraindicated during lactation and a similar problem occurs in dairy animals. The treatment of animals with ectoparasiticides and endoparasiticides can result in residues in milk if the withholding period before returning to milk production is not observed. Endoparasiticides used to control helminths (including tapeworms, roundworms, and flukes) may be administered as feed additives, by injection or cutaneously. The most commonly used compounds in the past were levamisole and the benzimidazoles, but have now been largely supplanted by ivermectin. Studies on the excretion rate of these drugs indicate that a withdrawal time of 5 days is adequate after therapeutic treatment. Cutaneous treatment of animals against ectoparasites includes a wide variety of pesticides that are evaluated as veterinary drugs. In most cases, a 2-day withdrawal period is adequate for assuring that residues are within the safe limits. Consequently, for these types of drugs, the safety of the milk of treated animals depends on their proper use. However, the use of pesticides to control environmental problems, such as insects and rodents, also need to be handled with care to avoid contamination.

A number of hormones are also used in relation to dairy animals, such as oxytocin and prostaglandins. However, one of the more controversial is bovine somatotropin (BST) (sometimes referred to bovine growth hormone) and its genetically engineered counterpart recombinant BST (rBST). Adopted by a contentious vote in 2012, the use of rBST to 'freshen' cows is recommended by the Codex Alimentarius Commission and is approved in the US, but not in the EU because of animal health reasons. However, the milk from rBST-treated cows may be traded without restrictions. This is because both BST and rBST are not hormonally active in humans and if ingested, they are rapidly digested because they are protein hormones.

Cleaning Agents and Sanitizers

Cleaning and sanitizing are essential components of any good manufacturing practice in the food industry, but are particularly important for milk and milk products to remove any bacteria from food contact surfaces. However, it is also important to remove unsafe residues of cleaning agents and sanitizers to avoid contamination. At the farm level, maintaining hygiene of the udder is of critical importance to prevent contamination and various disinfectants have been developed to clean the udder before milking. At the plant level, the use of cleaning-in-place methods requires careful cleaning, sanitizing, draining, and rinsing procedures. Some sanitizers, such as certain iodophores, do not require rinsing and therefore, occur in milk and dairy products at very low concentrations as indirect food additives. The most commonly used sanitizers, including iodophores, chlorhexidine, and hypochlorites, contain iodine or chlorine as the active agents. In addition, hydrogen peroxide and quaternary ammonium compounds are also used.

Generally, only limited information is available on the toxicology of these compounds and their occurrence in food, with the exception of iodine. Iodine levels in milk have been increasing in a number of countries. Milk was found to be an important dietary source of iodine in New Zealand and as the industry moved to quaternary ammonium compounds, the government found it necessary to initiate the fortification of bread with iodine to prevent deficiencies of this micronutrient in their population.

Industrial and Environmental Contaminants

Pesticide Residues

Pesticides include insecticides, herbicides, and fungicides. The most common insecticides in turn include organochlorines, the organophosphates, and carbamates. The organochlorine pesticides enter the food chain as a result of their lipophilic properties, in this way causing a potential health risk for consumers. Milk is considered as one of the more convenient indicators for measuring the extent of persistent residues that have originated in contaminated animal feed. The main route of human exposure to many organochlorine pesticides is through food of animal origin of which milk is the most important product. Typical contaminants of milk are persistent fat soluble organochlorine pesticides such as hexachlorobenzene, dichlorodiphenyltrichloroethane (DDT), and to a lesser extent the cyclodiene compounds. However, most of these pesticides have been withdrawn from use, but remain as environmental contaminants as they are quite stable in soil. If the cow is grazing in contaminated pastures, the intake of soil with these pesticides can occur.

Organophosphate and carbamate pesticides are the most widely used insecticides today, but degrade rapidly in the environment and are further metabolized by animals. Codex routinely establishes MRLs for these and other pesticides on animal fodders as the result of their use on crops. In some cases, MRLs are also established for residues in milk and in other animal products, such as eggs.

Dioxins and Polychlorinated Biphenyls (PCBs)

The term 'dioxins' covers a group of 75 polychlorinated dibenzo-*p*-dioxin and 135 polychlorinated dibenzofuran congeners of which 17 are of toxicological concern. The most toxic congener is 2,3,7,8 tetrachloro dibenzo-*p*-dioxin which is a known human carcinogen, but also possesses other toxic properties. No adverse effects of dioxins were considered to occur in humans at levels below a certain threshold, but this is being challenged by epidemiology studies showing effects at low doses. The maximum level set in EU regulations for dioxins in milk and milk products, including butter fat, is 3 pg World Health Organization toxic equivalents (WHO-TEQ) per g fat.

The PCBs in turn are a group of 209 congeners which can be divided into two groups according to their toxicological properties. Twelve congeners exhibit toxicological properties similar to dioxins and are therefore termed 'dioxin-like PCBs.' The other PCBs have a different toxicological profile.

Dioxins and PCBs are extremely resistant to chemical and biological degradation and therefore persist in the environment and accumulate in the feed and food chain. Dioxins and PCBs arise during the production of chloroorganics and in emissions of industrial by-products and municipal incineration and other pyrolysis processes. Contamination of animal

feed occurs via particle-bound distribution on grass and other fodder plants. The accumulation of dioxins in animals is mainly from these contaminated feeding stuffs. Human foods of animal origin in turn contribute to approximately 80% of the overall human exposure to dioxins.

For these reasons feeding stuffs and in some cases soil, raise concern as potential sources of dioxins. Like the organochlorine pesticides, the dioxins and PCBs are fat soluble. Case studies that have involved these contaminants include the Belgian PCB/dioxin incident in 1999. Feedstuffs produced from a contaminated source were sent to 2500 farms and nearly every category of agrifood (pork, milk, chicken, and eggs) was affected.

Based on 13 797 food samples taken between 1995 and 2010, the European Food Safety Agency has estimated that the percentage of individuals exposed to dioxin and dioxin-like PCBs above the tolerable weekly intake of 14 pg WHO-TEQ per kg bodyweight was between 1.0% and 52.9%. The major contributor to total exposure was the food category of milk and dairy products for almost all groups of infants and toddlers, whereas for most of the groups of adolescents, adults, elderly, and very elderly, fish and shellfish were first, followed by milk and dairy products. For the total dioxins and dioxin-like PCBS, the upper bound estimate for 1422 samples of milk and milk products was 1.92 pg WHO-TEQ kg^{-1}. The corresponding EU maximum limit for milk and dairy products is 5.5 pg WHO-TEQ kg^{-1}. Of all samples, 0.5% exceeded this limit by a small margin. As the EU has implemented source directed measures, however, the exposure levels have been falling for many years.

Heavy Metals

The term heavy metals is a general term that applies to a group of metals and metalloids, including elements such as cadmium (Cd), chromium (Cr), nickel (Ni), copper (Cu), zinc (Zn), mercury (Hg), and lead (Pb). This sometimes includes arsenic (As) because of its toxicity.

The widespread distribution, contamination and multiple effects of heavy metals in the environment has become a global problem. Pb is one of the most common heavy metal pollutants and tolerable levels have fallen as the adverse effects of Pb, especially on the development of cognitive brain function in children, have been recognized. Pb is readily transmitted to milk as it is associated with calcium metabolism. However, in a 1999 study, the highest metal concentrations in dairy cattle feeds were for Zn and Cu. Mineral supplements contained higher concentrations of Ni, Pb, Cd, As, and Cr than did other feed components.

Allergens

Cow's milk allergy or hypersensitivity is commonly encountered with a prevalence of 2–3% in infants and 0.5–3% in adults, but this varies among different populations. This allergy in infants and children is in most cases a transient condition lasting from several months to a few years, after which tolerance is inclined to develop. The dietary management of this ailment includes strict avoidance of the allergenic proteins.

Detailed information on the allergenic epitopes of the major bovine milk proteins, namely α-s1-casein, β-lactoglobulin and α-lactalbumin, indicates that in individual patients, several proteins and per protein, several epitopes (allergenic segments or polypeptides), are often involved. Furthermore, multiple combinations of allergenic proteins and epitopes may occur. Allergenic epitopes are located in specific regions of the proteins, both on the hydrophilic surface as well as in hydrophobic regions, which become exposed on denaturation and/or digestion.

Because present knowledge of the exact mechanisms of sensitization and tolerance induction is still far from complete, it cannot be excluded that specifically fractionated and/or modified cow/s milk proteins, in combination with other bioactive components, will in future be useful in preventing sensitization and/or inducing tolerance.

Other Potential Chemical Hazards

The addition of water to milk is probably one of the oldest forms of economic adulteration of food. However, other materials, such as chalk, were often added to mask this fraud. The most recent variation of this practice was the addition of melamine to milk in China. This was done to avoid detection by the standard analysis of crude protein in milk, sometimes called total protein, which is used to monitor and control milk quality in the dairy industry. The Kjeldahl analysis measures the total nitrogen content of milk, which is then simply multiplied by 6.38 to express the result on a protein equivalent basis. Melamine is chemical substance rich in nitrogen, inexpensive and widely available as it is used in the manufacture of many laminates, plastics, coatings, glues, and kitchenware. In 2008, infant formula made with melamine-adulterated milk resulted in illness in a reported 300 000 infants, including over 50 000 hospitalizations and 6 deaths. A range of other products including, liquid milk, ice cream, and yoghurt were also contaminated. Because melamine can be present in milk and other products as a result of legitimate uses, the Codex Alimentarius Commission has recommended MLs to accommodate these uses at 1 mg kg^{-1} in infant formula and 2.5 mg kg^{-1} in other foods and animal feed.

Other contaminants that may be found in milk and milk products include radioactive isotopes whose sources are both anthropogenic and nonanthropogenic. For instance, background radiation in milk may vary from 40 Bq l^{-1} for potassium-40 to below 0.1 Bq l^{-1} for cesium-137. Radioactivity of food may increase following certain human activities such as weapons testing and nuclear accidents. The latter presents the greatest source of contamination as demonstrated by the Chernobyl accident in 1986 and the Fukushima disaster in 2011. Codex has developed derived intervention levels for milk and other foods for various radionuclides following such accidental releases.

Milk and dairy products may contain a range of other chemicals, usually at very low levels. In recent years, contaminants resulting from food processing and food contact materials have raised some concerns. In relation to infant formula, advanced glycation endproducts and 3-monochloropropandiol esters are being examined. Acrylamide may be a concern depending on what other ingredients, such as

chocolate, are added. In regard to food contact materials, bisphenol A, an endocrine disrupter, has been banned from baby bottles because of possible migration to milk and infant formula. Certain components of inks have been banned because printed cartons have contaminated milk. Cheese can be a source of biogenic amines, notably hisamine and tyramine, both of which cause intense, but transient intoxications. Furans have also been found in milk and dairy products, but at levels that pose little risk to the consumer. In this regard, the application of risk assessment to low-level contaminants in milk and dairy products is the best means to ensure that priorities for risk management are evidence-based.

Possible Procedures to Minimize the Risks of Feed and Milk Contamination

The production, processing, storage, transport and distribution of safe, suitable feed and feed ingredients is the responsibility of all participants in the food chain. These participants include farmers, feed ingredient manufacturers, feed compounders, transport contractors, etc. Each participant is responsible for all the activities under their direct control, including compliance with applicable statutory requirements. The Dutch Animal feed sector has opted for a quality assurance system based on the HACCP approach applied by the European food industry. This emphasizes that quality control in the animal feed industry and by preceding ingredient suppliers, which are integral role-players in the food chain, is essential.

Production of Feed and Feed Ingredients on the Farm

Adherence to good agricultural practices (GAP) is encouraged in the production of natural, improved and cultivated pastures, and forage and cereal grain crops used as feed or feed ingredients for food producing animals. Following GAP prescriptions will minimize the risk of biological, chemical, and physical contaminants from entering the food chain.

Crop residuals and stubble used for grazing after harvest should also be considered as livestock feed. The same applies to livestock bedding because most livestock will consume a portion of their bedding. Straw or wood shavings should therefore be managed in the same manner as animal feed ingredients. Rational grazing and dispersion of manure droppings should be applied to reduce cross contamination between animals.

Other factors should also be taken into consideration such as the proximity of the agricultural land to industrial operations where effluent or air emissions can lead to feed contamination. Similarly chemical fertilizers, manure, pesticides, and other agricultural chemicals should be stored, managed, and disposed of correctly.

Monitoring and Identification of Health Hazards

When purchasing feed ingredients from suppliers, such suppliers should be able to demonstrably guarantee product safety. Audit procedures can include inspection, sampling, and analysis for undesirable substances. Feed ingredients should meet acceptable and, if applicable, statutory standards for levels of pathogens, mycotoxins, pesticides, and other undesirable substances that may constitute a health hazard for the consumer. Any contaminated feed or feed ingredient is unsuitable for animal feed and should be discarded. Traceability of feed and feed ingredients, including additives, should be enabled by proper labeling and record keeping at all stages of production and distribution.

Processing, Storage, and Distribution of Feeds and Feed Ingredients

The effective implementation of GMPs and where applicable HACCP-based approaches should ensure that the following areas are addressed.

Premises

Buildings and equipment must be constructed to permit ease of operation, maintenance, and cleaning. Water should be of a suitable quality and effluent should be adequately disposed off.

Receiving, Storage, and Transportation

Feed and feed ingredients should be stored separately from fertilizers, pesticides, and other potential toxic materials. Processed material should also be stored separately from unprocessed ingredients. The presence of undesirable substances should be monitored for and controlled. The finished products should be delivered and used as quickly as possible. During storage special precautions should be taken to restrict microbial growth in feedstuffs and ingredients.

Personnel Training

Personnel should be adequately trained and aware of their role and responsibilities in protecting food safety.

Physical Hazards

Physical hazards, like microbiological and chemical hazards, can enter a food product at any stage in its production. There is a huge variety of physical items that can enter food as foreign material and most of these hazards pose risks of injury or choking. The main physical food safety hazards include items such as glass, metal (including metal particles resulting from friction between metal parts), stones, wood, plastic, dust, and hair. The main risk area for physical contamination of milk at the farm level is the stored milk in the bulk tank. Producers should, therefore, assess potential physical hazard risks in storage areas (e.g., breakable glass, loose material, etc.). Corrective action to be taken in the area housing the bulk milk storage tank is, for example, to use shatterproof light-covers to prevent glass contamination from taking place.

During the processing of milk, it is invariably subjected to procedures that will remove any physical contaminant. Examples of such procedures may include filtration, although centrifugal clarifiers are standard equipment in any commercial

milk processing operation. Glass fragments caused by glass bottle breakage may result in serious injury, and such breakage can be caused in a number of ways, including damage to the bottles in transit to the processing plant, or damage to bottles during mechanized handling (cleaning, filling, or capping) of the bottles. Similar to food beverages such as fruit juice, consideration of potential hazards associated with glass breakage should be part of a HACCP plan in any processing plant that may be packaging liquid milk products in glass. The most efficient control procedure is a glass-free policy in the plant and replacing glass bottles with other types of packaging.

If glass jars or bottles are preferred, on-line glass detection equipment such as X-ray detection, as a verification measure, may be used. Metal fractions may derive from equipment or from friction between metallic surfaces. Prevention consists of hygienic engineering of equipment and preventive maintenance. Additionally, sieving of milk powder or use of magnets can be used to remove any incidental presence of metal. Metal detectors can be also be used as a last resort, as a means of verification.

Dairy Products: Cheese

M Mühlemann, Agroscope Liebefeld-Posieux Research Station ALP-Haras, Bern, Switzerland

Glossary

Cheese The product of casein coagulation in the milk followed by separation and removal of the whey from the curd.

Cheese made from pasteurized milk High temperature/short-time pasteurization: heat treatments of milk at 71.7 °C for at least 15 s or any equivalent combination; low temperature/long-time pasteurization: heat treatments of milk at 62–65 °C for 30–32 min, followed by cheese making.

Cheese made from thermized milk Cheese made from milk that has undergone a lower heat treatment than that of pasteurization – i.e., at >40 to <72 °C (typically 57–68 °C) for at least 15 s.

Cheese made from unpasteurized milk It may either be cheese made from raw milk or cheese made from thermized milk.

Hard cheese Cheese with 47–55% moisture content on a fat-free bases (MFFB).

Raw milk cheese Cheese made from milk that has not been heated beyond 40 °C.

Semihard cheese Cheese with 55–62% MFFB.

Semisoft cheese Cheese with 62–68% MFFB.

Soft cheese Cheese with more than 61% MFFB.

YOPI Vulnerable people, referred to as young, old, pregnant, and immunocompromised.

Introduction

In many parts of the world, the milking of dairy herd animals and cheese production has a long history. Before the 1980s, cows' milk cheese had caused several well-documented outbreaks (from hundreds to thousands of cases) due to different pathogenic microorganisms – mainly *Salmonella* spp. and *Listeria monocytoge*nes – in different countries (Tables 1 and 2). With the growing awareness of microbiological food safety problems from 1980s onwards, corrective actions have been taken, adequate control schemes adopted, and quality assurance and well-managed food safety systems implemented. In industrialized countries, these actions caused a shift toward outbreaks with lower numbers of cases due to cows' milk cheeses from industrial production. Nevertheless, outbreaks occur; however, nowadays they often cause fewer cases and either involve fresh, soft, or semisoft cheese or ewes' or goats' milk cheese. Furthermore, small-scale artisanal cheese production on farms, in mountain regions, or at home pose a higher risk of microbiological contamination. In outbreaks, pasteurized cheeses also are involved. Globally, the most frequently occurring pathogens in cheese are *Staphylococcus aureus* and its enterotoxins, *Salmonella* spp., *L. monocytogenes*, verotoxin-producing *Escherichia coli* (VTEC), and *Campylobacter* spp. VTEC and *L. monocytogenes* are the main vectors of severe illnesses and deaths. Raw milk cheeses have a long tradition in Europe (e.g., France, Italy, Spain, and Switzerland), and other countries (e.g., New Zealand) are allowing its production.

Numerous preconditions to food hygiene, food safety systems, and controls are essential for the production of adequately safe raw milk cheese. As an example, the correct manufacturing process of traditional Swiss raw milk cheeses encompasses several steps: (1) Raw milk may not contain more than 80 000 germs per ml, more than 350 000 somatic cells per ml, and may not contain inhibitors. These requirements are officially controlled 24 times per year and farm. (2) The processing of milk takes place within a maximum of 18 h after milking. (3) The continual heating period of the cheese curd at 53–60 °C lasts 30–60 min and is followed by several hours at temperatures above 50 °C under the press. (4) The acidification of the cheese mass by adding mesophilic or thermophilic starter cultures reduces the pH in the cheese mass to less than 5.3 within one day. (5) During ripening and maturation, the cheese is regularly salted. (6) The cheese is ripened for at least 60 days (up to several years). This leads to a significant loss of water (reduced water activity (a_w)).

The method developed to evaluate food safety is the risk analysis framework, with the scientific risk assessment being central to this process. For microbiological contaminations, a detailed description of this process is given in other articles of this encyclopedia and elsewhere. In brief, risk-based food safety covers the complete food chain. In chronological order, it involves raw materials at the farm level, the processes they undergo in production, transportation and storage of the finished products in retailer locations, transportation and storage in the homes of consumers, and, finally, the expiration date, the end of shelf life or the preparation and ingestion by

consumers. The general problem with microbiological hazards is that they often are present in the environment and are capable of multiplying in food production facilities as well as in foods and on food surfaces (like cheese rind). This means that slightly re- or cross-contaminated food (e.g., soft cheese) may develop considerable numbers of pathogenic microorganisms and its toxins until the time of consumption. However, food producers must guarantee the safety of their products during the entire shelf life. For this reason, food producers require substantial reductions of pathogenic bacteria in raw milk. Raw milk cheese production strongly relies on minimal microbiological contamination in the initial milk as well as the prevention of growth. Hurdles along the production and aging of cheese further minimize growth. Outbreaks related to cheeses made from unpasteurized milk can often be related to animals shedding pathogenic bacteria and inadequate temperature profiles during the storage of milk and the processing and ripening of cheeses. However, industrial production often applies a process step for eliminating present pathogenic microorganisms (i.e., pasteurization) and then avoids recontamination of the products. Outbreaks related to fresh, soft, or semisoft cheeses made from pasteurized milk can usually be linked to failure in pasteurization and inadequate postpasteurization hygiene resulting in recontamination.

Concerning chemical contaminants in milk and milk products, residues of medical, hormonal, or antibiotic treatments in animals and humans pose some problems and are, therefore, strictly controlled. Pesticide residues in feeds, as well as environmental contaminants such as dioxins, polychlorinated

biphenyls (PCBs) or polycyclic aromatic hydrocarbons (PAHs), and toxic metals, for example, cadmium or lead, can be found in milk and milk products. Naturally occurring plant toxins or mycotoxins from molds, especially aflatoxins, lead to problems in (dairy) herds; in addition, some carryover into milk takes place. For that reason, these contaminants must be controlled. The Chinese melamine scandal once again highlights the importance of controlling milk adulteration all over the world.

In-depth information on chemical risk assessment again is given in other articles of this encyclopedia and elsewhere. In brief, undesired substances in foods may enter the feed and food chain via numerous routes: Air, soil, and water may contaminate food and feed on the field; plants may form toxins; pesticides are applied for plant or crop protection, molds grow on plants and crops; farming animals are treated with medicines including antimicrobial agents; additives may be used in the production and storage of foods; and contaminants are formed in heat-treating processes during food production and food preparation. Of special importance to feed and food risk assessment are: (1) data in mammals on absorption, distribution, metabolism, and excretion of a chemical providing insight into its metabolic behavior and the kinetics of excretion; (2) data on acute and long-term toxic effects in animals; (3) the toxicological mechanism of action; (4) *in vivo* and *in vitro* testing of carcinogenicity, genotoxicity, neurotoxicity, reproductive, and developmental toxicity; (5) the intake of a chemical through food and feed; and (6) access to data from human epidemiological studies. This combined information usually allows for conclusions on the safety of ingested amounts of chemicals, toxins, and plant-inherent substances.

Microbial Contamination of Cheese

The risk of pathogens in cheese has been assessed in the three categories of high, medium, and low risk. The high-risk group is composed of *Salmonella* spp., *L. monocytogenes*, and enteropathogenic *E. coli*. *Salmonella* spp., widely spread in the environment, presents some species with low-infectious doses and heat resistance. Furthermore, *L. monocytogenes* grows at low temperatures, survives in some hard cheeses (e.g., Cheddar, Colby, and Swiss semihard cheeses) and multiplies in fresh and soft cheeses. Enterohemorrhagic *E. coli* (EHECs) are very virulent and may have low-infectious doses. The medium-risk group includes mastitis-causing agents like *Streptococcus* Groups A and C, *Brucella abortus*, *Mycobacterium bovis*, and *Coxiella burnetii*. The latter three are relatively heat tolerant; however, they are eliminated by pasteurization. The low-risk group is dominated by some viruses: *Clostridium perfringens* and *Bacillus cereus*, both with no or few outbreaks associated to cheese, and *S. aureus* and *Clostridium botulinum*, both well-known, and with effective control measures. Nevertheless, *S. aureus* and its toxins are often found in raw and recontaminated pasteurized milk cheese.

In Europe and the USA, milk and milk products were implicated in 2–6% of total bacterial foodborne outbreaks. In 2011, Batz *et al*. estimated the health impact in monetary cost of illness and loss of quality-adjusted life years in the USA for the food category dairy products at 8.7% and 8.8%, respectively. Hereby, 8.7% is the proportion of the total cost of all the estimated foodborne-related illness in the USA due to milk and milk products and the 8.8% is the proportion of the total loss of quality-adjusted life years from the total of foodborne diseases in the USA attributed to milk and milk products. Concerning proportions attributable to single pathogenic microorganisms coming from milk and milk products, De Buyser *et al.* found for France (from 1988–97) 24.9%, 1.8%, and 1.1% for *S. aureus*, *Salmonella*, and *C. perfringens*, respectively. Cheese, mainly fresh and soft cheese, was the responsible food vehicle, and milk accounted for another 10% of cases. However, Batz *et al.* found *Campylobacter* spp., *L. monocytogenes*, *E. coli* non-O157, and *E. coli* O157 responsible for 48.8%, 28.6%, 20%, and 6.5% of outbreaks attributable to milk products, respectively. The Centers for Disease Control and Prevention (USA) found severely higher rates of raw milk product-related outbreaks and that these led to much more severe illnesses and disproportionately affected people under the age of 20 in the USA. **Table 3** lists some cheeseborne disease outbreaks due to microbiological agents that are nowadays rarely found in cows' milk cheese. The responsible food vehicles now often are (raw) goats' and sheep's milk cheeses in Asia, Europe, and the USA. *Brucella* spp. and *Brucella melitensis* in cheese produced outbreaks in different countries well dispersed globally. The food vehicles were goats' or sheep's milk cheeses. The German outbreak was related to overseas infection by travelers. In Italy, five members of a family fell ill after consumption of sheep's milk cheese imported from a region with endemic *B. melitensis* presence. Neither outbreak resulted in fatalities. In the USA, the illegal importation of Mexican-style soft cheese was the cause of outbreaks due to *B. melitensis* as well as *M. bovis*, responsible for 35 human tuberculosis cases with one fatality.

Before the widespread use of pasteurization in the 1930s, the abovementioned (and other) agents were responsible for many disease outbreaks in humans and unpasteurized milk and milk products constituted an important vehicle for disease agents. In Austria, a tickborne encephalitis (TBE) virus caused an outbreak involving four patients and two asymptomatic persons. A shepherd in a mountain region produced homemade goats' and cows' raw milk cheese and fell ill. Three other family members, who had not been on the pasture, also exhibited flu-like symptoms and headaches. In recent years, TBE infections from dairy products were reported almost exclusively in Baltic countries.

The Most Threatening Pathogenic Bacteria in Cheese

Salmonella spp.

Salmonella spp., viruses, bacterial toxins, and *Campylobacter* spp. are the most relevant causes of foodborne disease outbreaks in Europe. Concerning *Salmonella* spp. in cheese, European Food Safety Authority (EFSA) data show that the vast majority of investigations were negative. Some positive samples of cows' and sheep's milk cheeses were reported; however, salmonellosis is mainly due to positive samples of other foods of animal origin. Moreover, salmonellosis, besides having a bimodal distribution within immunocompromised and elderly people

Note: ?, Not specified.

on one hand, and infants and young children on the other hand, develops relatively mildly and rarely results in fatalities. Growth of *Salmonella* spp. is not observed in hard cheeses with $a_w < 0.95$. However, some *Salmonella* spp. are able to survive the fermentation of milk by lactobacilli and the maturation process of soft and other cheeses.

Canada also has had several reports of cheese-associated outbreaks of *Salmonella* serotypes (Table 1), where unpasteurized Cheddar or recontaminations by raw milk during processing were the vehicles of contamination. In 1982, the outbreak source was a single cow shedding 200 cfu ml^{-1} of milk. In some cheese lots, the pathogen survived under the press; in two lots, it survived the curing of the cheese for some days or weeks, and one lot tested positive after 125 days of maturation. In 1984, the largest-known outbreak caused between 1700 confirmed and 2700 estimated cases. The food vehicle again was Cheddar produced on a plant, where *Salmonella* spp. have sporadically been detected before the outbreak. The same *Salmonella* strain (*Salmonella typhimurium* phage type 10) was isolated from a cow's quarter, the cheese, a cheese trim bucket, and from infected employees. The source of salmonellae was two cows infected with different strains, and the workers might have served as reservoirs for recontamination of the produced cheese. Low numbers of *S. typhimurium* cells (1–6) and *Salmonella heidelberg* cells (100–500) in this outbreak led to many illnesses but no fatalities.

Campylobacter *spp.*

Campylobacter spp. was found mainly in sheep, and only occasionally in cows' milk cheeses throughout Europe. Again, human campylobacteriosis due to the consumption of cows' milk cheese seems extremely rare when compared to the number of positive samples of poultry and turkey meat or raw milk. Nevertheless, outbreaks of campylobacteriosis have been reported from many countries. *Campylobacter jejuni* is found in 1–12% of raw milk samples, where it rapidly decreases. At pH 5 it subsequently dies. In the USA, outbreaks before 1982 implicated raw milk consumption in 61%, and the outbreaks often involved high numbers of affected consumers. Three cheese-borne outbreaks were reported from 2004–10 related to soft cheese made from unpasteurized milk and to Mexican-style soft cheese illegally imported; together, they caused 79 illness cases without fatalities (Table 4). Batz *et al.* described the most important pathogen–food combination, with *Campylobacter* spp. in poultry occupying the first rank in the top-10 combinations with the greatest burden on public health. From 1998–2008, *Campylobacter* spp. as the causative agent of outbreaks involving dairy products was attributed to 48.8% of cases.

USA/Nevada	2010	1	Mexican-style soft cheese	MAF, 2011/58

S. aureus

In France, *S. aureus* was by far the pathogen most frequently associated with illness outbreaks from milk and milk

products, causing 1439 illnesses from 1992 to 1997. The source of the pathogen is usually the udder, where the prevalence in quarter milk samples ranges from 5% to 22%. Animals with mastitis (infection of the mammary gland) may shed from 10^4 (subclinical) to 10^8 (clinical) cfu per ml milk. Other sources are the udder skin, employees, and contaminated starter cultures used in cheese making. Thirty percent and more of the *Staphylococcus* spp. may produce enterotoxins. These enterotoxins are heat stable (and thus withstand heat treatment processes) and may cause intoxications without viable *S. aureus* left in the cheese. Known *S. aureus* populations exceeding 100 000 cfu g^{-1}, mainly with the genes encoding for type A, D, and B, may start the production of sufficient amounts of enterotoxins to cause illness. The onset of symptoms is acute; however, fortunately, recovery takes place within a few hours or days. Death is very rare but may occur among the elderly, infants, and severely debilitated persons.

Whereas sheep suffer peracute mastitis, which almost always leads to the death of the animals, in dairy cattle, *S. aureus* often causes chronic subclinical mastitis or acute symptoms accompanied by fever, resulting in substantial financial losses. Genotype B, in particular, was related to high contagiosity and pathogenicity affecting whole herds, whereas genotype C resulted in 1–3 affected animals per herd, and other genotypes only caused infection of single cows. Enterotoxigenic strains are commonly found in raw milk intended for cheese manufacture in Norway, the USA, Germany, Japan, and Switzerland. In Switzerland, 95% of *S. aureus* strains associated with bovine mastitis were positive for at least one enterotoxin gene. Cooling of the milk before cheese making and correct acidification by starter cultures normally overgrow the less competitive *S. aureus* strains. The safety of raw and pasteurized milk products depends on the prevention of recontamination by employees. Both modes of transmission are exemplified by two outbreaks in Brazil, in 1999, involving 378 individuals (Table 5). In the first outbreak, 50 individuals became ill after eating Minas cheese, a typical fresh white cheese in South America. Illness symptoms (diarrhea, vomiting, dizziness, chills, and headaches) appeared within 2 h after ingestion. The second outbreak affected 328 individuals after consuming raw milk. The analysis of the products in the first outbreak showed the presence of *Staphylococcus* and the enterotoxins A, B, and C, whereas the raw milk in the second outbreak contained coagulase-negative Staphylococci exceeding 2×10^8 cfu g^{-1} and the enterotoxins C and D. Sources of contamination were the food handlers in the first and cattle mastitis in the second outbreak. Infected food handlers as sources of contamination of different pathogens were identified in 57% of outbreaks involving pasteurized dairy products in the USA from 1993 to 2006.

L. monocytogenes

Worldwide, healthy farming animals like goats, sheep, and cows shed *L. monocytogenes* at 2–50%. In addition, humans with *L. monocytogenes* in their feces may be asymptomatic; the microorganisms are simply shed through the intestinal tract. Nevertheless, the ingestion of foods exceeding 1000 cfu g^{-1} may lead to fever and diarrhea and is thought to be responsible for 90% of all listeriosis cases. Young, old, pregnant and immunocompromised (YOPI) are at particular risk of invasive listeriosis and perinatals, and may present severe illnesses and high mortality including abortion, death of newborns and handicapped newborns. This maintains *L. monocytogenes* among the most important causes of deaths from foodborne infections in industrialized countries. In Central and South America, as well as Asia, *L. monocytogenes* is related to fresh and soft cheeses with high moisture content, often including home- or farm-made raw milk cheeses (e.g., Minas Frescal and Mexican-style cheese). Other cheeses often implicated in listeriosis outbreaks are red smear and mold-ripened cheeses. Therefore, *L. monocytogenes* poses a serious problem to cheese producers in many continents, and the *Listeria*–dairy products combination ranks at fifth place in the top-10 combinations with the greatest burden on public health. It should be noted that this ranking is the only one dominantly involving milk products. In the European Union (EU), the highest percentage was reported for soft and semisoft cheese (2.8%) made from raw or low heat-treated milk as well as from pasteurized milk. *Listeria monocytogenes* rarely reached levels >100 cfu g^{-1}. Between 2004 and 2009, the EU's Rapid Alert System for Food and Feedstuff documented a total of 97 *Listeria*-positive milk products – 34 of them concerned pasteurized and 22 raw milk products.

Table 2 lists some outbreaks in America, Asia, and Europe. Probably the two best-documented outbreaks of listeriosis share several similarities. In 1985, there was an epidemic outbreak of listeriosis in Los Angeles County, USA. During the following 12 months, listeriosis cases were sporadic. From 1983 to 1987, an epidemic outbreak of listeriosis was also

observed in the Canton de Vaud, Switzerland. Starting in this time period, the Swiss authorities maintained a monitoring program. In consequence, there exist two pairs of epidemic outbreaks followed by sporadic outbreak cases, a coincidence essential for the quality of the observed data during the sporadic outbreaks. Both outbreaks were caused by soft cheeses: Jalisco, a Mexican-style soft cheese in Los Angeles County and Vacherin Mont d'Or, a traditional, smear-ripened soft cheese in the Canton de Vaud. Moreover, both outbreaks caused more than 120 cases and more than 30 deaths each. In the case of Jalisco, the industrial pasteurization process was inadequate and responsible for the *L. monocytogenes* contamination. Closing down the concerned production plant stopped the epidemic listeriosis outbreak. In the case of Vacherin Mont d'Or, the artisanal production process involved several traditional proceedings, maintaining opportunities for *L. monocytogenes* contamination (i.e., the use of wooden hoops, brushes to treat the rind, and wooden shelves in ripening cellars). Thermization of the cheese milk accompanied by a systematic controlling program was successful to eliminate *L. monocytogenes*, and Vacherin Mont d'Or was, subsequently, relaunched. Although *L. monocytogenes* was demonstrated to survive in some hard cheeses like Cheddar and Colby, the DHHS/FDA/CFSAN Draft Assessment of the Relative Risk to Public Health from Foodborne *L. monocytogenes* (2001) derived a safe pattern for the consumption of hard cheese: 3.2×10^{-13}–2.9×10^{-10} illness cases were estimated per portion of hard cheese consumed. Concerning listeriosis, this made long-ripened cheese the second safest out of 20 analyzed ready-to-eat food groups. Another assessment calculated the listeriosis risk of YOPI from 7.39×10^{-12}–1.85×10^{-8} illness cases per consumed food portion. The calculation was performed with up to 3160 cfu *L. monocytogenes* in the consumed food, thus including elevated contamination in foods others than hard cheese.

EHEC and Illness

Escherichia coli, a member of the Enterobacteriaceae family, occurs naturally in the intestine flora of humans, mammals, and birds. A subgroup of the verotoxigenic *E. coli* (VTEC or Shiga toxin-producing *E. coli* (STEC)) with more than 400 serotypes constitutes the EHEC, which may cause serious illnesses. The EHEC prototype *E. coli* O157:H7 is most frequently implicated in group illnesses and the development of the hemolytic-uremic syndrome (HUS). As few as 10–100 microorganisms may cause infection. The annual incidence of STEC illnesses in Europe is approximately 0.7 cases per 100 000 inhabitants. EHEC O157:H7 survives cold storage of foods and freezing. Some strains reproduce at temperatures up to 49 °C. Adaption to lactic acid as well as an enhanced ability to survive in the presence of other acids has been observed. Specific survival capability under extreme conditions in pathogenic and nonpathogenic strains of *E. coli* with extensive variability is inherent in individual strains. These properties make EHECs a real new emerging threat to raw milk cheese producers, not only for farm- and home-made cheese varieties but also for the manufacture of hard cheese, because EHEC O157:H7 was reported to survive in, for example, Cheddar cheese (Table 6).

Cattles are recognized as the main natural reservoir of VTEC, in particular, VTEC O157. Worldwide, the feces of milk cows show prevalences of 0.2–49% and 0.4–74% for VTEC O157 and non-O157, respectively. The huge differences are due to the measuring of the prevalence of virulence genes with significantly higher figures than the prevalence of cultivable isolates (that is, typically, 0–2%). Thus, milk contamination mainly takes place by the fecal route. The relative importance of dairy products as transmission vehicle associated with VTEC O157 and non-O157 outbreaks were 12.5% and 10%, respectively. Dairy-related outbreaks were caused by raw milk cheeses and raw milk, such as the major outbreak with 135 cases in the USA in 2007 at a correctional facility with an onsite dairy (Table 6). Ten inmates presented STEC O111 infection, and a retrospective prevalence study revealed the same infection in 14 out of 100 other inmates. The human STEC O111 isolates matched the STEC O111 isolates from cattle at the onsite dairy. It was suspected that employees at the dairy might have acquired STEC O111 infection on the job by animal-to-human transmission or transported fecal contaminated clothing into the main correctional facility and kitchen, thereby exposing other inmates. Raw milk cheese from America, Asia, and Europe harbored STEC isolates in 7.8% (Peru), 2% (Venezuela), 4% (Turkey), and 0.2–2.4% (EU), respectively. Within the EU, the differences in presence range from 0% to13.1% for isolates and 2% to 45% for the *stx* gene.

Table 6 Some past and recent foodborne disease cases due to *Escherichia coli* and enterohemorrhagic *E. coli* (EHEC), respectively, in cows' milk cheese in different countries

Country	Time period	Cases	Type of milk or milk product	Literature

Note: ?, Not specified.

In Switzerland, *E. coli* O157 was isolated in 1.3% of fecal samples taken from healthy beef cattle. From 2006 to 2008, 1502 samples of Swiss raw unpasteurized semihard milk cheese were examined for STECs: 5.7% were polymerase chain reaction (PCR)-positive for STEC, and STEC isolates were extracted out of 29 samples (1.9%). None of the isolates was intimin positive; none belonged to the classic EHECs of serogroups O157, O26, O103, O111, and O145. Nine isolates carried the genes for EHEC-hemolysin, 17 isolates belonged to serotypes that are known to be human STECs; of these, in turn, 6 isolates belonged to serotypes O22:H8, O91:H10, O91:H21, and O174:H21, each of which can trigger HUS. Therefore, raw milk cheese producers must comply with good manufacturing practice, outstanding unpasteurized milk quality, and periodic controls. Swiss and other raw milk hard cheese varieties with elevated cooking temperatures ($>53\ ^{\circ}C$) as well as hard cheeses made from pasteurized milk are regarded as relatively safe and safe, respectively.

Mycobacterium avium Subspecies *Paratuberculosis* (MAP)

In the past two decades, there has been more evidence that MAP can cause Crohn's disease (CD); however, the direct link is still actively debated. The incidence of CD in Europe is approximately 5.6 cases per 100 000 inhabitants per year. It remains unclear as to whether there is a causal association or a secondary invasion following the onset of CD. A meta-analysis concluded that the association of MAP with CD seems to be specific; however, its role in the etiology of CD is yet to be defined.

MAP is found worldwide in numerous mammals, ruminants, and birds. In cattle, it causes Johne's disease, normally with symptoms like diarrhea, excessive weight loss, and lower milk production. In (bovine) herds, animals at different infection stages may spread and transmit MAP through feces, semen, colostrums, and milk. Many countries in Europe, Asia, and America run control or eradication programs for MAP in herds, where the prevalence may reach 70% (USA). However, the prevalence in single animals is low. As an example, the seroprevalence in Swiss herds was estimated to be between 6% and 8%, and single animal prevalence was estimated at 2% (culture positive). No viable MAP cells could be cultured from 143 raw milk cheeses; however, 4.2% tested positive with a real-time PCR system; evidently, MAP was present in the raw material. Because bovine herds constitute a main reservoir of MAP, it is recommended to significantly reduce the level of MAP in bovine herds, which serve as a main source of contamination of food of animal origin.

Pasteurization reduces MAP in drinking milk; however, survival was observed at time–temperature combinations of 15 s at 90 °C. In cheese, MAP is reduced mainly by the long-ripening time. *D* values are 45.5 and 27.8 days for Swiss hard and semihard cheese, respectively.

Antimicrobial Resistance

Since 2000, antimicrobial resistant *Campylobacter* spp., *Salmonella* spp., and *E. coli* have increasingly been reported in Europe and globally. It has been reported that extended-spectrum β-lactamases-producing Gram-negative bacteria pose a serious threat to public health in human medicine as well as increasingly in the veterinary context worldwide. β-Lactam antibiotics, such as the third generation cephalosporins, are a major drug class for the treatment of serious infections caused by *E. coli*. Concerning *E. coli*, β-lactamase production remains the most important mediator of β-lactam resistance. Extrachromosomal elements of *E. coli* can be laterally transferred to other species, thus contributing to inter- and intraspecies variability in genomic contents. β-Lactamases are bacterial enzymes that hydrolyze β-lactam antibiotics into treatment-ineffective compounds. The transmission of zoonotic multidrug resistant bacteria between food-producing animals and humans is reported, and there is a persistent fear of their transmission via the food chain.

Biogenic Amines

Very long-ripened raw milk cheeses especially may contain high concentrations of biogenic amines – low molecular organic compounds, mainly tyramine and histamine. These are formed by decarboxylation activity due to the proteolysis during the ripening and maturation. Microorganisms with decarboxylase activity may be present either in the native milk flora or, to a greater extent, in the starter cultures. Patients may suffer headache, migraine, hypertension, nausea, or even diarrhea and abdominal pain. The relevance of cheese consumption was ranked at third place for histamine and at second place for tyramine intake among different foods. Aged Swiss cheese, Cheddar, and extraordinarily-aged Gouda have caused reported outbreaks in England, France, and the USA. For the first time in March 2012, a histamine-contaminated Cheddar cheese was withdrawn from the British market. The cheese contained 1227 mg kg^{-1} histamine and caused illnesses in 38 children of a day nursery. Symptoms like red mouths and the break out of skin rashes arose shortly after consumption and disappeared within one day.

Presence of Chemical Residues and Contaminants in Cheese

Undesired substances in foods such as pesticides, their residues and metabolites, environmental contaminants, contaminants in plants and additives may enter the feed and food chain via numerous routes: Air, soil, and water may contaminate food and feed in the field, plants may form toxins, pesticides are applied for plant or crop protection, molds grow on plants and crops, farming animals are treated with medicines (including antimicrobial agents), food additives help in the production and storage of foods and contaminants are formed in heat-treating processes during food production and preparation. Moreover, migration from packaging materials like plastics, papers, and cans into foods may result in contaminations with monomers, catalysts and solvents, biocides, whitening agents, colors, and waxes, as well as can-coating resins. However, the migration of such

chemicals is typically very low, but might be, as seen with bisphenol A (BPA), of scientific and public health concern.

Pesticides

In Europe, Iceland, and Norway, in 2009, the majority of food of animal origin was free of detectable residues (99.7%). In total, 34 different pesticides were found in animal products; most of the pesticides were rather due to environmental contaminations with persistent pesticides that have been banned at EU level than actual uses of pesticides on feed crops. However, no milk or cheese was analyzed. Subsequently, in 2010, only 0.33% of noncompliant samples from food of animal origin including milk were reported.

At the Swiss national level in 2008, none of the milk samples analyzed exceeded any maximum residue level set to pesticide residues and antimicrobial substances. Such a positive outcome may be expected for organophosphate pesticides: because of their hydrophilicity, their presence in milk (and especially in fatty milk products like cheese) is not expected. However, this does not hold true for persistent organic pollutants (POPs), including, dioxins, furans, PCBs, and the organochlorine pesticides lindane, aldrin, and dichlorodiphenyl trichloroethane (DDT) as part of the 'dirty dozen.'

Organochlorine pesticides were used worldwide and intensively until the 1970s. Then, Europe and the USA restricted the application and other nations followed during the decades that followed. Meanwhile, these pesticides were still widely used in Africa, Asia, and Latin America because of their effectiveness in agriculture. Nowadays, especially countries with hot and humid tropical climate depend on these substances in disease vector control programs – for example, against malaria. In such countries, these lipophilic compounds may be found in cows' and buffalos' milk and milk products (like cheese) in amounts exceeding current international limits (i.e., those of the Food and Agricultural Organization of the United Nations (FAO)/World Health Organization (WHO)). Specifically, in African developing countries and countries in transition, DDT was found in milk at concentrations of 3.2–10.1 mg kg^{-1} (fat basis), thus exceeding existing actual international limits in a range of 100- to 1000-fold in the past. Measures of organochlorine pesticides in ultra high temperature milk of South American nations like Brazil and Argentina ranged from under to several-fold existing international limits. However, it has been reported that sterilization of milk (121 °C for 5 and 15 min) results in a certain loss of organochlorine pesticides. However, skimming of the milk was also shown to reduce these contaminants in cheese, milk, the contaminants would have been expected to be present in cheese at concentrations exceeding existing international limits (approximately 10- to 100-fold).

In Egypt, the different organochlorine pesticides were found in milk at concentrations exceeding existing international limits by approximately 10-fold. In the USA, despite the restricted use of DDT since 1972 (no more applications in agriculture, mainly cotton seed), its metabolite dichlorodiphenyldichloroethylene (DDE) almost persists (e.g., in ice cream and chicken), but significantly decreased in beef. In some parts of the world, adverse health effects in children may, at least in the past, have been expected.

Dioxins, Furans, and PCBs

In Europe, dioxins in foods and feeds have been the reason behind several scandals in the international food and feed industry. Dioxins, PCBs, dioxin-like PCBs (DL-PCBs), and nondioxin-like PCBs (nDL-PCBs) are widely present in the environment. Dioxins are aromatic hydrocarbons with polychlorinated dibenzo-*p*-dioxin (PCDD) and polychlorinated dibenzofuran (PCDF) congeners. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) is the most toxic compound and is classified as a known human carcinogen by International Agency for Research on Cancer (IARC). The congeners are unintentionally formed byproducts of some manufactured chemicals and in incineration and combustion processes.

PCBs, in contrast, formerly had been manufactured intentionally, and their properties (nonflammability, stability, and high dielectric constant) allowed applications in electrical equipment, plastic products, and building materials. DL-PCBs exert toxicity similar to dioxins (i.e., immunotoxicity, reproductive effects, teratogenicity, endocrine disruption, and carcinogenicity in humans). Moreover, they accumulate in the fat of living organisms throughout the food chain (biomagnification). Individual toxicity of congeners is assigned relative to the toxicity of 2,3,7,8-TCDD in order to obtain the toxic equivalency (TEQ) of mixtures. Till date, the toxicity of nDL-PCB remains unclear; however, it seems problematic for humans accumulating these substances very effectively when compared to experimental animals. At least 90% of the human exposure to dioxins, DL- PCB, and nDL-PCB comes from food of animal origin, with meat, dairy products, and fish as the main sources. Intake estimations vary from 0.4 to 1.5 pg TEQ (sum of 6 congeners) per kg bodyweight per day, 0.8 to 1.8 pg PCB-TEQ per kg bodyweight per day, and 10 to 45 ng per kg bodyweight per day for dioxins, DL-PCBs, and nDL-PCBs, respectively. For children and other specific subpopulations, no safety margin remains either to the WHO-tolerable daily intake (TDI) for dioxins and DL-PCBs (1–4 pq TEQ per kg bodyweight per day), nor to the tolerable weekly intake (TWI) (14 pq TEQ per kg bodyweight per week). Therefore, subpopulations exceeding these values exist. In Europe, milk and milk products contained between 0.95 and 2.4 pg g^{-1} fat of dioxins and DL-PCBs. Their contribution to the dietary intake was estimated to be 27% and 49% in the Netherlands and Switzerland, respectively. In Switzerland, 47 cheese samples showed a mean value of 0.92 pg g^{-1} WHO-TEQ in 2008, contributing to approximately 6% of the total intake of these substances from cheese consumption. In the USA, from samples taken in 1995–96, the mean intakes of 17 dioxin/furan congeners from butter, cheese, ice cream, and yogurt were estimated to be 0.5–11, 1.6–3.2, 4–19, and 0.8–28 pg per person per day, respectively. Butter samples from 24 countries showed WHO-TEQ for PCDD/PCDF >1 pg g^{-1} fat in China, Italy, and Spain and for PCBs values >2 pg g^{-1} fat in the same countries, as well as in India, Germany, the Netherlands, Czech Republic, and Tunisia. The Stockholm Convention,

aiming at eliminating or reducing POPs, was adopted in 2001 by the EU, the USA, and 90 other countries. The release of POPs since then has considerably diminished. However, certain groups of populations (i.e., children or ethnic groups depending on fish consumption) still ingest foods exceeding the internationally established maximum levels for different foods or their consumption of these toxic compounds exceeds existing international limits. Adverse effects on their health at low doses from milk and milk products are not expected.

Polycyclic Aromatic Hydrocarbons

PAHs, another class of organic compounds, also are formed in incineration and combustion processes and occur in mixtures. Fifteen of them, with benzo[a]pyrene (BaP) as the most toxic reference compound, are genotoxic as well as carcinogenic in animals. In 2008, the median dietary exposure in Europe was calculated both for mean and high dietary consumers, and varied from 3.9 to 6.5 ng per kg bodyweight per day for BaP and 28 to 51.3 ng per kg bodyweight per day for PAH8 (BaP and seven more carcinogenic PAHs). The major foods containing elevated concentrations of PAHs are meat and fish products, particularly grilled, barbecued and smoked products, oils and fats, cereals, and dry foods. High concentrations in soils and plants near areas of heavy transportation and industrialization have been reported. A Swiss study from 2006 evaluated the effects of the direct fuel oil method used to dry roughage fed to dairy cows. The sum of the PAHs in dry feeds amounted to $466 \pm 459\ \mu g\ kg^{-1}$ dry matter with low percentages of carcinogenic PAHs ($8.3 \pm 5.9\%$) and of BaP ($1.5 \pm 1.4\%$). Estimates showed milk and milk products to be responsible for the intake of 9% and 12% of the sum of PAHs and BaP, respectively. Meanwhile, the EU derived a margin of exposure (MOE) approach for BaP and PAHs, resulting in values approximately 10 000 for high level and $<20\,000$ for average consumers, thus MOEs of low concern for consumer health.

Similar results came from Australia. As for POPs, this will not hold true for all countries and all sites. Especially countries with ongoing open incineration and combustion processes (e.g., for plant oil production, land clearing, or energy production) may be confronted with higher intake values through food commodities. Additionally, in developing countries, residential heating and cooking is regarded as an important source of these contaminants. Subgroups of the population are expected either to have intakes passing the internationally established maximum levels for different foods or consumption of these toxic compounds exceeding existing international limits. Adverse effects on their health at doses from milk and milk products cannot be excluded without further studies.

Bisphenol A

The release of chemicals from packaging materials into food may be of human health concern (e.g., as seen with BPA from coating materials or sealants). BPA is suspected to be an endocrine disruptor and potentially carcinogenic in humans. The effects of long-time exposure at low levels are poorly investigated and remain controversial. In particular, canned (infant) food may show mean concentrations of <1–$2.6\ \mu g\ kg^{-1}$ food in Europe, Canada, and the USA, whereas the concentration may pass $15\ \mu g\ kg^{-1}$ food in Asia. In 2010, an FAO/WHO Expert Group estimated the mean exposure of adults and children to BPA at <0.01–0.40 and 0.1–0.5 μg per kg bodyweight per day, respectively. Assessments of WHO and other bodies support neither scientific nor statistical evidence on adverse human health effects, but may follow the precautionary principle and aim to lower or ban BPA release into (toddler and infant) food.

Melamine

In 2008, melamine in infant formula in China, Taiwan, Macau, and Hong Kong caused six deaths, 51 900 hospitalized infants and 294 000 illnesses. Food products containing melamine were exported internationally. In consequence, 68 nations recalled or banned Chinese products. In the USA, products recalled included biscuits, candy, coffee, cookies, milk, and flavored drinks; however, the melamine contamination in these products did not lead to health consequences. In China, melamine was added intentionally to animal feed at concentrations of 1.6–$410\ mg\ kg^{-1}$ and to milk at concentrations up to $6196\ mg\ kg^{-1}$ in infant formula. No action was taken in order to prevent a scandal before the Olympic Games. The maximal dietary exposure was estimated to reach 8.6–23.4 mg per kg bodyweight per day, a figure 40–120 times the TDI of 0.2 mg per kg bodyweight. The special susceptibility of infants is due to their higher concentration of naturally occurring uric acid when compared to adults. The combination of both substances is capable of forming kidney stones. Dairy cows fed melamine contaminated feed excrete approximately 0.5% of the dose into milk. Therefore, Chinese dairy products or products with high milk content contained 0.05–$3\ mg\ kg^{-1}$ melamine. This contamination alone would not have been expected to cause such a spectacular negative health outcome in Asia. Therefore, milk adulteration, especially the dilution with water and masking the lowered protein content with added nitrogen, is a fraud deserving control and combat all over the world.

Toxic Metals

Cadmium accumulates primarily in kidneys and liver and has a biological half-life of several decades. The toxic effect occurs in the kidneys; the TWI is currently set at 2.5 μg per kg bodyweight. Throughout Europe, the consumption of milk and milk products leads to an estimated intake of $0.22\ \mu g\ day^{-1}$ for adults (milk: 0.05–$0.4\ \mu g\ day^{-1}$; cheese: 0–$1.49\ \mu g\ day^{-1}$), contributing for approximately <1–4% and <1–2.3% of the TWI for milk and milk products, respectively. In the USA, cadmium concentrations in milk from uncontaminated areas was between 7 and $37\ \mu g\ kg^{-1}$ (ww) and intake estimates for whole diets ranged from 13 to $79\ \mu g\ day^{-1}$. Milk from foreign foods from contaminated areas was not analyzed. Plants, especially leafy vegetables, root crops, and cereals, incorporate cadmium more easily than they do other toxic metals. Because the intake of cadmium is

mainly via food and children occupy a much higher percentage (65%) of the TWI, the contamination of food with cadmium must be limited. Lead also accumulates in the body. The adverse health effect is on the development of the central nervous system in perinatals, with the consequence of diminished intelligence. A TWI is set at 25 mg per kg bodyweight. The mean contribution from milk and cheese is less than 1% of the provisional TWI. It has been shown that, over recent decades, the lead level in food has decreased significantly owing to source-related efforts to reduce the emission of lead, and improvements in quality assurance of chemical analysis. Lead is present at low concentrations in most foods. Offal and mollusks may contain higher levels. Contamination of food during processing or food production in contaminated areas is the main reason for enhanced lead intake via foodstuffs. Plants usually do not absorb lead. However, elevated contamination may occur if crops are grown at contaminated sites. Inorganic mercury exerts adverse health effects in the kidneys. A TWI is set at 5 mg per kg bodyweight for mercury. The intake through milk seems to be no cause for concern.

Mycotoxin Aflatoxin M_1 (AFM_1)

Industrialized countries have imposed strict regulatory and control actions in order to reduce the presence of mycotoxins in feed and food. However, in developing countries, chronic and even acute human health implications due to mycotoxin problems in food may be severe (e.g., due to tropical climates favoring the growth of mycotoxin-producing fungi). Evidence of acute aflatoxicosis in humans has been reported from many parts of the world (in Africa and Asia). Chronic exposure to various mycotoxins is of public health concern because of the carcinogenic property of mycotoxins such as aflatoxins and ochratoxin A. AFB_1 is a potent, naturally occurring carcinogen with the IARC-classification as a known human carcinogen. Mammal species (including humans) show similar clinical symptoms under acute aflatoxicosis, including vomiting, subcutaneous and pulmonary edema, hepatic injury, and lethargy. The target organ is the liver, but other organs may also show dysfunctions. Subacute doses of AFB_1 are metabolized, and most metabolites are excreted in the bile and urine within 24 h. Remaining metabolites are concentrated in the liver, where they are mainly found as deoxyribonucleic acid (DNA)-adducts. No description of a specific DNA repair mechanism for N^7-guanine–AFB_1-adducts was found in mammals. This fact might help to explain the high mutagenic potential of AFB_1-8,9-epoxide.

Food and feed commodities especially susceptible to AF contamination are cereals, oilseeds, spices, and tree nuts. Major food intake may result from the consumption of maize, peanuts, and figs; major feed contamination usually is due to maize, peanut-, and cottonseed cake. Milk and milk products may contain the AFB_1-metabolite AFM_1 and, therefore, substantially contribute to the aflatoxin intake in toddlers and small children. Data at the EU level show that the incidence of samples exceeding the limit of 0.05 μg AFM_1 per kg milk was 0.06% at the bulk milk level and 1.8% at the individual farm level. The carryover of AFM_1 into milk is usually 1–3%, but may reach up to 6% in high-yielding animals. In contrast, the carryover of other mycotoxins present in feeds, like ochratoxin A, deoxynivalenol, T2-toxin, zearalenone, and fumonisin B1 is approximately 100 times lower. The EFSA recommends monitoring not only AFs in known susceptible feeds and AFM_1 in cows' milk but also the milk of other species and AFM_1 in milk products of those species. The total dietary aflatoxin intake from Africa (Uganda, Swaziland, Kenya, and Mozambique), Asia (the Philippines, Thailand, and China), and South America (Ecuador) in the past showed a range from 3 to 222 ng per kg bodyweight per day and correlated well with the liver cancer incidence. The exposure in the USA is estimated at 2.7 ng per kg bodyweight per day. AFM_1 concentrations in milk were reported to be 0.05–0.37 (Brazil), >0.5 (Cuba), 0.05–0.18 (Greece), 0.1–3.5 (India), and 0–6.6 ng g^{-1} (Thailand). Most samples from the southwest and south of the USA showed AFM_1 levels between 0.05 and 0.5 ng g^{-1} and 8.1% >0.5 ng g^{-1}. AFM_1 in different Turkish cheeses was detected in 48–92% and exceeded established EU limits in 17.1–27.1%. Maximal contamination reached 7.2 ng g^{-1}. Cheeses from Japan and the USA showed maximal levels of 1.2 and 1 ng g^{-1}, respectively. Cheese samples from Egypt showed contamination between 0.05 and 0.5 ng g^{-1}. AFM_1 levels in milk and cheeses produced in tropical countries of Africa, Asia, and South America may exceed actual EU limits 10- to 100-fold and actual limits set in the USA by a factor of 10. In consequence, the systematic control of feedstuffs and milk and milk products for AFB_1 and AFM_1, respectively, would be desirable, but not of first order importance for public health in such countries.

Actual Concernment for POPs and Toxic Metals

New work discusses weight gain effects and diabetes in animal studies after exposure at low concentrations to a variety of chemicals, including, among others, organochlorine pesticides, organophosphates, PCBs, polybrominated diphenyl ethers, chemicals used in plastics such as phthalates and heavy metals such as cadmium and lead. The concern that chemicals in the environment may be partly responsible for the increasing occurrence of obesity in human populations is based on a significant and growing number of mechanistic studies and animal experiments, as well as on some clinical and epidemiological studies. The weight of evidence is compelling, although ethical and logistic factors have so far made it difficult to prove such associations in human studies. In the light of such possible implications of some POPs and trace metals on the human endocrine system, more attention will have to be paid to the research and management of low concentrations of these substances in basic food items such as fish, meat, and milk products.

SAFETY OF FOOD AND BEVERAGES

Cereals and Derived Products

RL Beverly, Kellogg Company, Battle Creek, MI, USA

Glossary

Celiac disease A genetic disorder in which an autoimmune response causes damage to the small intestine when gluten proteins are contained in certain foods.

Cereal bars Processed grains and various edible additives that are assembled together with a sugar-based binding solution and compressed under low pressure.

Cereals or cereal grain Grasses cultivated for the edible components of their fruit seeds: the endosperm, germ, and bran. Cereal grains have been categorized as wheat, maize (corn), oats, rye, rice, barley, millet, and sorghum.

Dough A mixture of flour, milk and/or water, sugar, salt, and other ingredients that produces a batter dry enough to handle rolling, cutting, or sheeting. Baker's yeast is often added to the formulation.

Gluten A 33-amino acid protein that breaks down into smaller peptide units called the gliadins and glutenins.

Mycotoxins Secondary metabolites produced by molds that are capable of causing disease and death in humans and other animals.

Sponge A fairly stiff batter made of flour, sugar, water, and yeast. When mixed together, these ingredients are left to ferment for a set time and temperature, depending on the quantity of yeast used.

Introduction

Cereal grains supply humans and livestock with their primary and most efficient source of calories and nutrients. This is due to nutritional properties of the edible seed which comprises the endocarp, germ, and bran. The term 'cereal grains' includes a reference to wheat, barley, corn (maize), durum, millet, oats, rice, rye, sorghum, and soybeans. Cereal grains vary greatly in their processing and consumption. Rice is the main cereal grain for greater than half the world's population. Barley, rice, and wheat are used in the fermentation process for the production of beer. Most cereals are milled for flour or meal that is used in dough formation for baking breads, cakes, and pastries. Cereal grain products comprise flours, breakfast cereal, snack foods, corn meal, doughs, pasta, and a variety of dry mixes.

Although botanically classified as grasses, humans have cultivated this important energy source for greater than 9000 years serving as the first crop for agriculture. Maize, wheat, and rice account for 87% of all grains produced worldwide and serve as a vital source of calories for a hungry world. Other cereal grains produced in less quantities include barley, sorghum, millet, oats, rice, triticale, fonio, and buckwheat. Although some grains are consumed after cooking, most are dried to enhance the quality and are then further milled to create fractions, used to create flour or meal, for additional products. In more developed countries the harvest, drying, and milling occurs with precision, utilizing machinery and automation. However, in developing countries the process may be rudimentary and susceptible to climatic influences that may adversely impact grain quality and safety.

The growth of various spoilage microorganisms on cereal grains and the finished product held at improper temperatures can occur. Nevertheless, microbial growth can be controlled if good manufacturing practices (GMPs) are followed.

Effects of Processing and Storage

Nearly all cereal grains are allowed to dry in the field. Properly dried to below 14% moisture and stored, cereal grains are intrinsically resistant to spoilage due to their low water activity (a_w). In developing parts of the world the sun and wind are employed to dry the grains while in developed countries more automated mechanical equipment like mowers and threshing combines are used to dry and then maintain the low-moisture level of the grains during storage. When adequately dried and maintained under hygienic conditions, these grains provide the world with a stable and nutrient-dense food commodity.

The methods used to further process cereal grains into other products are added avenues for contamination. The additional sources of potential contamination of cereal grains are mills, conveyers, and processing equipments. The grains are typically milled to separate the bran and germ from the endosperm to produce flour and bran. The flour and bran are recombined to create a variety of nutritionally and functionally useful derivatives including graham flour and whole grain.

Although the grain cleaning and milling process would be expected to reduce the level of microorganisms, the process cannot be expected to eliminate spoilage or pathogenic microorganisms. The exposure to moisture during the milling process

is a possible source of contamination. Hence, the design of foods and food manufacturing processes must take into account the potential presence of pathogenic microorganisms in foods. However, spoilage microorganisms can thrive on cereal grains and further processed products if maintained at improper storage conditions.

Water Activity

Water activity (a_w) is just one of the many factors that determine the bioload on cereal grains. a_w is the measure of free moisture in a product as defined by the ratio of the vapor pressure of a substance to that of pure water at a specified temperature. It is the primary factor that regulates the growth of microorganisms in cereal grains especially during storage. Storage fungi are capable of growth at low a_w levels, whereas field fungi cannot. Few field fungi are able to grow when the a_w is below 0.90. A decrease in a_w restricts the temperature range for optimal microorganisms to grow. Mold does not have the ability to grow in cereal grain when the a_w is below 13%. Studies that have monitored a_w and the absence or growth of mold have demonstrated that dry grains stored below 13% have a shelf life of up to 1 year. This finding is however dependent on the type of cereal grain and the final moisture level.

Temperature Control and Heating

The external surface exposure of cereal grains to certain microorganisms is dependent on where the grains are grown and processed. The temperature is a factor that dictates the growth of the microorganisms during storage. Moderate to tropical ambient temperatures, 10–35 °C, provides the optimal temperature range for fungal growth. Temperature that is not controlled can lead to heating in stored grains. This heating allows the thermophilic fungi to grow and become dominate. This form of heating in grains is a direct result of fungal growth and metabolism. Even when cereal grain moisture is below 12%, increases in temperature is not safe for long-term storage. Nevertheless, in order for most grain-based foods to be considered edible, they must be given some type of heat treatment. Under the prescribed conditions, the heat supplied is sufficient to inactivate most microorganisms.

The use of low temperatures for grain storage aids in extending product shelf life. The harvest process for maize is done when the grain has greater than 20% moisture available for possible microbial growth. Storage for rice is done at refrigerated temperatures soon after harvest and drying is done in a slow methodical manner until the desired moisture level is achieved. However, this process must be continually monitored because some fungi can grow at these low temperatures.

Inherent Microflora

Cereal crops in their natural field state are exposed to a wide variety of microorganisms due to dust, diseased plants, insects, soil, fertilizer, and animal droppings. The nutritious composition and near-neutral pH of cereal grains make them the optimal substrate for microbial growth. The number and type of microorganism present will be influenced by temperature, sunlight, soil, and general climatic conditions during the growing and harvesting season. This diversity in microorganisms is compounded by the introduction of microorganism during grain transportation that likewise can be affected by these climatic influences and hygienic practices. For this reason cereals are considered as raw or nonprocessed agricultural commodity as one can expect the bioburden of the cereals to be a function of these natural conditions. These microorganisms may include both spoilage and pathogenic microorganisms and may originate in the feces of warm-blooded animals. In general, these microorganisms will either reside on the outside of the grain or invade the inner grain kernel. Although many microorganisms may be present, few are capable of invading the grain kernel without damage of the cereal crop due to the stresses of weather, mechanical injury, and insect infestation. The presence of these invasive microorganisms is inconsequential if the cereal grains are dried to a moisture level below 12% (0.70 a_w). The difference in grain varieties is commonly not a factor in the type of microorganism present.

Bacteria and Bacterial Toxins

Cereal grains may become contaminated with microorganisms originating in the field. However, further contamination is evident during harvest, distribution, storage, and processing. Although these microorganisms will not grow in cereal grains that are properly dried to less than 13% moisture, certain microorganisms will persist through grain cleaning and milling and may affect product quality or safety. Bacteria commonly found in cereal grains belong to the families *Pseudomonadaceae*, *Micrococcaceae*, *Lactobacillaceae*, and *Bacillaceae*. Observations have shown that bacterial populations may appear in numbers 10-times higher than mold populations. Bacterial populations in cereal grains may be present at levels of $10^6\ g^{-1}$. The extensive variety of species detected may include aerobic mesophilic sporeformers, lactic acid bacteria, coliforms, and pseudomonads.

The primary bacterial hazard of concern within cereal grains is *Salmonella*. The variation in seasonal conditions, processing, and distribution make an accurate estimate of the incidence of *Salmonella* contamination within milled cereal grains challenging. The incidence of *Salmonella* within wheat flour has been reported to be at 0.14%. Studies have demonstrated that viable *Salmonella* can be detected in dry flours after several months of storage. *Salmonella* contamination in low-moisture foods can be traced back to substandard sanitation practices, inferior facilities, poor equipment design, improper maintenance, and inadequate following of GMPs.

A number of foodborne illnesses are caused by intoxication. Bacterial intoxication is the ingestion of a toxin present in food before consumption. *Clostridium botulinum*, *Staphylococcus aureus*, and *Bacillus cereus* are the most common bacteria that cause bacterial intoxication.

Clostridium botulinum is a Gram-positive anaerobic spore that produces seven serologically distinct toxins. The toxin types are A, B, C, D, E, F, and G. The toxin types are associated with the strain based on the toxin produced. The species are further

subdivided according to the degree for proteolytic activity. Strain types A, B, and F, group I proteolytic strains, are of major concern in foods. In group II, nonproteolytic strains, B, E, and F are also a concern in foods. The deactivation of the *C. botulinum* spores is through a process that delivers a 12-D reduction, the heat required to inactive a theoretical contamination by 10^{12} *C. botulinum* spores.

Staphylococcus aureus, is a Gram-positive facultative cocci that has the ability to withstand high levels of salt. The enterotoxins of *S. aureus* are A, B, C_1, C_2, C_3, D, and E. Other strains of *S. aureus* are F, H, and G. Enterotoxin F and G have not been associated with food. Staphylococci are ubiquitous and their presence in foods at low numbers are not uncommon. *Staphylococcus aureus* is not heat resistant. Freezing and thawing have little effect on the viability of *S. aureus*. The use of heat is the most effective form to deactivate *S. aureus* in foods.

Bacillus cereus is a Gram-positive facultative spore-forming anaerobic rod. The *B. cereus* emetic toxin and diarrheal enterotoxin are causes of food poisonings. The deactivation of the *B. cereus* spores is dependent of the type of food it is in.

The consumer's kitchen and food manufacturing facility share the same hazard of the presence of *Salmonella* when it comes to handling various flours. Owing to the presence of *Salmonella* in wheat flour, handling and cooking practices must be clearly and effectively communicated to ensure the destruction of this organism. The importance of these handling and cooking practices was evident when *E. coli* O157:H7 was epidemiologically and analytically determined to be present in refrigerated cookie dough. Although the presence of this organism in wheat flour was unexpected, the consumption of raw cookie dough by consumers before baking was not. The linkage of foodborne illness to cookie dough illustrates the need for a farm to fork hazard analysis through revalidation of foods. This revalidation needs to consider the factors of consumer behavior and package communication language. Consumers must recognize that foods prepared with cereal grains that have not undergone further processing to eliminate pathogenic microorganisms may indeed contain these pathogens and must be adequately cooked before consumption.

Molds and Mycotoxins

Fungi capable of significance to grains stability and safety can be classified as field and storage molds. The field molds represent strains capable of survival and growth on cereals before harvest. These field molds following harvest and drying eventually die yet storage molds rapidly contaminate the grains and predominate. The storage molds in general are capable of growth under lower moisture levels, down to 0.70 a_w whereas the field molds do not. These storage molds reside within the grain handling, distribution, processing, and storage equipment and can be minimized within the stored cereal grains with diligent sanitation of all steps from the field through storage. Species of *Aspergillus* are common and an important storage fungi in grains. Damage of the cereal's natural barriers by mechanical, weather, and stress enables insects to invade the grain and damage the cereal grains. The destruction of the crop is exacerbated by vectoring of molds through insect activity through the germ or whole kernel.

The beneficial effects of some molds in fermented foods have been well documented. However, it is also known that some molds produce toxic chemicals. The primary spoilage microorganisms in cereal grains are molds in which growth at reduced a_w levels can occur. The invader of wheat grains are molds such as *Alternaria*, *Fusarium*, *Helminthosporium*, and *Cladosporium* species. Mycotoxins are typically found in obviously deteriorated kernels (dark color visible mold, broken pieces). Extensive mycotoxin reduction can be achieved through the sorting of grains to remove the dark and broken kernels. The ability of field and storage molds to produce mycotoxins in grains is common yet the factors and conditions controlling the production of these metabolites are not fully understood.

The potential to produce mycotoxins is the principal concern of spoilage caused by molds. The consumption of cereal grains with the presence of mycotoxins in flours, meals, and dry mixes is a greater health risk than the presence of *Salmonella* in the same products. The mold producing these mycotoxins may originate in the field and opportunistically invade the cereal grains when the moisture level exceeds 28–33% dry basis. The moisture level within stored grains that exceed 12% may produce other species of mold and may produce mycotoxins. Climactic and storage conditions may challenge the uniform drying of stored grains at moisture levels below 12% creating pockets of mold growth and mycotoxin production. Yeasts and molds may contaminate cereal grains to levels of 10^4 g^{-1}.

The production of mycotoxins, due to mold growth, is an important health hazard of cereal grain products. Some factors that affect mycotoxin production by molds are moisture, pH, and competitive and associative growth of other fungi and microorganisms. *Aspergillus*, *Penicillium*, and *Fusarium* are the primary molds of greatest concern that produce mycotoxins. At present, there are approximately 20 known mycotoxins found in nature from cereal products with sufficient frequency and large toxic amounts to be of concern for food safety. There are five toxin groups in which the 20 naturally occurring mycotoxins have been categorized into. These five groups are aflatoxins, ochratoxin, zearalenone, deoxynivalenol, and fumonisins. As the awareness of mycotoxins increases, patulin, cyclopiazonic acid, and moniliformin are toxins of emergence.

The consumption of any amount of mold growth on grains is a risk to humans and animals, yet animals may be more at risk given the likelihood they will eat larger quantities of moldy material. Mold contamination of raw cereal grains is not completely preventable. The awareness of the types of mold present in cereal grains are an early indicator of the types of mycotoxins that may be produced.

Heavy Metal in Cereal Grains

The bioavailability of metals in soil is important for the development and growth of cereal crops. Heavy metal contamination of soil is due to factors such as the use of sewage sludge and areas surrounding industrial activities. Heavy metals that are often reported are copper, lead, and zinc. Cadmium is a heavy metal that has high toxicity and bioavailability numbers. Among cereal grains, wheat accumulates much higher amounts of cadmium. However, these amounts

can be decreased with the use of fertilizers. There is a need to reduce the uptake of crops heavy in metal to crops based on amounts of heavy metal found in the overall human diet.

Mixed Weeds in Cereal Grains

The process of harvesting various cereal grains is one point of possible contamination due to mixed weeds or grasses. Weeds that are not controlled with effective control procedures compete with cereal grains for water, light, nutrients, and space, causing reductions to yield quality and quantity. The harvesting of weed grasses with cereal grains can cause grain contamination that may result in the crop being rejected at the mill or failing certification. This rejection and contamination of weed grass in cereal grains is less of a concern in industrialized countries.

Classification of weeds is usually in two common groups, grass weeds or broadleaved weeds. Weeds with established populations can cause approximately 25% yield losses. Grass weeds can carry the cereal disease ergot, caused by the fungus *Claviceps purpurea*. Ergot ruins the grains of developing crops and renders them toxic to both livestock and humans. *Claviceps purpurea* affects rye grains, but can also harm triticale, wheat, and barley crops. The florets of cereal grains are infected by the *C. purpurea* spore which mimic pollen grain growing cycles. Climbing weeds in the broadleaved weed group, such as cleavers, affect the profitability of a cereal crop by interfering with crop growth and harvest.

Acrylamide

Acrylamide, a naturally occurring reactive unsaturated amide with a double bond, is found in plant-based, high-carbohydrate foods after they are heated. It is a monomer used in water treatment facilities, in mining operations, and in the paper production industry. The Swedish National Food Administration along with the University of Stockholm announced in 2002 the high levels of acrylamide in processed and cooked foods that used high temperatures during process. Acrylamide in thermally processed foods has been linked to the Maillard reaction. During the Maillard reaction, reducing sugars and the amino acid asparagine are the major reactants. Acrylamide formation is also produced when decarboxylated asparagine is heated.

The findings that acrylamide is present in many processed foods caused many to have an apprehensive reaction due to the fact that the International Agency for Research on Cancer as a class 2A 'probable human carcinogen.' Toxicity studies of acrylamide demonstrate that, depending on the dosage and the length of exposure, neurotoxic, reproductive, and carcinogenic effects can occur.

Acrylamide is found in highest concentrations in french fries and potato chips, but it is also detected in diverse foods such as breads, cereals, cakes, and coffee, and cocoa. It is ubiquitous in the human diet. More than one-third of the calories we take each day come from foods with detectable levels of acrylamide.

Taeymans *et al.* (2004) describe several methods of detecting acrylamide in food. One method is gas chromatography–mass spectrometry. This method allows for the detection in certain foods that approach the range of 1–2 $\mu g\,kg^{-1}$. Other methods for detection are liquid chromatography–mass spectrometry and proton-transfer reactions mass spectrometry.

Cereal-Derived Products

The diversity in the types of microorganisms that can be indentified with various cereal grains is small in comparison to the diversity in the number of products that are produced from cereal grains. Products that are produced from cereal grains fall into several main categories of products: flours and starches, doughs, breakfast cereals and snacks food, baked goods, soy protein, pasta, and dry mixes. Each product categories has its own normal microflora associated with it.

Flours and Starches

Cereal grains that are processed into flour, meal, or grits carry the inherent risk of microbial contamination based on the conditions present in the fields and transportation. Grains that are milled have been bombarded with numerous cleaning and aspiration measures before tempering. This reduces the microbial load that is present as the grains are milled. The process of tempering the grains introduces moisture for a predetermined amount of time is a processing technique in which microorganisms can grow. The dry milling process for corn meal and corn grits avoids the addition of moisture to the grains. Processed flours that are properly handled should not be higher in microbial counts than levels in raw grains. In wheat flours, it is known that *Salmonella* maybe be present at levels up to 5%. Because of the *Salmonella* risk, some manufactures are using flour that has been heat treated to reduce the possible microbial load. These flours and starches then are used in a variety of sauces, doughs, and confections as the main ingredient.

Doughs

The microflora of doughs is due to ingredients such as flour, dry milk, eggs, sugar, spices, flavorings, yeast, and water use in the formulation. Yeast is the principal contributor to flavor in dough formation. However, moisture levels in dry cereal grain at 17% or higher will allow undesired yeasts to growth. *Saccharomyces cerevisiae*, one form of yeast, is important for flavor development during the proofing phase. The equipment used in the manufacturing of refrigerated or frozen doughs plays an important part in the finished product microbial load. The sanitation practices for this processing equipment must be followed to reduce potential contamination.

In some commercially produced dough products, processors have decided to use heat-treated flour. This added step is done as another safety measure to reduce any possible microbial loads present in the flour. However, in refrigerated doughs, bacterial growth is hindered due to the low a_w and pH formulated into the product. Likewise in frozen doughs, microbial growth does not occur when prescribed low temperatures are maintained during transport and storage.

Dry Mixes

Dry mixes are a combination of dried ingredients that are dry blended. These ingredients include items such as: flour, sugar, salt, dried eggs, and flavors. The microbial loads for the finished product of such manufacturing requires that diligence is given to various individual ingredients and manufacturing ingredients. The processing of dry mixes does nothing to reduce the microbial counts. Quality of the final product is affected if microbial load and the moisture level of the product are not controlled.

Baked Goods

The term 'baked goods' refers to breads and pastries. The process of baking or frying has been proven to destroy most microorganisms that are present. A common spoilage organism for breads and other baked goods is mold. Bread is targeted for spoilage and a short shelf life due to the high a_w of approximately 0.95 in the finished product.

Bacillus subtilis, a spore-forming bacterium, can survive the temperatures used for baking or frying. Spores of *B. subtilis* are known to cause 'rope.' Rope is a condition in which the bread exhibits a ropy and stringy texture of the product interior. The spores survive the baking process and begin to germinate. The bacteria produces amylases and proteases that breakdown the bread structure.

The use of various fillings supports additional spoilage microbial growth that is normally controlled in the baked part of the cereal product. Fillings, fruit, or custard have inherent ingredients like eggs or milk products that support microbial growth. The potential for growth is furthermore due to the processing parameters that may not supply enough heat and time to destroy microorganisms. The final filling product normally has a neutral pH and a high a_w which are contributing factors for microbial growth.

The prevention of mold spoilage is controlled when a_w is reduced. Another measure used to control spoilage in breads is the usage of preservatives such as propionic acid, sorbic acid, calcium propionate, or other weak acids. Spoilage of bakery products has been controlled by good sanitation procedures and bakery practices.

Soy Protein Products

Soybeans are not cereal grains, but a pulse. A pulse is a grain legume. Soybeans in nature need no industrial fertilizers, because they enjoy a natural symbiosis with a *Rhizobium* bacterium. This relationship provides organic proteins that are made directly from the surrounding atmosphere's nitrogen content, while eliminating the need for commercial nitrogen-based fertilizers. Grain legumes are cultivated primarily for their seeds, rich in both energy and protein. As a food, they provide humans with this protein and energy as well.

The finished food products using soy exhibit many of the same properties as cereal grains. The primary ingredient in soy protein products is soy flour. Soy flour is derived from soybeans that have been dried and ground.

Breakfast Cereals and Snack Foods

Breakfast cereal processing falls in the categories of flaking, puffing, or extrusion. In each of these processes, moisture is introduced. The introduction of moisture provides the opportunity for microbial growth that can be reduced by the heat applied during production. Post-heat contamination may happen as vitamins, minerals, sweeteners, colors, or flavors are applied to the grain. The addition of ingredients after postheat treatment must be free of microorganisms to maintain a contamination-free product. Processing equipment after post-heat processing must be maintained in sanitary conditions to avoid post-production contamination.

Owing to low-moisture levels of breakfast cereals, it was long considered that this would prevent any further microbial growth. However, it has been discovered that microbial contaminants may not grow in these low-moisture products, but they can survive. This discovery has been evident based on breakfast cereal recalls due to *Salmonella* contamination.

Under the heading of snack foods, the emergence of grain-based bars with or without filling or coating is ever increasing. These cereal bars are made using the process of agglomeration. Agglomeration is a process during which primary particles are fixed together to form larger, porous secondary particles. Cereal bars are made with flaked, puffed, or extruded grains that are assembled together with a sugar-based binding solution and compressed under low pressure.

Cereal bars are considered ready-to-eat products. The ingredients used to produce agglomerated bars require an added degree of diligence to ensure that the cereal grains and additive ingredients are free of microbial contamination. This is because there is no heat step used in the production of cereal bars to reduce the initial microbial counts that raw cereal grains inherently encompass. The heat used to mix the binding syrup is not sufficient to reduce the microbial load that may be present on contaminated cereal grain products. Added care must also be taken to ensure that cross-contamination does not occur during the processing of the agglomerated product from outside factors such as personnel or processing equipment.

Pasta

The manufacture of pasta does not include a heat step that may reduce the initial microbial load of durum wheat flour, water, enrichment nutrients, and/or egg ingredients commonly used. Microorganisms can proliferate during the mixing and drying process. The microbial load may also increase during the extrusion component of the process. There are two types of pasta productions: egg-based and macaroni-type. Egg-based pasta has an added bacterial risk of *Salmonella* contamination from the addition of fresh or dried eggs. Even when the egg-based pasta is dried, the potential for *Salmonella* to survive the drying process is a possibility. The initial microbial load is directly related to microbial load of the individual ingredients. As the pasta is being manufactured, it contains approximately 30% moisture which can support microbial growth. The potential for microbial growth is not inhibited until the product is dried below 13% moisture. Freshly dried pasta has had counts as high as $10^7\ g^{-1}$. This number was subsequently lowered during the drying process. Spoilage of dry pasta is rare during storage and distribution.

However, vegetative cells will be destroyed during normal boiling preparation with the staphylococcal enterotoxin remaining.

Gluten versus Gluten Free

Gluten is a protein that appears in foods processed from wheat and other cereal grains, including barley and rye. It gives elasticity to dough, helping it to rise and keep its shape, and often giving the final product a chewy texture.

Gluten, when dried and milled to powder and added to ordinary flour dough, improves rising and increases the bread's structural stability and chewiness. On digestion, the 33-amino acid gluten protein breaks down into smaller peptide units. There are two main groups of proteins in gluten, called the gliadins and glutenins.

The demand for cereal grain products labeled as 'gluten free' has grown over the past few years. One cause for the demand is the increase of people diagnosed with celiac disease. Celiac disease, also known as gluten-sensitive enteropathy, nontropical sprue, and celiac sprue, is a genetic disorder in which people are predisposed to an autoimmune response that causes damage to the small intestine when gluten proteins are contained in certain foods. Approximately three million people, 1% of the population, have been diagnosed with celiac disease.

Australia, Europe, and the USA have diagnosed celiac disease. The Food and Drug Administration (FDA) has proposed a gluten-free labeling rule for voluntary use in foods. The current standard proposed by FDA is that food mostly contain no more than 20 ppm to claim a gluten-free status. A gluten-free label means that the food being produced does not contain any species of prohibited grains such as, wheat, rye, barley, or a crossbred hybrid. In addition, it does not contain any ingredients that is derived from prohibited grains and has not been processed to remove gluten.

Manufactures that want to make 'gluten free' claims need to view gluten in the same manner as an allergen. Companies must design policies and systems within their facilities based on the presence or absence of gluten-containing products. Facilities that are not completely free of gluten-containing products increase the chance of not meeting the proposed labeling rule. However, systems can be designed to have the needed segregations and sanitation procedures. Plants must have segregated areas for receiving raw ingredients and develop systems to avoid cross-contamination. Processing equipment must be properly sanitized to ensure the absence of the gluten protein.

SAFETY OF FOOD AND BEVERAGES

Oils and Fats

G van Duijn, Vlaardingen, The Netherlands

Glossary

Coconut oil Oil derived from the kernel of the coconut (*Cocos nucifera*).
Crude oils Vegetable oil obtained by the oil extraction process before refining.
Maize or corn oil Oil derived from maize germ (the embryos of *Zea mays*).
Oil extraction Recovering of vegetable oil from the oil crop.
Oil Refining The purification of oils and fats to remove minor components like free fatty acids, phosphatides, and also color and off taste.
Palm kernel oil Oil derived from the kernel of oil palm fruit (*Elaeisguineensis*).
Palm oil Oil derived from the fleshy mesocarp of oil palm fruit (*Elaeis guineensis*).
Peanut or groundnut oil Oil derived from groundnuts (*Arachis hypogaea*).
Rapeseed oil Oil produced from seeds of the *Brassica* family.
Soybean oil Oil derived from soya beans (seeds of *Glycine max*).
Sunflower oil Oil derived from sunflower seeds (*Helianthus annuus*).
Vegetable oils Foodstuffs which are composed primarily of glycerides of fatty acids being obtained only from vegetable sources.

Introduction

Functionality

Oils and fats have been used from ancient times for food preparation as well as in non-food applications like lamp oil, lubricant, soap manufacturing, and skin care. This article will only deal with the use of oils and fats for food preparation or as an ingredient in food.

Oils and fats provide functionality in food preparation and use as well as nutritional benefits. They serve as the heat transfer medium at elevated temperatures (e.g., frying), improve the mouth feel (spreads and dressings) and give texture and flavor to a wide range of foodstuffs. A balanced intake of oils and fats is essential for human health. They supply a concentrated source of energy, deliver critical building elements for the body and act as a carrier for essential minor components like vitamins A and D.

Supply Chain

Oils and fats originate from plant and animal sources. The plant based oils and fats dominate in current food applications and will be the main focus of this article.

The supply chains of vegetable oils and fats consist of:

- The growing of oil seeds, fruits, kernels or nuts,
- Oil extraction to recover the oil; the by-product meal is mostly used as animal feed,
- Purification and modification to optimize the oil properties for its use,
- All transport from grower to end user.

Until the industrial revolution in the ninteenth century, rapeseed, linseed, olives and nuts were the main sources of vegetable oils. Today, the world market is dominated by palm and soybean oil, followed by rapeseed and sunflower oil. This also led to a change of the extraction and purification/modification processes. Originally, the oil extraction process consisted of cleaning, crushing, heating and pressing. From 1900 onwards, solvent extraction was also applied to recover the residual oil from the pressed cake or to replace the pressing process completely (e.g. for soybean oil). At more or less the same time, the oil purification process changed from a simple decanting and filtration to a combination of neutralization with caustic, bleaching with active clay and deodorization at high temperature under vacuum with steam. By this refining process, minor components could be reduced to improve taste and appearance while the removal of processing residues was required after the introduction of solvent extraction and nickel catalyzed hydrogenation.

Later, the introduction of improved analytical techniques showed that the refining process also reduces the levels of many of the contaminants present in the crude (=extracted) oil. This article gives an overview of the most important contaminants in the crude oil and the validation of the refining process for the removal of these components.

Contaminants in Crude Oils and Fats

Crude Oil Risk Hazard Analysis

The presence and levels of contaminants in crude oils depend on:

- Agricultural practices.
- Procedures of oil crop storage, drying, and handling.
- Oil extraction practices.
- Contamination and degradation during crude oil transport.

The risk of contamination and the type of contaminant will differ per oil type and origin. Information on the presence of contaminants in various oil types from different origins has been collected in three ways:

1. Visits of all steps of the crude oil supply chains.
2. Analyses of crude oils brought for further processing.
3. Sharing of contaminant information in industry organizations and during conferences.

The following contaminants were found at detectable levels: Pesticide residues, poly aromatic hydrocarbons, hydrocarbons of mineral origin, and mycotoxins. The following sections give the analysis of hazards associated with crude vegetable oils.

Pesticide Residues

Plant protection products or pesticides can be used during the cultivation and storage of oil seeds, fruits, kernels and nuts, to protect the crop during growing, to reduce weeds and to protect seeds during storage and transport. To guarantee pesticide use according to good agricultural practices and to protect consumer's health, authorities introduced limits for the residual levels of pesticides in the harvested crops; the so-called maximum residue limits (MRL). These limits are requested by pesticide manufacturers on the basis of residues found after pesticide use according to good agricultural practices (GAP). These MRL's are crop and pesticide specific and must be much lower than the harmful toxicological thresholds (see Figure 1). For crop/pesticide combinations for which a MRL has not been requested or the request has not been granted, the pesticide level in the crop has to be below the level of determination (LOD). For instance, in the EU directives the LOD is given for individual pesticides. Pesticides are considered to be chemical hazards if the level in the crop exceeds the MRL of the pesticide/crop combination.

Depending on their physical/chemical properties, the pesticide residues present in the oil crop will concentrate differently in the products of the oil extraction process:

- They will concentrate in the crude oil if they are oil or hexane (in case of solvent extraction) soluble. The maximum concentration factor, X(max), of oil- or hexane-soluble pesticides going from crop to crude oils is:

$$X(\text{max}) = 100\%/C_{\text{oil}}$$

  where C_{oil} is the fraction of oil in the crop (%).
- In palm oil extraction, they will concentrate in the sludge if they are water soluble.
- The concentrations in oil and meal fractions are both equal to the level in the crop if the pesticides are not soluble or equally soluble in oil and meal.

Hence, oil extraction may result in a pesticide level in the crude oil that is higher than the MRL of the oil crop.

The pesticides used in the seed oil supply chain are mainly organophosphorus insecticides. These are applied to protect

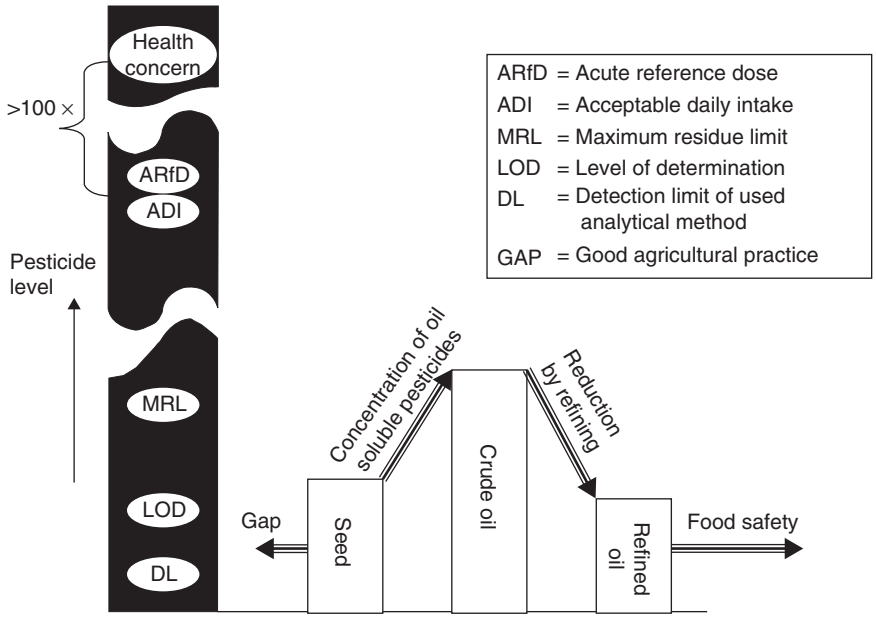

Figure 1 A qualitative picture of the change of a pesticide level by oil extraction and by subsequent refining. The vertical column shows a relationship with the different health levels, legal limit, and detection limit.

oil seeds during storage and transport after harvesting (post-harvest treatment). The following pesticides were found at detectable levels in crude rapeseed, crude sunflower, and crude soybean oil samples: Fenitrothion, Malathion, Pirimiphos-methyl, Parathion-methyl, Dichlorvos, Chlorpyriphos, Chlorpyriphos-methyl, and Endosulfan. Approximately 15% of the sunflower oil samples contained pesticide levels higher than the oil seed MRL valid in the EU; this percentage was much lower for rapeseed and soybean oil.

Oil palm fruits are processed within a few days and preferably within 24 h after harvesting for quality reasons. Post-harvest treatment of palm fruits is therefore not required and detectable pesticide levels in the crude palm oil samples were never found.

In the supply chains of palm kernels and coconuts, chemical crop protection is not applied, resulting in non detectable levels in the crude oils.

Poly-Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) constitute a large class of organic compounds that are composed of two or more fused aromatic rings. They are primarily formed by incomplete combustion or pyrolysis of organic matter. PAHs generally occur in complex mixtures which may consist of hundreds of compounds. Humans are exposed to PAHs by inhalation if they are smokers and by the consumption of contaminated food. Oil crop can be contaminated with PAHs by the absorption of these components from exhaust gasses, when these gasses are in direct contact with the crop during drying.

Oil mills set specifications for the moisture levels of oil seeds. At too high moisture levels, oil seeds need to be dried before arrival at the oil mill or by the mill itself. Drying by direct contact with exhaust gasses has been observed for soybeans in wood-fired packed bed dryers and for sunflower seeds in diesel-fired counter current dryers. Indirect dryers are used in the EU and the USA. In these dryers hot air is generated via a heat exchanger, this excludes contact between exhaust gasses and the product.

In the coconut supply chain drying is an essential operation, it avoids aflatoxin formation and releases the copra (coconut meal) from the shell. In the most commonly used method in the main producing country, the Philippines, halved coconuts are dried upside down on a grid over an open fire, burning coconut shells. Thousands of these drying installations are operated by small farmers.

Palm kernels are washed and dried after the removal of the shells in the palm oil mill by cracking and air separation. A majority of oil mills dry the kernels in indirect dryers, however, a minority use direct dryers. Oil palm fruit is not dried since it is processed shortly after harvesting while the fruit itself contains approximately 50% humidity.

Benz(a) pyrene (BaP), a PAH with 5 aromatic rings, is generally used as a marker for the presence of PAH in crude oils. Figure 2 shows the results of BaP analyses in various crude oils. This graph confirms that the contamination level and frequency of crude coconut oil is very high (maximum BaP level: 70 $\mu g\ kg^{-1}$, fraction of samples with BaP > 1 $\mu g\ kg^{-1}$ (frequency) was almost 80%). Crude sunflower oil was both high in maximum (40 $\mu g\ kg^{-1}$) and in frequency (12%), followed by crude rapeseed oil (maximum 10 $\mu g\ kg^{-1}$, frequency 9%), crude palm kernel oil (maximum 6 $\mu g\ kg^{-1}$, frequency 6%) and water degummed soybean oil (maximum 2 $\mu g\ kg^{-1}$, frequency 7%). Other oils which may contain PAHs are grape seed oil and cotton seed oil.

Hydrocarbons of Mineral Origin

Hydrocarbons of mineral origin consist mainly of alkanes of different chain length. They are manufactured from crude mineral oils in various refining steps such as distillation, extraction, and crystallization followed by purification. Mineral oil products can be divided in product groups on the basis of their carbon number and/or viscosity. Of importance for this

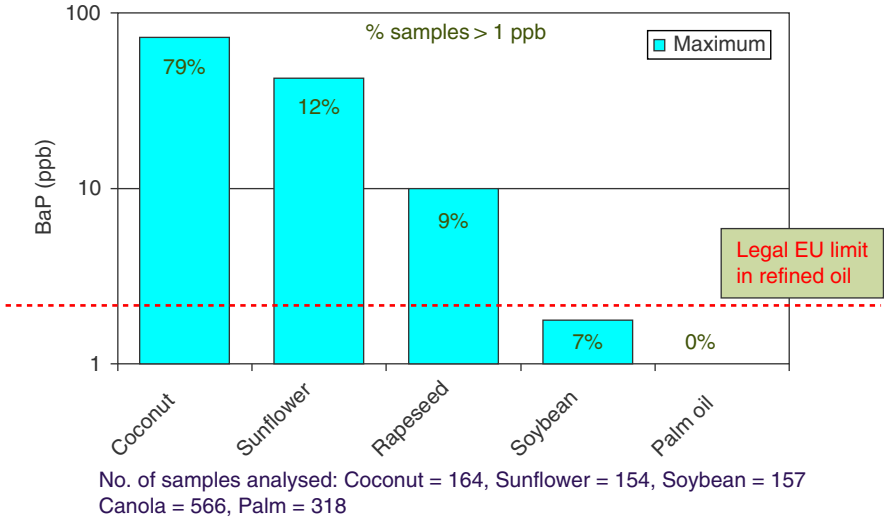

Figure 2 Results of BaP (benz(a)pyrene) analyses in crude oils. This graph shows the average of the samples containing more than 1 $\mu g\ kg^{-1}$ BaP and the maximum observed levels.

section are the following product groups (classified on basis of carbon number):

C6: Hexane, used as solvent for vegetable oil extraction.
C6–C10: Gasoline.
C10–C24: Mid-fraction, consisting of kerosene, diesel, and light fuel oil.
C20–C55: Medium and high viscosity oils such as grease oil, hydraulic oils, etc.
Carbon number >56: Solids.

Based on toxicity studies, the Joint FAO/WHO Expert Committee on Food Additives accepted different acceptable daily intakes (ADI) for mineral oil with high viscosity (ADI of maximum 20 mg kg^{-1} body weight) and for mineral oil with medium and low viscosity (ADI of maximum 10 mg kg^{-1} body weight for class I and maximum 0.01 mg kg^{-1} body weight for classes II and III).

Mineral oil products can be present in crude edible oils due to contamination during processing (lubricants and hydraulic oils), as residues from previous cargoes during transport and storage, and by fraudulent addition. However, their presence can also be the result of an allowed use as a processing aid, like hexane in solvent extraction, as a solvent for pesticides and as an anti dusting agent in oil seeds storage. It should be noted that long chain alkanes are synthesized by a large number of edible plants and animals, resulting in considerable levels of naturally occurring alkanes in crude edible oils (e.g., maximum 160 mg kg^{-1} in sunflower oil). Natural alkanes are characterized by a strong predominance of odd carbon numbers.

Oils and fats have to be free from contamination with hydrocarbons of a mineral origin. This can be ensured by supply chain auditing and by setting analytical limits. These limits should take into account the presence of mineral oil products from allowed practices, the presence of 'natural' alkanes, and the analytical detection limit. The following limits are industry standards based on good agricultural and manufacturing practices.

- Short chain hydrocarbons (shorter than C10) are volatile and are contractually limited by the flashpoint (temperature at which escaping gasses can be detected by flashing). The flashpoint has been introduced to exclude explosion risk during transport and storage. The contractual limit is minimum 121 °C.
- After an incident of diesel contamination in crude palm oil, the Dutch, Malaysian and Indonesian government agreed on a limit of 25 mg kg^{-1} diesel (expressed as C10–C24) in crude palm oil and palm products.
- In 2008, imported crude sunflower oil from the Ukraine had been contaminated with high viscosity mineral oil. The acceptable limit for imported crude sunflower was set at 50 mg kg^{-1} presence of total hydrocarbons (C10–C56). This is after correction for known amounts of natural alkanes. These known amounts follow from an historical analytical data base of non-contaminated samples.
- For all other vegetable oils an action limit was set at 300 mg kg^{-1} of total hydrocarbons (C10–C56). This limit includes an unknown level of natural alkanes and the allowed use of mineral oils as processing aids.

Table 1 Aflatoxin analyses in crude oil deliveries to Unilever

Samples taken from deliveries 1992–94

Aflatoxin B1		*Coconut oil*	*Groundnut oil*	*Rapeseed oil*
No of samples	–	42	11	3
Minimum	μg kg^{-1}	1	4	ND
Maximum	μg kg^{-1}	75	34	ND
Average	μg kg^{-1}	14	10	ND

Aflatoxin G1: Around 30% of B1 level.
Aflatoxin B2, G2: Not detectable.

Mycotoxins

Aflatoxin

Aflatoxins are mycotoxins that are produced by a number of different strains from the Aspergillus family (molds). They are found as contaminants in human and animal food as a result of fungal contamination during growing, and usually to a larger extent, post harvest storage. Carcinogenic effects of aflatoxins to humans are no longer doubted and legal limits for aflatoxins in foodstuff are very low. Aflatoxins are most commonly associated with groundnuts (peanuts), dried fruit, tree nuts (such as almonds, pecans, walnuts, pistachio, and brazil nuts), spices, figs, crude vegetable oils (peanut oil, coconut oil), cocoa beans and a range of agricultural products, the most important being maize, rice, cottonseed, and copra. The aflatoxins that may appear in oilseeds and vegetable oils are aflatoxin B1, G1, B2, and G2 of which B1 and G1 are the most common. In general, no more than 10% of the aflatoxins present in seeds, peanuts, and copra are transferred to the crude oil after pressing and extraction. This is due to the fact that aflatoxins are mainly protein bound.

An inventory of aflatoxin levels by Unilever in the mid nineties demonstrated the frequent occurrence of aflatoxins in crude coconut and peanut oil. The average aflatoxin B1 concentration for coconut oil was 14 μg kg^{-1}, with a maximum of 75 μg kg^{-1}. The average value for the peanut oil was 10 μg kg^{-1}, with a maximum of 34 μg kg^{-1}. The aflatoxin G1 levels in these oils were approximately 30% of the aflatoxin B1 levels, aflatoxin B2 and G2 were not detected (<1.0 μg kg^{-1}). Crude rapeseed oil showed no aflatoxin contamination (<1.0 μg kg^{-1}) (see Table 1).

Zearalenone in Crude Maize Germ Oil

The fungi (Fusarium species) producing the toxin Zearalenone (ZEN) are common soil fungi which mainly develop during flowering. The Fusarium fungi are usually found on cereals grown in the temperate regions of America, Europe, and Asia. The weather conditions during the two week flowering period have a determining effect on the toxin level. High ZEN levels are found at relatively low temperatures and high humidity. Various studies reported a negative effect of ZEN on the fertility of pigs.

In the maize milling process, where the germs are separated from the rest, ZEN is concentrating in the germs. The maize producer's industry organization (Association des Amidonniers et Feculiers (AAF)) estimates that the concentration factor is between 3 and 5. In the last ten year period, high ZEN levels were found in the European harvests of years

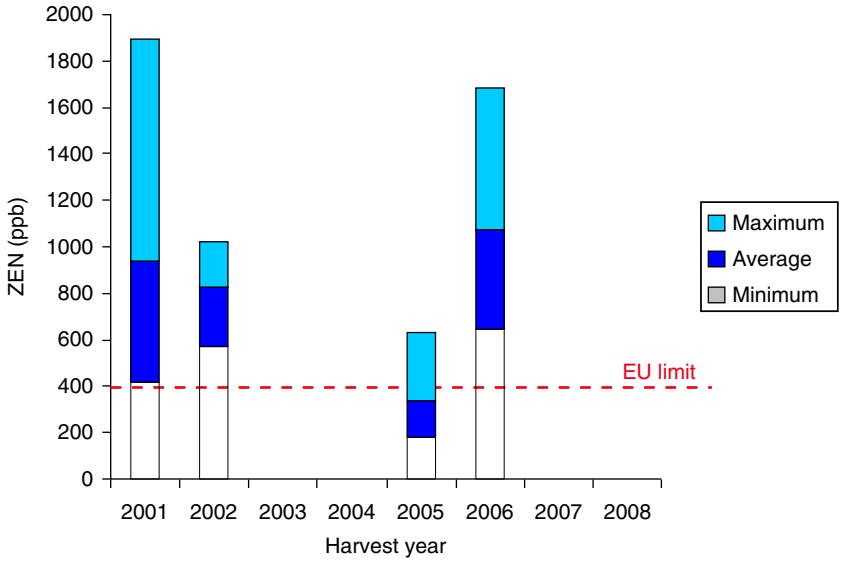

Figure 3 Results of Zearalenone analyses in crude maize oil. The x-axes shows the year of harvesting. The samples were taken from the crude oils produced from the harvested crop during the year following harvesting.

2001, 2002, 2005, and 2006. The other years showed very low ZEN levels (see Figure 3). The flowering period of summer 2006 was specifically unfavorable for ZEN formation (cold and wet). The maize producers found in 236 samples of unprocessed maize an average ZEN level of 370 μg kg^{-1}. With a concentration factor of 3 to 5, this results in an average level of 1100–1850 μg kg^{-1} in germs. Oil producer's data showed that the level in crude maize oil was almost equal to that in maize germs. Levels up to 1810 μg kg^{-1} were found in crude maize oil produced in the first quarter of 2007.

Residues of Previous Cargoes

The general principle is that the transport of both crude and fully refined oils and fats is only permitted in conveyances which are dedicated to foodstuffs. Conveyances include containers, road tankers, rail tank cars, river barges, coastal ships, deep sea vessels, land tanks, direct pipelines, and other handling facilities that may come into contact with the oils and fats. This general principle is applied in the EU and in most other countries.

Intercontinental transport of oils and fats in bulk is carried out in sea going vessels with a capacity of 30 000 to 70 000 ton. This bulk transport of oils and fats represents approximately 30% of the total bulk transport in this type of vessels. A restriction to foodstuff dedicated transport would result in an insufficient availability of ships to serve the overseas oils and fats trade. Therefore, the EU and the international trade have accepted a derogation of the general principle of foodstuff dedicated transport for this type of transport.

In the EU as example, this derogation was based on the following criteria:

1. It should not introduce toxicological concerns for which a threshold is difficult to establish (genotoxic or carcinogenic potential).
2. It is based on efficient procedures to clean ship tanks between cargoes.
3. The residue of the previous cargo after cleaning is diluted in the transported quantity of oil or fat.
4. The validated removal of the previous cargo residue by refining after unloading is considered a pre-requisite for crude and semi-refined oils.
5. It assumes the availability of analytical methods to verify the absence of residues of previous cargoes in the refined oils and fats.

These criteria led to the following set of rules for bulk transport in sea going vessels:

1) For crude and semi-processed oils and fats which are to be further processed before being used for human consumption (further processing has to be refining according to industry standards):
   a) The immediate previous cargo transported in that tank shall have been a foodstuff or a cargo from the list of acceptable previous cargoes, if the oil or fat is transported in a stainless steel tank, or a tank with epoxy resin coating. This list of acceptable previous cargoes is published by the EU and regularly updated.
   b) If the oil or fat is transported in a tank of a different material than those mentioned under (a), than the three previous cargoes transported in that tank shall have been a foodstuff, or a cargo from the list of acceptable previous cargoes.
   c) The buyer must obtain access to written information on the three previous cargoes carried in the relevant tanks.
2) For fully refined oils which are not further processed before being used for human consumption:
   a) If the ships tank is stainless steel or epoxy resin coated, the three previous cargoes transported that tank shall have been foodstuffs.

b) In all other cases, the transport must be dedicated to foodstuffs only.

The international trade of oils and fats is using standard contracts. In particular the standard contracts issued by FOSFA (Federation of Oils, Seeds, and Fats Associations Ltd, London, UK) contain conditions similar to those mentioned above.

Heavy Metals and Dioxins

The presence of heavy metals in crude oils and fats may originate from the oil crop due to uptake from the soil. Contamination risk during processing and transport of oil crop and during transport and handling of crude oil is very limited since heavy metals are not used in contact materials in this supply chain. Crude oil analyses confirmed that heavy metals are seldom present at detectable levels. Metals like iron and copper are commonly present in crude oils and fats, however, these metals only affect quality (they are catalysts for oxidation) but not health.

Monitoring programmes for dioxins, furans, and dioxin like PCB's showed levels well below the allowed level for oils and fats intended for direct human consumption. Only crude fish oil may contain relatively high dioxin levels due to concentration of dioxin in the fish feed chain.

Crude Oil Risk Matrix

The crude oil risk matrix, shown in Table 2, gives the risk classification (high, medium, or low) for presence of a contaminant in a crude oil, in case the origin of this crude oil is unknown. Knowledge of practices or procedures in dedicated supply chains may further reduce the risk classification in case these practices reduce contamination risk. The crude oil risk matrix can be used to determine the frequency of contaminant analyses in crude oils. The proposed frequencies are:

- High risk → check every delivery
- Medium risk → quarterly monitoring
- Low risk → annual monitoring

Crude oils and fats limits are set for pesticides, hydrocarbons of mineral origin, and previous cargoes.

- The pesticide level in the crude oil should not exceed the MRL for the pesticide/oilseed combination after correction by the concentration factor occurred during oil extraction (to be confirmed by updated EU regulation).
- The level of hydrocarbons of mineral origin should not exceed the limits defined by the industry (see above section on hydrocarbons of mineral origin).
- Previous cargoes are checked by comparing the previous cargo from the ship's logbook with the EU or FOSFA positive list of allowed previous cargoes, taking into account the construction material of the ship tanks. This activity is normally performed by an independent superintendent.

The other contaminants have no legal or industry limits in crude oil, but are regulated in the fully refined product. The

Table 2 Crude oil risk matrix. This shows the risk classification for contaminant presence in a crude oil, in case the origin of this oil is unknown. The matrix can be used to determine the frequency of analyses. Examples of limits are given for the EU

	Pesticides	*PAH*	*Mineral oil in edible oil imported in EU*	*Previous Cargoes in sea going vessels*	*Dioxins and PCBs*	*Aflatoxins*	*ZEN*
LIMIT	*> MRL*		*FEDIOL Code of practice*	*EC/4/2004*			
Soybean oil							
Sunflower oil							
Rapeseed oil

Olive							

		Occurrence	Monitoring frequency:
High risk		Regularly (> once a year)	Every batch
Medium risk		Occasionally (every 1–5 years)	Minimum once per quarter
Low risk		Seldom (< once every 5 years)	Maximum once per quarter
Regulated		Not applicable	Every batch

crude oil analytical results are therefore the input for the process validation for contaminant removal.

Refining Process Validation for Contaminant Removal

The levels of most contaminants are regulated for fully refined oils but not for crude oils. The refining process validation will assure that the contaminant level in the fully refined oil is below regulated limit, even for the crude oil feedstock with the highest observed contaminant level. The validation process is as follows:

1) The refinery is informed in case of a crude oil delivery with a contaminant level higher than the refined oil limit (or the highest level used in previous process validations) and the contaminated lot is blocked.
2) A minimum batch of contaminated oil is processed in the refinery using the standard refining recipe. The contaminant levels are analyzed in deodorized end product (and preferably also after the intermediate refining steps).
3) The crude oil is de-blocked and the whole lot can be processed if the contaminant level in the deodorized oil is below regulated limit. The validation process needs to be repeated with modified process conditions if the contaminant level in the deodorized oil is still too high. Alternatively, the crude oil can be sold for non-food application (feed or bio-fuel) in case removal is technically or economically not feasible.
4) This validation process needs to be repeated for every delivery of crude oil with a contaminant level higher than the levels used in previous process validations.

Pesticide Residues Removal

Pesticide concentrations will reduce during the refining steps. The effect of each step on residual level depends on the physical/chemical properties of the pesticide.

Water soluble pesticides dissolve in the alkaline solution during neutralization and are removed with the soap stock.

Some pesticides (e.g., Pirimiphos-methyl) are absorbed by acid-base interactions onto the bleaching earth.

Volatile pesticides are removed with the steam during the deodorization process. All organophosphorus insecticides have a higher volatility than free fatty acids and will be removed at increased temperatures (220–270 °C).

Figure 4 gives an example of a process validation experiment for pesticide removal.

Poly-Aromatic Hydrocarbons Removal

Poly-Aromatic Hydrocarbons (PAH) are removed by active carbon dosing in the bleaching process. Volatile PAH will be additionally reduced during high temperature deodorization. The volatility depends on the number of aromatic groups in the PAH compound; 4 or less are called light PAH, while 5 or more are called heavy PAH. The tracer compound BaP has 5 aromatic groups and is a heavy PAH. For example: The current EU regulation sets limits for PAH levels for oils and fats intended for direct human consumption or used as ingredient in food. The current EU limits are: A limit of 2 ppb for BaP and an additional limit of 10 ppb for 4 specific PAH including BaP.

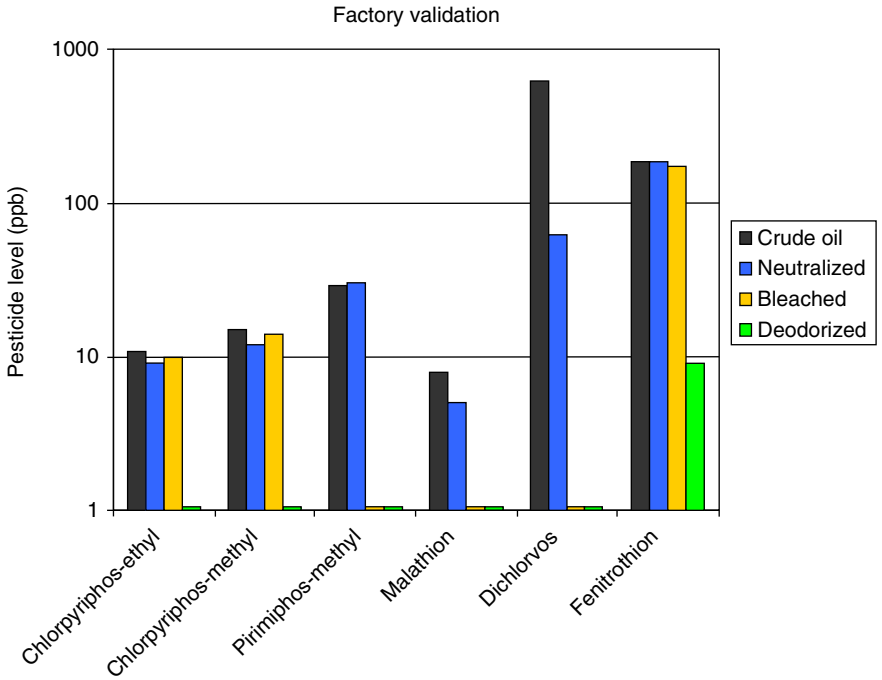

Figure 4 An example of process validation of pesticide removal. The graph shows the levels of the pesticides present in the crude oil and the levels after neutralization, bleaching, and deodorization.

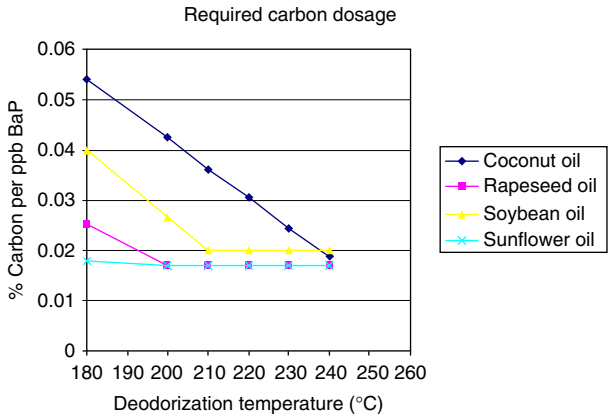

Figure 5 Process validation for BaP removal. The graph shows the percentage of active carbon, per percentage of BaP in the crude oil, needed to reduce BaP below the legal limit of 2.0 μg kg^{-1} and the total of 13 tested PAH below 25 μg kg^{-1}. The horizontal axis gives the deodorization temperature; this mainly influences the light PAH.

Light PAH will be partly removed during deodorization, the degree of reduction depends on deodorization temperature (approximately 50% reduction at 180 °C, up to 90% reduction at 240 °C).

There are two ways for determining the required active carbon dosage for PAH removal:

a. Measure the BaP content in every incoming parcel of oil and add active carbon according to experience from previous process validations. Figure 5 shows the results of process validations performed in Unilever refineries.
b. If BaP analysis is not available (on time), the dosage should be based on a realistic worst case BaP level in the crude oil. The standard active carbon dosage will then be the dosage of the successful process validation performed with this worst case crude oil.

Removal of Hydrocarbons of Mineral Origin

Hexane (C6) is partly removed by the vacuum systems of neutralization and/or bleaching whereas the remainder is removed in the deodorizer to a level below the detection limit (0.1 mg kg^{-1}).

Gasoline has never been detected as chemical hazard in crude oils and fats. Therefore, the refining process has never been validated for gasoline removal. However, experiences with compounds of a similar or even lower volatility indicate a complete removal during deodorization.

The upper limit for presence of mineral oil mid fraction (C10–C24, including kerosene and diesel) in crude palm oil is 25 mg kg^{-1}. Process validation has shown that this level can be reduced to below detection limit (10 mg kg^{-1}).

Mineral oil fractions with a carbon number above C24 will hardly be removed in the refining process. The physical and chemical properties of these components differ insufficiently from the properties of edible oils and fats to enable separation.

Mycotoxins Removal

Aflatoxin Removal

Both the chemical and physical process sequence will reduce the aflatoxin levels to below the detection limit (1.0 μg kg^{-1}). The processes that are responsible for aflatoxin reduction are neutralization with lye (in chemical refining) and bleaching. The activated bleaching earth is responsible for the removal during bleaching; addition of active carbon will hardly increase the separation efficiency. Deodorization, even at high temperature, gives only a modest contribution to aflatoxin removal. The EU limits for aflatoxin in oils and fats intended for direct human consumption or as ingredient in food are: Maximum 2.0 for aflatoxin B_1 and maximum 4.0 for the sum of aflatoxins B_1, B_2, G_1 and, G_2.

Zearalenone Removal in Maize Oil

The refining process will largely reduce the Zearalenone (ZEN) content in maize oil, however, a complete removal will not be obtained under standard refining conditions. Additionally, the removal efficiency depends on the refining process used (chemical or physical). Chemical refining will remove 80–98% of ZEN whereas the removal efficiency of physical refining varies between 70% and 80%. The EU limit for refined maize oil is 400 μg kg^{-1} based on ALARA principle.

Other Contaminants

Residues of Previous Cargoes

The validated removal of substances by a standard refining process is one of the criteria for the acceptance of these substances as allowed previous cargo. Further refining process validation is therefore not required for the substances on the allowed (positive) list. Oils and fats cannot be accepted for food use (even after refining) when the previous cargo is not on the positive list.

Heavy Metals

Heavy metals are seldom present at detectable levels in crude oils and fats. Therefore, the refining process cannot be validated for heavy metal removal except in exceptional cases where heavy metals are present in the crude oil. Metals like iron and copper are effectively removed by neutralization and bleaching with acid pre-treatment. It is assumed that also heavy metal levels will be reduced by these processes. The EU has only regulated the level of lead in oils and fats (maximum 0.1 mg kg^{-1}).

Dioxins

The dioxin level in fish oil is reduced by active carbon addition during bleaching followed by deodorization at moderate temperature (maximum 190 °C to limit isomerisation). The EU sets limits for the sum of dioxins and dioxin like PCBs, taking into account the toxicity equivalents of the individual compounds. The limit for the sum of dioxins in vegetable oils and fats is 0.75 pg g^{-1} (WHO PCDD/F-TEQ) and 1.5 pg g^{-1} (WHO PCDD/F-TEQ) for the sum of dioxins and dioxin like PCBs. The limits for fish oil are higher: Sum of dioxins is 2.0 pg g^{-1} (WHO PCDD/F-TEQ) and 10.0 pg g^{-1} (WHO PCDD/F-TEQ) for the sum of dioxins and dioxin like PCBs.

Table 3 The refining link table. This table summarizes process validation experience of contaminant removal. Examples of limits are given for the EU

Contaminants	*Hydrocarbons < C20*	*Hydrocarbons > C20*	*PAH (BaP)*	*Pesticides*	*Aflatoxin B1*	*Zearalenone*
Legal or industry	*LOD*	*LOD*	*2.0 μg kg⁻¹*	*MRL or LOD*	*2.0 μg kg⁻¹*	*400 μg kg⁻¹*
Crude oil						
Degumming Neutralization					93%	
Bleaching					77%	
Deodorizaton						

= Chemical refining.
= Physical refining.
= Chemical and physical.

Refining Process Validation Experience

The refining process validation experience can be summarized in a refining link table (see **Table 3**). This link table shows the contaminants, the regulated or industry limits in refined oil, and the process step which reduces the concentration of this contaminant in the product. This link table gives a quick reference for process optimization and trouble shooting. It can also be the basis for the application of the hazard analysis and critical control points system in an oil processing plant.

Conclusions

Contaminant levels below the legal limit or industry standard can be assured by the combination of preventive measures (good agricultural practices, crude oil analysis, and validated refining processes). This system should be regularly checked by internal and third party (customer) audits and by monitoring of the contaminant levels in the refined product. Crude oil supply hazard analyses should be periodically repeated by a combination of supply chain visits and analyzing of crude oils for a wide range of potential oil soluble contaminants.

At the end, consumer good manufacturers are responsible for the quality and food safety of the products they put on the market. They may not own the supply chains of their ingredients but they need to assure the food safety by participation in determining and controlling the preventive measures.

SAFETY OF FOOD AND BEVERAGES

Spices and Seasonings

J Farkas and Cs Mohácsi-Farkas, Corvinus University of Budapest, Budapest, Hungary

Glossary

Water activity Water activity (a_w) is an equlibrium parameter defined as $a_w p_{food}/p_{water}$, where p_{food} is the partial pressure of water over a food at a given temperature and p_{water} is the vapor pressure over water at the same temperature.

Definition and Classification

Spices are a large number of plant products or blends thereof used for flavoring, improving fragrance, and other sensorial properties of foods. From a food safety point of view, the importance of spices and seasonings/condiments depends on the dietary habits of the communities. Although in certain countries they are only used as minor food ingredients, in other areas they constitute an important part of the daily menu for some societies and are consumed in considerable quantities. The so-called ethnic foods which feature a variety of spices, seasonings, and condiments become more-and-more a part of the mainstream consumption pattern. Many spices are of tropical or subtropical origin. Certain spices improve color qualities or may extend shelf-life of foods by their antioxidant and antimicrobial activities. Some dehydrated vegetable seasonings (e.g., onion and garlic powders) can be discussed collectively with spices.

Spices and seasonings are a chemically and histologically heterogeneous group of commodities which are important items of the international trade. Their extracts and oleoresins are also generally recognized as safe (GRAS) or approved food additives. The spice industry is global and the regulations and standards differ around the world.

Many spices from developing the countries are sourced from thousands of farmers who grow, harvest, and dry spices on small plots of land. Some spices grow wild and are gathered in many different areas from the source country. Most of these countries lack the infrastructure for modern food production, have problems with pollution, and lack clean potable water.

Spices are classified according to the parts of the plants from which they are derived, such as seeds (e.g., anise, caraway, and coriander), fruits (e.g., capsicums and cardamom), berries (e.g., peppers and allspice), flowers (e.g., camomile), leaves (herbs) (e.g., bay, basil, peppermint, oregano, and thyme), roots (e.g., horseradish), and rhizomes (e.g., ginger). Various spices require widely diverse harvesting and post-harvest methods which affect the microbial content in different ways. A list of some frequently used spices is given in Table 1.

Table 1 List of some frequently used spices

Common name	*Parts used*	*Form used*
Allspice (pimento)	Fruit	Whole or ground
Anise	Fruit	Whole or ground
Basil (sweet)	Leaves	Whole or ground
Bay (Laurel)	Leaves	Whole or ground
Capsicum (chili)	Fruit	
Caraway seed	Seeds	Whole
Cardamom seed	Fruit	
Cassia	Bark	Ground
Cayenne	Fruit	Whole or ground
Celery seed	Fruit	
Chervil	Leaves	
Cinnamon	Bark	Ground
Cloves	Flower bud	Whole or ground
Coriander seed	Fruit	Whole or ground
Cumin seed	Seed	Whole or ground
Dill seed	Fruit	Whole
Fennel seed	Fruit	Whole or ground
Fenugreek	Fruit	Whole or ground
Garlic	Bulb	Chopped, dried, powdered
Ginger	Rhizome	Dried, ground
Horseradish	Root	Ground
Mace	Aril	Whole or ground
Marjoram	Leaves (part of tops permitted)	Whole or ground
Mustard	Seed	Whole or ground
Nutmeg	Seed	Whole or ground
Oregano	Leaves	Whole or ground
Paprika	Fruit	Whole or ground
Parsley	Leaves	Dried
Pepper (black)	Berry	Whole or ground
Pepper (white)	Berry	Whole or ground
Peppermint	Leaves	
Poppy	Seed	Whole
Rosemary	Leaves	Whole or ground
Sage	Leaves	Whole or ground
Savory	Leaves and tops	
Sesame	Seed	
Taragon	Leaves and tops	Whole or ground
Thyme	Leaves and tops	Whole or ground
Tumeric	Rhizome	Whole or ground

Selected Spices and Seasonings with Particular Importance for Food Safety and International Trade

Berries

Pepper is the most widely used spice. It is a small globular berry of the pepper vine *Piper nigrum* (Piperaceae). The major producers of pepper are Brasil, Malaysia, Indonesia, and India. Black pepper is a dried, unripe fruit of this tropical plant. When the harvested fruits are boiled for a short time in water and dried, they become brownish or black, with coarse wrinkled surface; whereas the seed is almost white adhering to the pericarp. The pepper fruits are aromatic and pungent. White pepper is prepared by soaking the berry and then removing the pericarp and the pulpy covering before drying. White pepper can also be prepared from black pepper corn by grinding off the outer parts. Owing to its irregular surface, black pepper holds more surface dirt than the smoother white pepper, and usually carries larger microbial load.

Bulbs

Garlic (*Allium sativum*) products used as seasonings are garlic flakes, dehydrated garlic powder, and garlic paste. Garlic has a long history of folk use in a wide range of ailments. Its active components are the various sulfur-containing compounds (e.g., alliin, allicin, etc.).

Fruits

Capsicum spices are produced from the dried fruits of the genus *Capsicum* (Solanaceae).

Cayenne pepper and red pepper are the two synonyms of *Capsicum frutescens*, whereas paprika or chili is derived from *Capsicum annuum*. Diverse groups of *Capsicum* cultivars encompass pungent and nonpungent fruits. They also have a large variability for fruit size/shape. The pungency is caused by alkaloids called capsaicinoids whereas the color originates from the carotenoid pigments. The commercial value of paprika and its oleoresin depends mostly on their coloring capacity. Drying of fruit should be performed at a relatively low ($<60\ ^{\circ}C$) temperature. The fruit moisture content of approximately 8% is considered to be optimal because more than 11% moisture content allows mold growth and less than 4% moisture causes extensive color loss. Selecting cultivars with high antioxidant content (Vitamin E as fat soluble and Vitamin C as water soluble) has an effect on reducing color loss. Appropriate cultivars, standardization, and adoption of proper drying and storage conditions are the important quality management factors.

Cumin is the dried, ripened fruit of *Cuminum cyminum* (Apiaceae). The fruits have bristly hairs along the ribs. The crop is threshed and after partial drying, winnowing, sieving, and cleaning, is dried. The principal volatile components are cuminaldehyde and p-cymene.

Coriander is derived from the dried ripe fruits of *Coriandrum sativum* (Apiaceae). The major component of the essential oil of coriander seed is linalool.

Leaves

The olive green to brown bay (laurel) leaves are derived from the plant *Laurus nobilis* (Lauraceae). They are characteristically fragrant when crushed, but taste bitter and aromatic.

Oregano consists of the dried leaves and the flowering tops of *Oreganum vulgare* (Laminaceae). They have a strong camphoraceous odor and a warm, pungent bitter taste. The plant is collected when in flower and dried at less than 35 °C.

Peppermint consists of the dried, dark green leaves and the flowering tops of *Mentha piperica* (Laminaceae). Peppermint has a characteristic aromatic odor and taste, with a cooling sensation while drawing-in breath. The plant is harvested when in bloom and the harvested herb is allowed to dry. After attaining the desired brittleness, the leaves are stripped from the stem, completely dried, and fragmented.

Rosemary is the dried leaves of *Rosmarinus officinalis* (Lauraceae). The upper surface of the leaves is dark green, whereas the lower one is wooly white. The odor of rosemary is aromatic, the taste is pungent, aromatic, and bitter. The rosemary extract shows good antioxidant activity that makes it useful as a food additive.

Sage is the dried leaves of *Salvia officinalis* (Lauraceae). The leaves are gathered for use while the plants are in flower.

Thyme consists of the dried leaves and the flowering tops of *Thymus vulgaris*. Its volatile oil is rich in linalool and terpene hydrocarbons: thymol and carvacrol.

Rhizomes

Ginger is derived from the underground plant part, rhizome, of *Zingiber officinale* (Zingiberaceae). It is harvested in different stages depending on the requirements of the user. There are three primary products of ginger rhizome: (1) fresh or green ginger, (2) preserved ginger in syrup or brine, and (3) dried ginger. Dried ginger is used directly as a spice and also for the preparation of its extracts, ginger oleoresin and ginger oil. Principal volatile constituents are sesquiterpene hydrocarbons, predominantly zingiberene.

Turmeric is obtained from the rhizomes of *Curcuma domestica/Curcuma longa*, also a member of Zingiberaceae. The rhizomes when dried and ground provide a brownish-yellow and flavored powder, which is an important constituent of curry powder.

Curcumin is the principal curcominoid polyphenolic compound that gives turmeric its yellow color. Curcumin acts as a free radical scavenger and an antioxidant, inhibiting lipid peroxidation and oxidative DNA damage. Some studies suggest that curcumin may be useful for prevention and treatment of several diseases, although further studies seem to be necessary to establish the benefit/risk profile of the compound.

Seeds

Fenugreek is the dried seed of the leguminous plant *Trigonella foenum-graeceum* (Fabiaceae). The pods split easily and are threshed to free seeds, winnowed, cleaned, and further dried. Their characteristic components are trigonellin and δ-cadinene.

Nutmeg is the dried, large, oval kernel (nut) and mace is the dried aril surrounding the seed of *Myristica fragrans* (Myristicaceae). The fruits are harvested when split on the tree, or gathered after they have fallen to the ground. Nutmegs are dried in their shells at low (35–40 °C) temperature. Nutmeg is sold as whole nutmeg or further ground to adjusted mesh size for spice powder. Its major volatile constituents are safrole and myristicin.

Sesame is the seed of *Sesamum indicum* (Pedaliacae). The hulled seeds are cream or pearly white in color. The seeds possess a faint nutty odor and taste.

Barks

Cinnamon is the inner bark of an evergreen tree (*Cynnamomum zeylanicum*) whereas cassia is made from the entire bark of a related species (*Cynnamomum aromaticum*). They are used especially in the powdered form.

Production and Primary Processing Methods

Various spices obtained from plants require diverse cultivation conditions, harvest or postharvest methods, as well as primary processing techniques. The main methods of primary processing are cleaning, fermentation, drying, grinding, and extraction. Most spices, like other raw agricultural materials must be dry at harvest or dried quickly after harvest to prevent their spoilage by molds. Fermentation is used for a few products, for example, for cassia bark to facilitate removal of the outer layer and for allspice berries to develop color and appearance.

Spice Oleoresins and Essential Oils

Oleoresins are the concentrated extracts of spices obtained by using organic solvents and evaporating the solvents from the extract in vacuum. Oleoresins contain all of the volatile and nonvolatile flavor components and the natural antioxidants of the spices. Certain extraction methods use extraction with water or aqueous alcohol. The process used for extraction depends on the nature of vegetable matter, and depending on its thermal instability, the operating temperature ranges from ambient to the boiling point. Vibrating the material by means of ultrasonic treatment facilitates, greatly, the dispersion. The CO_2 extraction system uses high pressure and applies either liquid carbon dioxide or supercritical carbon dioxide. This extraction technique is based on good solubility of most odorants and vegetable matters in carbon dioxide and has the advantage that it does not leave residual solvent. It is performed at low process temperature (30–50 °C) and is energy efficient.

Oleoresins are hygienic and can be standardized. However, despite these advantages over ground spices, the sensitivity of oleoresins to light and oxygen is a disadvantage. One approach to overcome this is microencapsulation by spray-drying with specific carrier materials, which convert the oleoresins into a more stable and free-flowing powder.

Oleoresins are free from enzymes, superior to native spices in microbial control, and some of them with high antioxidant capacity may reduce lipid oxidation when used in meat products. However, the product acceptability may be decreased by their too strong taste/flavor.

Essential oils are the volatile aromatic substances prepared by steam-distillation of ground spices. They are comprised of two basic groups of compounds which are hydrocarbons including terpenes, sesquiterpenes, and diterpenes, and oxygenated hydrocarbons such as alcohols, esters, aldehydes, ethers, and ketones.

Oleoresins and essential oils are free from the microbial burden of the natural spices.

Antimicrobial Properties

The composition and content of essential oils, and their antimicrobial activities, vary from spice to spice and even within the same spice depend on agricultural practice, geographic and climatic conditions during the growing season. The major antimicrobials present in some spices and herbs are listed in Table 2.

Spices and herbs that contain the most inhibitory essential oils are cloves, thyme, oregano, cinnamon, allspice, cumin, and caraway. Onion and garlic juices also contain antimicrobial components. Concentrations of essential oils in some spices and antimicrobial activity of active components are given in Table 3. However, these data must be considered with caution because they are derived from different investigations and different test conditions, and many flavor-intense herbs and spices possess too little antimicrobial activity when used in food at organoleptically acceptable concentrations. In general, yeasts are more readily inhibited than bacteria.

Microbiological Contamination and Safety

Microbiological Ecology and Sources of Contamination

Initially, spices and herbs contain those microorganisms which are indigenous to the soil and plants from where they originated and survive the drying process. Dust, insects, fecal material from birds and rodents, and the water used in some processes (e.g., soaking peppercorns in the preparation of white pepper) may be the sources of contamination. Closed drying systems reduce the risk of contamination. Microbial counts are a function of original bioload, proliferation, and die off. Counts frequently decrease during storage of dry spices.

The viable microbial cell counts of spices and herb samples of various origin might show deviations in several log cycles and extremely large variations occur in the microbial count of different lots of the same spice. Black

Table 2 Major antimicrobials present in some spices

Spices	*Antimicrobials*
Allspices	Eugenol
Anise	Anethol
Cassia	Cinnamic aldehyde
Cinnamon	Cinnamic aldehyde
Cloves	Eugenol
Cumin seed	Cuminaldehyde
Garlic	Allicin
Oregano	Thymol, carvacrol
Rosemary	Ursolic acid
Sage	Thymol
Savory	Carvacrol
Thyme	Thymol, carvacrol

Table 3 Concentration of essential oils in some spices and antimicrobial activity of active components

Spice	*Essential oil in whole spice (%)*	*Antimicrobial compounds in distillate or extract*		*Antimicrobial concentration (ppm) lab media*	*Target organisms*
		Compound	*%*		
Allspice (*Piementa dioica*)	3.0–5.0	Eugenol Methyl eugenol	73–79 9.6	1000 (G) 150 (I)	Yeast, *Acetobacter* *Cl. botulinum*
Cassia (*Cinnamomum cassis)*	1.2	Cinnamic aldehyde Cinnamyl acetate	75–90	10–100 (G)	Yeast *Acetobacter*
Clove (*Syzgium aromaticum*)	16.0–19.0	Eugenol Eugenol acetate	72–92	1000 (G) 150 (I)	Yeast *Cl. botulinum* *V. parahaemolyticus*

pepper, turmeric, paprika, allspice, and marjoram are the spices most highly contaminated with bacteria. The aerobic plate count of these spices may sometimes reach the 80–100 millions g^{-1} level. Anaerobes are less numerous than aerobic bacteria.

For certain sectors of the food processing industry (e.g., canning), the contamination of ingredients with heat-resistant bacterial spores is especially troublesome. In some canned foods, the microbiota of the major components consists of relatively heat-sensitive organisms. However, if even a minor ingredient, for example a natural spice, contributes highly heat-resistant microorganisms such as bacterial spores in terms of the process applied, then this item becomes the single most important component determining the bacteriological quality of the product, and control over the finished product involves control over the spore load of this ingredient. Thus, a major concern of the food processors is that the microbial load of ingredients and processing aids do not contribute to spoilage of foods they produce and do not diminish their microbial safety. In many spices, the major part of the microbial load is composed of spores of mesophilic (aerobic) sporeforming bacteria (e.g., *Bacillus subtilis*, *Bacillus licheniformis*, *Bacillus megaterium*, *Bacillus pumilus*, *Bacillus brevis*, *Bacillus polymixa*, and *Bacillus cereus*), because many vegetative cells die during the drying stage whereas spores survive. Thermophilic anaerobes and aerobes are found occasionally, sometimes in moderate numbers. Thus, some spices are potential sources of highly heat-resistant bacterial spores, including thermophilic 'flat sours,' 'putrefactive anaerobes,' and 'sulfide stinkers.' Regarding nonsporeforming bacteria, coliforms are also often found. Generally, psychrotrophic bacteria (growth at 7 °C) are less numerous in spices and herbs than mesophilic ones.

Several seasonings which are used as herbal products/nutraceuticals have been investigated for prevalence of antibiotic-resistant bacteria and a considerable number of the bacterial isolates proved to be resistant to multiple antibiotics.

Mold contamination can also be an important contaminant. White pepper, black pepper, chili, and coriander seem to be most heavily contaminated with molds. The *Aspergillus glaucus* group, *Aspergillus niger* and *Penicillium* spp. are normally prevalent. Molds may grow on spices and herbs before drying or during drying, storing, and shipping. Yeasts have been found in spices in low numbers only.

From the point of view of microbiological stability and eventual mycotoxin formation (see Mycotoxins in Spices), the mold contamination of spices, herbs, and dry vegetable seasonings is of importance. Fungal spoilage of these commodities may occur at high relative humidity and elevated temperature, or, if localized wetting occurs.

Microbial Risks and Outbreaks

Excessive numbers of various bacterial spores introduced with spices into food can induce spoilage if further food processing is not sufficiently severe to inactivate them. Moldy spices may introduce off-flavors and unwanted enzymes, for example, pectinases.

Spices are not the major contributors of foodborne diseases, however, they occasionally contain bacteria that can cause foodborne infections (see Pathogenic Bacteria).

Mold counts of spices may reach the 10^5 propagules per gram level, and a relatively high incidence of toxigenic molds has also been found. Climate changes and global warming is expected to increase the problem of mycological safety of spices.

According to the European Community's Rapid Alert System for Food and Feed (RASFF), 1179 (10%) of the 11 403 hazard notifications were related to the product category 'spices and condiments' during the 4-year period of July 2003 to June 2007. Regarding 'microbiological hazards,' 229 notifications were concerned with this product category.

Pathogenic Bacteria

Among the spore-formers, *B. cereus* and *Clostridium perfringens* that are capable of causing gastroenteritis when ingested in large numbers frequently occur in spices but usually in low numbers. In extreme cases, however, *B. cereus* counts up to 10^5 CFU g^{-1} have been reported. Even when *B. cereus* and *Cl. perfringens* may be present in spices and herbs at counts below 10^3 CFU g^{-1}, they may multiply to high levels (10^5–10^6 CFU g^{-1}) in food to which the spice is added, if the food is inappropriately handled. Thus, rapid cooling of food in shallow containers is important for microbiological safety of seasoned commercial meals.

Several other *Bacillus* spp. that are opportunistic pathogens are more frequently isolated from spices. Because bacterial spores may survive cooking temperatures, ingredients harboring these spores must be considered as a potential health hazard.

Conditions of the growing regions of most spices make them susceptible to contamination by Enterobacteriaceae, including, albeit infrequently, salmonellae and *Escherichia coli*. However, depending on the temperature and water activity, salmonellae can remain viable in spices and condiments for considerably long storage periods. Their presence is of special concern when spices are used in foods that are consumed raw, or when the spices are added to food after cooking. According to the 2005 Food Code, the USA Food and Drug Administration (FDA) considers spices by nature to be ready-to-eat (RTE) products. The general public would not consider spices to be a safety risk and frequently uses them without the benefit of a lethality step, such as cooking at the appropriate temperature and time by boiling, baking, etc.

Salmonella spp. are the most common bacterial pathogens associated with product recalls and outbreaks caused by spices. During the period of 1970–03, the FDA monitored 21 recalls involving 12 spice types contaminated with bacterial pathogens. In all but one instance, the recalled spices contained *Salmonella*. A wide variety of countries were the sources of the recalled spices.

Recent knowledge gathered about microbiology of various low-moisture foods shows that *Salmonella* cells appear to be more tolerant to inactivation procedures and their infectious dose in low-moisture conditions may be very low (often less than 10 CFU g^{-1}), as evidenced by outbreak investigations. In this sense, contamination of dry spices and herbs by *Salmonella* may also present a considerable human health hazard.

A European Commission Recommendation required the Member States in 2004 to perform a co-ordinated program of sampling and testing of dried spices and herbs from the manufacturers, packing centers, and retail premises to gain insight on prevalence of contamination by *B. cereus*, *Cl perfringens* and *E. coli*. Such an assessment has been executed in the United Kingdom and the results have been published. *Salmonella* spp. were detected in 1.5% (2/132) of production batches and 1.1% (31/2833) of retail samples. Overall, 3.0% of the herbs and spices contained high counts of *B. cereus* (1%, $\geq 10^5$ CFU g^{-1}), *Cl. perfringens* (0.4%, $\geq 10^3$ CFU g^{-1}), and *E. coli* (2.1%, $\geq 10^2$ CFU g^{-1}).

Outbreaks

It is not easy to link spices to outbreaks of illnesses because spices are used in so many ways and people do not recall eating them. In spite of this fact, in relation to their contamination, spices, particularly black and white peppers, have been implicated in serious salmonellosis outbreaks in the past decades of the twentieth century in several countries. In 1993, a nationwide outbreak of salmonellosis occurred in Germany following ingestion of paprika-powdered potato chips contaminated with a great variety of *Salmonella* serovars. The majority of cases were in children aged 14 years or less. This largest documented outbreak (an estimated 1000 cases), due to contaminated spices, proved that even extremely low numbers of salmonellae adapted to the dry state were able to cause illness. (A quantitative analysis performed on a sample of the paprika powder yielded 2.5 salmonellae per gram.) The infective dose was estimated at 4–45 organisms with an attack rate of 1 in 10 000 exposed persons. Other outbreaks of salmonellosis have been also linked to the consumption of chili, turmeric powder, aniseed, and curry powder.

Multistate outbreaks of salmonellosis illnesses in 2009/10 in the US connected with white and black peppers and crushed red pepper sparked large recalls of these spices as well as the salami products made with them.

Chemical Safety

Chemical safety of spices and seasonings requires the necessity to minimize the potential for contamination by heavy metals (particularly lead and cadmium), pesticide residues, and mycotoxins.

Heavy metals are usually toxic in low amounts and they can arise, for example, from soil that the crop is grown in. Once they become incorporated into the food they cannot be removed.

Pesticide residues found in spices and herbs are mainly organo-chlorine compounds, organo-phosphorus compounds, and carbamates.

Adulteration of certain spices, i.e., the intentional addition of an adulterant to make the product seem more attractive or valuable, may occasionally also be a public health issue when a toxic substance is added to them as an adulterant (e.g., Sudan Red pigment to curcuma/turmeric).

In 2003, chili powder and related products in the European market, which originated in India, turned out to be contaminated with Sudan I–IV. This chili powder was incorporated into various sauces, which were then used as ingredients in a range of ready meals. The withdrawal of more than 1000 products involved a significant cost for the food industry.

More detailed aspects of chemical safety can be found in other articles of this encyclopedia. However, mycotoxin contamination and certain naturally occurring toxicants are briefly dealt with below.

Mycotoxins in Spices

Mycotoxins are produced by certain molds that can grow on foods such as cereals, nuts, dried fruits, spices, and legumes under certain environmental conditions – usually at high moisture levels – at various points within the supply chain. Different mycotoxin-producing molds exist in temperate climates and tropical climates. Mycotoxins can be produced both before and after harvest and most mycotoxins are stabile and survive food processing. Products of countries with a warm and humid climate and poor storage conditions are especially susceptible to fungal contamination and development, which can lead to accumulation of mycotoxins. The most commonly observed mycotoxins include the aflatoxins and ochratoxin A. Permitted legal limits for aflatoxins and ochratoxin A have been established, for example, by the EU legislation. The problem is that mycotoxins are seldom uniformly distributed throughout food or feed commodities. Therefore, appropriate sampling procedures are needed to obtain an estimation of mycotoxin contamination and the measurement uncertainty has to be taken into account when comparing the observed levels of mycotoxins with legal limits.

By the 1970s, several authors had found aflatoxins in a range of spices (black pepper, ginger, turmeric, celery seed, and nutmeg) although the levels of aflatoxins recorded were generally low. However, pepper was implicated as the source for the toxigenic *Aspergillus flavus* and for high level of aflatoxins in sausages and pepper cheese. Aflatoxins, which are carcinogenic compounds, are produced by *Asp. flavus* and *Aspergillus parasiticus*.

Although certain spices and herbs, especially cinnamon, cloves, and possibly oregano and mustard, inhibit mycelial growth and subsequent toxin production, others, particularly sesame seed, ginger, and rosemary leaves appear to be conducive to aflatoxin occurrence.

Besides aflatoxins and ochratoxin A, zearalenone, fumonisins and trichotecenes have also been found in certain spices. In the 2003–2007 period, 161 notifications were related to mycotoxin hazards in the 'spices and condiments' product category in the frame of the European Community's RASFF rapid alert reporting system.

Other Naturally Occurring Toxicants

Phytochemicals present in commonly consumed plant foods are normally nontoxic, some of them even have the potential for preventing chronic diseases. Some spices have been used historically from ancient medicine even up to current clinical trials. However, besides mycotoxins, potential risks and adverse effects of some spices are also studied. There are a number of naturally occurring compounds in spices, as in other food items, that are carcinogenic or have some other toxic or detrimental effect. These compounds are present in low concentrations, therefore a grossly exaggerated consumption of the food, usually over an extended period of time, is required before their toxicity can be translated into a hazard.

Coumarin is a natural flavoring that is found in small concentrations in many plants. It occurs in higher concentrations (up to 5%) in the types of cinnamon grouped together under the name 'cassia cinnamon'; in contrast 'ceylon cinnamon' only contains low levels (0.45%) of coumarin. According to the risk assessment by the Federal Institute of Risk Assessment (BfR), Germany, there is some risk of moderate liver inflammation of particularly sensitive individuals by consuming relatively small amounts of coumarin. However, the effects are reversible. Thus, it is advisable that, for example, cinnamon biscuits which contain considerable concentration of this flavoring should be eaten in moderation. The BfR and the European Food Safety Authority established a tolerable daily intake (TDI) as 0.1 mg coumarin per kilogram body weight per day.

Safrole is a compound naturally occurring in a variety of common spices (e.g., star anise, cumin, black pepper, ginger, cinnamon, and nutmeg) and herbs such as basil. This compound has been shown to be carcinogenic in rodents and several of its metabolites are mutagens. However, mutagenicity of some spices due to presence of safrole can be destroyed during drying, or during cooking or irradiation. In the US, safrole was once widely used as a food additive in root beer and other common goods, but was banned by the FDA after its carcinogenicity in rats was discovered.

Nutmeg is widely used as a traditional medicine in the Middle East and Asia. However, nutmeg contains myristicin, a hallucinogen that is not toxic in small amounts but can cause death when taken in excess. Thus, children may be at risk where nutmegs are widely available as a cooking additive, or in the course of its use in traditional medicine if overdose occurs. However, based on the available data, it seems unlikely that the intake of myristicin from essential oils and spices in foods, estimated to a few mg per person per day, would cause adverse effects in humans.

Anethol, the major volatile oil component in anise and fennel has been found to have estrogenic activity. Sage and parsley have also been shown to have estrogenic property.

Some spices (mustard, celery, and sesame seeds, and, even coriander) have been classified as having potential allergenic

properties. Certain consumers have allergenic reactions to the presence of sulfur dioxide traditionally used within the spice industry either to improve the visual appearance of spices or as a pest prevention method. In the EU, if a spice contains more than 10 ppm of sulfur dioxide residues then it has to be clearly labeled as such.

Control Measures

Managing the supply chain is a key to ensuring clean, safe spices using good agricultural practice (GAP), good manufacturing practice (GMP) (including pest management), and hazard analysis and critical control point (HACCP) programs.

Herbs and spices should be grown on soils where heavy metal levels are low, and any possible contamination with heavy metals during preharvest and postharvest operations should be avoided.

Prevention of microbial contamination of spices and seasonings and outbreaks thereof lies in the application of good hygienic practices during growing, harvesting, and processing 'from farm to fork' and an effective decontamination as risk mitigation. The International Organisation of Spice Trade Association (IOSTA) issued General Guidelines for Good Agricultural Practices for Spices in 2008.

Although testing of spices for pathogens, including *Salmonella*, may be useful to screen for high rates of contamination, it cannot eliminate risk because negative results do not always ensure safety. The International Commission on Microbiological Specification for Foods (ICMSF) has published more information and a decision tree on this subject.

Microbial Decontamination Methods

All the problems described above have led to attempts to reduce the viable cell counts of spices and seasonings by a decontamination treatment. A 'Guide for the Microbiological Quality of Spices and Herbs Used in Processed Meat and Poultry Products' has been prepared for the Codex Committee on Processed Meat and Poultry Products. This Code contains recommended procedures for the decontamination treatment together with the end-product specifications of spices and herbs to improve and assure their utility in processed meat and poultry products.

Fumigation with ethylene oxide routinely, or, to a lesser extent, propylene oxide, was practised for many years but it has been banned in many countries because the fumigants are now recognized as potential carcinogens.

Satisfactory decontamination of certain spices is possible by various heat treatments, particularly, 'steam sterilization' under superheated steam and subsequent drying and cooling, but many spices and seasonings may suffer serious loss of quality (flavor, color) from less sophisticated methods of heat processing.

Efficient treatment of spices and seasonings by ionizing radiations on commercial scale is also a reality in numerous spice-producing and spice-importing countries. Radiation decontamination is dealt with in another article ('Food Irradiation') of this Encyclopedia.

SAFETY OF FOOD AND BEVERAGES

Oilseeds and Legumes

E Sedaghati, Vali-e-Asr University of Rafsanjan, Rafsanjan, Iran
H Hokmabadi, Iranian Pistachio Research Institute, Rafsanjan, Iran

Glossary

Cross-contamination Cross-contamination occurs when microbes or pesticides are transferred from a contaminated surface to a one which is not contaminated.

Genetically modified organisms (GMOs) GMOs or genetically engineered organisms (GEOs) are organisms whose genetic material has been altered using genetic engineering techniques.

Maximum residue levels (MRLs) The upper legal levels of a concentration for pesticide residues in or on food or feed based on good agricultural practices and to ensure the lowest possible consumer exposure.

Introduction

Vegetable oils are a kind of oil made from many different plants. They are used in food and for cooking. Some kinds of plant oils that people use are African oil palm, maize, olive, peanut, rapeseed, soy, and sunflower. Margarine is an artificial butter made from vegetable oil. Oilseed crops are grown primarily for the oil contained in the seeds. The oil content of small grains (e.g., wheat) is only 1–2%; that of oilseeds ranges from approximately 20% for soybean to over 40% for sunflower and rapeseed. The major world sources of edible seed oils are soybeans, sunflowers, rapeseed, cotton, and peanuts. Edible vegetable oils are used as salad or cooking oils, or may be solidified to make margarine and shortening. These products supplement or replace animal products (e.g., butter and lard), to meet the needs of an increasing world population. Although there are many uses for industrial vegetable oils, total world production is only approximately 3% of that of edible oils. This summary report provides risk factor associated with oilseeds and legumes. All commonly known oilseed plants include soybeans, sunflower seeds, cottonseeds, flaxseeds, sesame, and canola seeds.

Legumes have been widely grown and seeds of legumes are used as human food, to provide calories and protein. The legumes used by humans are commonly called food legumes or grain legumes. The food legumes can be divided into two groups: the pulses and the oilseeds. Pulses consists of dried seeds of cultivated legumes, which is being consumed from a long time. The oilseeds consists of those legumes used primarily for their oil content that may be extracted by pressing or by solvent extraction. The oil is known as vegetable oil and is used as cooking oil. The residue, called 'oil cake', normally has high protein content and is used as food and animal feed. Generally, legumes can be classified into those that are relatively low and high in edible oil. Several crops from both the groups may be eaten raw as cooked or green vegetables, but invariably are harvested as dried grains. The most widely cultivated legumes are the two principal oilseeds: soybean and peanut. In 2008, they represented approximately 75% and 16%, respectively, of the total world production of grain legume crops. The other dried legume grains, mung bean, chickpea, pigeon pea, cowpea, etc. represent only 9% in the same year (Tables 1 and 2).

Legume cultivation in developed countries is mechanized, starting from planting, harvesting, handling, storage, and processing. But legume cultivation in developing countries use traditional methods and they incur postharvest losses of approximately 20–25%. The traditional processing and utilization of legumes also require further research attention.

Sources of Oilseed and Legume Contamination

There are four main types of food contaminants: microbiological, chemical, physical, and genetically modified (GM) foods. Foods can become contaminated during growth and harvesting of raw materials, storage and transport to the factory, and processing into finished products. The final product may then become recontaminated during subsequent storage and

Table 1 World oilseed production

Oilseeds	*Production quantity (million metric tons)*
Dry bean	18.82
Faba bean	3.26
Chickpeas	8.28
Cowpeas	5.19
Lentils	2.07
Pigeon peas	3.75

transport to shops, and during storage and preparation by the consumer. The main sources of contamination are the environment, animals, and people. The main transmission routes (vectors) of contamination are contaminated surfaces, air, water, people, and pests. Processing, packaging material and equipment, and transport vehicles may also act as vectors. Public health concern with foodborne diseases emerged around the 1880s. This was after the microorganisms had been found to be infectious agents. Pathogenic microorganisms are the major safety concern for the food industry. The vast majority of outbreaks of food-related illness are due to microbes.

Beside the microorganism contamination, transgenic plants are another aspect concerning food safety. The term GM foods or GM organisms (GMOs) is most commonly used to refer to crop plants created for human or animal consumption using the latest molecular biology techniques. These plants have been modified in the laboratory to enhance desired traits such as increased resistance to herbicides or improved nutritional content. The enhancement of desired traits has traditionally been undertaken through breeding, but conventional plant breeding methods can be very time consuming and are often not very accurate.

The development of the modern molecular plant breeding methods that employ DNA technology and DNA-mediated transformation provided breeders with a powerful tool for crop improvement. Over the past dozen years, transgenic crops that are resistant to insects, viruses, fungi, bacteria, and herbicides have increased yields and profitability of agriculture, and reduced the environmental impact of agriculture, in both developed and developing countries. Plant breeders have also used the technology to improve the nutritional value of crops designed to reduce malnutrition and improve health. To date, transgenic high-lysine maize and oilseeds with modified oil content are being planted; many nutritionally enhanced crops are undergoing development and testing. The key areas of controversy related to genetically engineered (GE) food are food safety, the effect on natural ecosystems, gene flow into non-GE crops, and corporate control of the food supply. It is not possible to make general statements on the safety of all GM foods.

A Food Safety Perspective on Novel Foods

Transgenic crops are subjected to rigorous premarket safety assessment, in spite of the fact that they can be less GM than crops produced by other modalities of breeding. They pose no new or different risks to humans or animals. Precautionary regulation was triggered because these crops were considered to be novel foods (foods that humans had not previously consumed). This definition is itself debatable because it is fair to ask if an organism into which one or two genes have been added to 20 000 or 30 000 genes in the plant genome makes the plant a novel food. Some degree of care and safety consideration should be taken before one consumes a food that one has never seen before and which is not commonly eaten.

Mycotoxins and Food Safety

Mycotoxins found primarily in grains, tree nuts and groundnuts, oilseeds, legumes, juices, and wine, can also be passed through animals into products such as milk. It has recently been suggested that the adverse health effects of two classes of mycotoxins, fumonisins and aflatoxins, have been seriously underestimated, particularly in many developing countries where products that are prone to mycotoxin contamination make up for a large portion of the diet.

The Safety Issue of Pesticide Residues in Food

A pesticide is any product that kills or controls various types of pests. A pest is defined as a plant or animal that is harmful to man or the environment. Pesticides may be used in a variety of different ways during the production of food. Sometimes, small amounts of pesticides used in these ways can be found in or on foods. The pesticides found in or on foods are called 'residues.' Some pesticides, even though no longer used, persist and remain in the environment. Residues of these pesticides are sometimes found on food grown on contaminated soil, or in the fish that live in contaminated waters. The consequences of using pesticides for food production and the realization that some foods do contain pesticide residues are of paramount importance to today's health-conscious consumer. Specifically, the public continues to voice its concerns by ranking pesticide residue as one of the top five food safety issues. Pirimiophos-methyl was also the most commonly detected substance in sunflower seeds more than the quantification lower limit in 20–39% of samples. The mean concentration of pirimiophos-methyl in sunflower seeds is 19–25 $\mu g\ kg^{-1}$. Dichlorvos and malathion were detected in excess amounts of the maximum residue levels (MRLs) in 18% of samples of sunflower seeds and 18% of samples of rapeseed, respectively.

Pesticides Residues Arise from Cross-Contamination at Storage

Pesticide residues such as organophosphate insecticides (pirimiophos-methyl, malathion) are found in oilseeds that are mainly used in empty storage facilities and for direct application to stored cereal grains. These residues arise from cross-contamination from storage bins and grain handling equipment of grain stores, and not from illegal use. This uptake

of insecticide residues from their storage environment by oilseeds may lead to residue contents that exceed regulatory limits. The insecticides that were most commonly detected were pirimiophos-methyl, malathion, dichlorvos chlorpyriphos-methyl, and deltamethrin in sunflower. Cross-contamination could have occurred when cereal grains were treated on receipt, when rapeseed was delivered, especially when treatments were done systematically to the cereal grains.

To reduce cross-contaminations, the storage managers had been advised to avoid sharing same receipt circuits when cereals are systematically treated, and to avoid accumulation of risky situations. It is also very important to periodically verify the proper use of insecticide treatment equipment. storage companies should be aware about insecticide cross-contamination, and to understand how cross-contaminations can occur in their silos and how to avoid them. MRLs of pesticides allowed by European Communities Commission (ECC) are 0.05 mg kg^{-1} for pirimiophos-methyl, 0.05 mg kg^{-1} for chlorpyriphos-methyl on rapeseed, and 0.1 mg kg^{-1} for deltamethrin in rapeseed. The MRL for malathion in oilseeds is 0.02 mg kg^{-1}.

Oilseeds

Soybean

Soybean (*Glycine max* L. Merr.) is an Asiatic leguminous plant cultivated in many parts of the world for its oil and proteins, which are extensively used in the manufacture of animal and human foodstuffs. Soybean rank fifth in the world production of major crops after wheat, maize, rice, and potato. The major use of soybean as food is its oil, whereas the 96% of soybean meal is used as animal feed.

Soybean Mycotoxin Contamination

Soybean is often attacked by fungal infections during cultivation or postharvest. These fungi can be potential mycotoxin producers. The most frequently studied mycotoxins are produced by species of *Aspergillus*, *Penicillium*, *Fusarium*, and *Alternaria*. The occurrence of fungi in soybean seeds has received far more attention than the occurrence of fungi in pods and flowers. This is understandable from a practical standpoint: Infected seeds and infected seedlings developing from them represent greater economic risks in soybean production, and seed contamination with mycotoxins represents a health risk to humans and animals. The *Fusarium* species identified are: *F. equiseti*, most frequently recovered from flowers, pods, and seeds (40%), followed by *F. semitectum* (27%) and *F. graminearum* (11%). Members of *Fusarium* genus are known to produce a broad spectrum of toxins including trichothecenes A and B. Among B-type trichothecenes, deoxynivalenol (DON) and nivalenol are important mycotoxins produced by members of the *F. graminearum* species complex. DON is the most distributed *Fusarium* mycotoxin and occurs worldwide in crops from temperate regions. Most *Alternaria* species are opportunistic plant pathogens. *Alternaria* species are also well known as postharvest pathogens. Some *Alternaria* species are well known for the production of toxic secondary metabolites, some of which are powerful mycotoxins that have been implicated in the development of cancer in mammals. Among these metabolites with mammalian toxicity are alternariol (AOH) and AOH monomethyl ether (AME). Recently it has been reported that AOH and AME possess cytotoxic, genotoxic, and mutagenic properties *in vitro*. Tenuazonic acid (TA) is a mycotoxin and phytotoxin, produced primarily by *A. alternata*. TA has been shown to be more toxic than other mycotoxins produced by *Alternaria* species such as AE, AOH, and AME. These mycotoxins have been demonstrated to be produced by *Alternaria* species on wheat, tomato, sorghum, pecans, sunflower, and cotton.

Natural Contamination of Alternaria *Mycotoxins on Soybean Seeds*

Alternaria toxins have recently received much attention, both in research programs and in risk-assessment studies. From a survey of 50 soybean seed samples evaluated for AOH and AME contamination, it was found that 44% of them were contaminated with AME. AME was found in levels ranging from 62 to 1.153 ng g^{-1}. Although a limited number of samples were evaluated, this data were the first report on the natural occurrence of *Alternaria* toxins in soybean seeds and is relevant from the point of view of animal public health. Also the results showed that AOH and AME are produced on soybean seeds at harvest time. These data agree with other studies in which it has been demonstrated that the environmental conditions optimum for growth and mycotoxin production by *A. alternata* on soybean-base media were similar to those occurring during soybean development in the field until harvest.

Fate of Fungal and Mycotoxin Contamination During Soybean Meal Production Process

Hygienic safety of soybean and by-products depends on fungal contamination among other microorganisms. With respect to fungal contamination, the levels of fungal propagules in all points of the process were no higher than 104 cfu g^{-1}, a value considered safe. However, several potential toxigenic fungi were detected, especially species belonging to the genera *Fusarium* and *Aspergillus*. Among *Fusarium* species, *F. verticillioides* was most frequently recovered (60% of isolates), followed by *F. oxysporum*, *F. subglutinans*, *F. proliferatum*, *F. semitectum*, and *F. graminearum*. The genus *Aspergillus* was the second most frequent genus isolated and the dominant *Aspergillus* species identified belong to the sections *Flavi* (*A. flavus*) and *Nigri* (*A. niger* aggregate). According to the species identified, the natural occurrence of aflatoxins (produced mainly by *A. flavus* and *A. parasiticus*), fumonisins (produced by *F. verticillioides* and *F. proliferatum*), and DON and zearalenone (produced mainly by *F. graminearum*) were analyzed at six points in soybean meal-production process. This result showed that DON contamination of soybean seed occurred at field stage previous to harvest.

The Effects of Isoflavone-Rich Soy Products on Fertility and Hormonal Imbalance

There has been considerable investigation into the effects of isoflavone-rich soy products and isoflavone supplements on hormone levels in both men and women. Decreases of testosterone and estrogen levels might indicate a possible role of soy in reducing prostate and breast cancer, respectively.

However, the proposed chemopreventive effects of soyfoods appear to be due to some other mechanism as the vast majority of studies have shown no effects on hormone levels in response to the intake of soy protein or isoflavones in men or women. Nor is there any evidence that isoflavones contribute to infertility in humans, despite the effects seen in some animals when exposure to isoflavones is very high.

Soyfoods and Breast Cancer Risk

The estrogen-like effects of isoflavones form the concern that soyfoods might be contraindicated for women at increased risk of breast cancer or for those with estrogen-sensitive tumors. More importantly, human data suggest that isoflavones do not exert stimulatory effects on breast tissue. The National Cancer Institute states that, for breast cancer survivors, 'soyfoods, as a part of a healthy diet and in moderate amounts, are safe to consume'.

Soy, Isoflavones, and Thyroid Function

Concerns about antithyroid effects of soy are based primarily on animal studies involving isoflavones. Preliminary results indicate that soy also has no adverse effects on thyroid function in people who are marginally hypothyroid.

Effects of Soy on Mineral Status

Soyfoods are frequently used in place of animal proteins, many of which are good sources of iron and zinc, and of dairy foods, which provide calcium. Consequently, there is a need to understand the impact of soy on mineral status. The consumption of relatively little red meat meets daily iron and zinc requirements, so questions about the effects of soy on the status of these two minerals pertains mostly to those eating a predominately plant-based diet.

Soybeans, like other legumes and whole grains, are high in phytate, which reduces the absorption of some minerals; especially divalent cations. Zinc absorption from soyfoods is only modestly lower than that from other sources. But because soybeans are not naturally rich sources of this mineral, unfortified soyfoods are not particularly good sources of zinc. Because zinc status is difficult to assess, vegetarians are advised to identify good plant sources of zinc in their diet or take a zinc supplement. In contrast to zinc, soyfoods are relatively high in iron. However, new research using improved methodology indicates that iron absorption from soy may be higher than previously thought because most of the iron in soy is in the form of ferritin. Finally, in addition to phytate, soybeans are high in oxalate, another inhibitor of calcium absorption. However, calcium absorption from soy is good despite the presence of oxalate and phytate.

Allergic Reactions to Soy Protein

Soy protein can cause allergic reactions in sensitive individuals. But allergy to soy protein is actually relatively rare. Approximately 1 out of 2500 adults reported having doctor-diagnosed allergies to soy protein. The rate is undoubtedly higher in children.

The Risk of Soybean Transgenic Plant

Transgenic crops are spreading more rapidly than any other agricultural technology in history, suggesting that farmers perceive important advantages in growing them. Developing countries now account for 38% of global transgenic crop area despite continuing controversy surrounding them. The most extensive *ex post* studies of transgenic crop adoption in developing countries have been conducted for insect-resistant (IR) cotton in Argentina, China, India, Mexico, and South Africa. Transgenic herbicide-tolerant (HT) soybeans are being grown in Argentina, Brazil, Paraguay, and elsewhere, but Argentina is the only developing country for which peer-reviewed studies have been published. Some developing countries also produce HT and/or IR maize, but the only peer-reviewed *ex post* analyses of their impacts published so far are for Argentina and South Africa.

Pesticide Residue: Safe Preharvest Interval after Cypermethrin Application

Cypermethrin is a synthetic pyrethroid used as an insecticide on a large scale. Cypermethrin is highly toxic to fish, bees, and aquatic insects, according to the National Pesticides Telecommunications Network. It is found in many household ants and cockroach killers, including Raid and ant chalk. Cypermethrin 10% emulsifiable concentrate (EC) when sprayed at the concentration of 100 g ai ha^{-1} showed a residue level of 0.71 mg kg^{-1} at 0 day followed by 0.52 mg kg^{-1} at 1 day in dry season, which were higher than the recommended MRL of 0.5 mg kg^{-1} set for beans with pods. The average residue level of any insecticides depends primarily on the quantity of its active ingredient. A preharvest interval of 3 days might be considered for dry season. But in case of early wet season where crop canopy was smaller allowing higher deposition of cypermethrin residues on pods, it showed a preharvest interval of 10 days for the safe use. So vegetable soybean should be harvested after 10 days of cypermethrin application to avoid any health risk of consumers.

Peanut

The peanut, or groundnut (*Arachis hypogaea* L.), originated in South America and is now grown throughout the tropical and warm temperate regions of the world. Peanut, an important oil and food crop, is currently grown on approximately 42 million acres worldwide. It is the third major oilseed of the world next to soybean and cotton. China, India, and the USA have been the leading producers for over 25 years and grow approximately 70% of the world crop.

Peanut Food Allergy

Food allergy affects approximately 6–8% of children younger than 4 years of age and approximately 2% of the population beyond the first decade of life. Food allergy accounts for approximately 30 000 anaphylactic reactions, 2000 hospitalizations, and 200 deaths each year in the USA. Allergies to peanuts and tree nuts account for the majority of fatal and near-fatal anaphylactic reactions. A national survey indicated that approximately 1.1% of people are allergic to peanuts, tree nuts, or both. More than 80% of patients were not given appropriate information to avoid accidental, food-induced

allergies. The cause of the rising prevalence of peanut allergy is the growing demand for highly nutritional, 'quick-energy' foods in the diet. Breastfeeding is increasingly common, and peanut products have increasingly been promoted as excellent nutritional sources for pregnant and lactating women. In patients with peanut allergy, approximately 85% had been breastfed and more than 70% had had their first allergic reaction after their first apparent contact with peanuts. Currently, treatment of peanut allergy consists of teaching patients and their families on how to avoid the accidental ingestion of peanuts, how to recognize early symptoms of an allergic reaction, and how to manage the early stages of an anaphylactic reaction. There is some findings about inverse association between consumption of peanuts in the first year of life and the development of peanut allergy. This means that children who eat peanut-containing foods before 1 year of age appear to be protected against peanut allergy.

Mycotoxin Contamination in Peanut

The plant pathogens are of concern not only for their ability to destroy several ergonomically important food crops, but also due to their ability to produce several mycotoxins. These mycotoxins are associated with specific species or subgenera of the *Aspergillus* and are in general toxic to livestock, poultry, fish, and humans. *Aspergillus flavus* is an important storage fungus associated with the deterioration of wheat, corn, rice, barley, bran, flour, soybeans, peanut, and other seeds. It has also been reported as a pathogen of humans and animals and as a plant pathogen. Aflatoxin, a natural toxin and carcinogen, is produced by certain strains of the mold *A. flavus* and *A. parasiticus*. Crops with the highest risk of aflatoxin contamination are corn, peanuts, and cottonseed, but aflatoxins are detected occasionally also in milk, cheese, nuts, almonds, figs, spices, and a variety of other foods and feeds. Milk, eggs, and meat products are sometimes contaminated due to feeding animals aflatoxin-contaminated peanut, corn, and cottonseed feed. Aflatoxins often occur in peanut crops in the field before harvesting. Postharvest contamination can occur if crop drying is delayed and during storage of the peanuts, when excessive moisture produces fungal growth.

Salmonella *Contamination in Peanut*

Salmonella poisoning has dramatically increased since the 1990s. Every year, approximately 42 000 cases of salmonellosis are reported in the USA. It is estimated that approximately 400 persons die each year with acute salmonellosis. The actual number of infections may be many times greater. Children are most likely to get salmonellosis. The rate of diagnosed infections in children less than 5 years old is higher than the rate in all other persons. Young children, the elderly, and the immunocompromised are the most likely to have severe infections. Most persons infected with *Salmonella* develop diarrhea, fever, and abdominal cramps 12–72 h after infection. The bad thing about peanut butter is that because of its fat, the *Salmonella* bacteria can survive for a long time. Some American company recalled their peanut butter, after the Food and Drug Administration and the Centers for Disease Control and Prevention linked 29 *Salmonella* illnesses in 18 states to peanut butter.

Flaxseed

Flax (*Linum usitatissimum*) is a member of the genus *Linum* in the family Linaceae. Almost all domestic flaxseed produced is used for extracting linseed oil. Flax grown for fiber is a different type, and is not suitable for oil production. Flaxseed yields approximately 36% of its weight in linseed oil, with the residual linseed cake or meal used for feeding livestock. The value of linseed oil obtained from flaxseed represents three-quarters of the combined value of the linseed oil and the linseed meal. Linseed oil can be used only for inedible purposes. Flaxseeds are also used as birdfeed. Study on mycoflora of flaxseed in birdfeed market showed that *Aspergillus* section *Nigri*, *Flavi*, *Circumdati* and *Aspergillus* followed by *Fusarium*, *Nigrospora* and *Penicillium* are the most prevalent fungi associated with seeds. Most of these fungi are mycotoxin producers.

Sesame

Sesame seed (*Sesamum indicum*) is grown chiefly in tropical countries; none is grown domestically. Sesame can be used whole, or it can be crushed for oil and meal. In the USA, the whole seed is used primarily as a topping for bakery products, principally in competition with poppy seed, and as a filling in pastries and candy. Some low-grade sesame seed is also used as birdseed. When crushed, sesame seed yields an exceptionally high proportion of superior quality oil (approximately 47% of the weight of the seed).

Allergic Reaction to Sesame

Some people are allergic to sesame seeds and sesame oil. Even some infants have been found to exhibit allergies to sesame. In Australia, the occurrence of allergy to sesame seed was estimated to be 0.42% among all children, whereas in the UK the allergic reaction was found to affect 0.04% of adults. Prevalence of sesame allergy varies per country. While it is one of the three most common allergens in Israel, sesame allergy prevalence is considered small relative to other allergens in the USA. Some experts consider sesame allergies to have 'increased more than any other type of food allergy over the past 10–20 years' in the USA. Such increasing prevalence led Canada to issue regulations that require food labels to note the presence of sesame.

Contamination of Sesame Seed and Tahini with Salmonella

Foods of nonanimal origin, which have been shown to be contaminated by *Salmonella* spp. include coconut, barley, cereal powder, yeast, cottonseed, chocolate, peanut butter, soybean sauce, cider, watermelon, white and black pepper, and watercress. Tahini, a product made from crushed sesame seeds, has been contaminated with *Salmonella* spp. and caused a number of outbreaks worldwide, including New Zealand and Australia. Growing sesame seed crops can be exposed to *Salmonella* from many sources such as soil, manure, irrigation water, wild birds, and animals. Seeds may also become contaminated during the drying process. If the seeds are infected thus, there is a high risk that the Tahini produced also contains the bacteria; not forgetting the risk of contamination if processing was not well controlled and properly monitored.

Thus, illness can be prevented for ready-to-eat seeds by hygienic manufacturing applications in the field, during harvesting and during processing of seeds.

Tahini, or sesame seed paste, is a known vehicle for foodborne bacteria such as *Salmonella*. The substance is high in fats, and therefore provides an ideal home for bacteria, much as peanut butter does. Products that are made with imported sesame pastes have been shown to be associated with *Salmonella* outbreaks and that they should be considered as possible sources of foodborne illness.

Sunflower

Sunflower (*Helianthus annuus* L.) is one of the few crop species that originated in North America. Commercially available sunflower varieties contain from 39% to 49% oil in the seed. Sunflower accounts for approximately 14% of the world production of seed oils. One of the world's major oil-bearing seeds is obtained from the sunflower, a hardy drought-resistant plant well suited to the colder or arid areas where many other oilseed crops cannot be grown. Although primarily used as a source of vegetable oil, sunflower seed is also eaten as an edible snack nut and used in bird feed mixtures. Typical sunflower seed yields oil equivalent to approximately 40% of the weight of the kernel and hull. Consumption of sunflower seed oil was used primarily for salad and cooking oil and secondly for frying and shortening. There are two distinct types of sunflower seed: oil stock and confectionery. The oil stock sunflower seed used to produce oil and meal ('crushed') accounted for approximately 61% and confectionery sunflower seed accounted for 39%.

Allergic Reactions to Sunflower

Allergic reactions to sunflower seeds are rare, but those who are allergic can experience symptoms worse than a peanut allergy. People who are allergic to nuts should make sure their sunflower seeds were not packed in a nut facility.

Sunflower Seed Mycotoxigenic Flora

The following mycotoxigenic fungi and the related mycotoxins were isolated from sunflower seeds: *A. flavus*, *A. flavus* var. *columnaris* (aflatoxin), *A. aureolatus* (sterigmatocystin), *A. quadrilineatus* (sterigmatocystin), *A. melleus* (ochtratoxin A), *A. ustus*, and *Penicillium*.

Pesticide Residues in Sunflower

MRLs of pesticides allowed by European regulations according to ECC are 0.05 mg kg^{-1} for pirimiophos-methyl, 0.05 mg kg^{-1} for chlorpyriphos-methyl on sunflower, and 0.05 mg kg^{-1} for deltamethrin in sunflower. The MRL for malathion in oilseeds is 0.02 mg kg^{-1}.

Cottonseed

Pesticide Residues in Cottonseed

Few people think of cotton as a food. If you drink milk or eat beef or processed foods, you are likely an indirect consumer of a crop that is grown and regulated with slight attention to its importance as a foodstuff. Chemicals that have been banned for food crops are still being used on cotton. Some extremely toxic pesticides are sprayed on cotton than on any other crop. The industry view is that pesticide residues are removed from cottonseeds during their chemically intensive processing: The seeds are washed with caustic lye or sodium hydroxide and the oil is extracted with hexane, a highly volatile solvent, and is then filtered through sulfuric acid-laden clay. Cottonseed oil is sometimes extracted with a mixture of hexane and benzene, a known carcinogen that is very difficult to remove. Residues from pesticides such as the defoliant have frequently appeared on cottonseed and other cotton by-products. The most direct entry for pesticides into the human food supply is through the spent seed hulls and gin trash that are regularly fed to cattle. Estimation of the risk of pesticide residues in cotton products and meat consumed from pastures adjacent to cotton fields showed that the following parameters affect the residues: rate of application, frequency of usage, timing of application, partitioning into lipid (fatty) phases from water, and persistence in plants. Study the residues of different insecticides in lint and cottonseed showed that endosulfan was detected in all samples of lint for the first and second picking, respectively. Low levels of cypermethrin were also detected in some lint samples. The residues of organophosphate insecticides were detected in 12% and 33% lint samples from first and second picking, respectively. Chlorpyriphos was detected in 30%, quinalphos in 20%, triazophos and profenophos each in 8%, and malathion in 1% of the samples. Analysis of cottonseed from the same samples showed low levels of endosulfan residues in nine and seven samples ranging from Tr-0.070 μg g^{-1} to Tr-0.081 ng g^{-1} for the first and second picking, respectively. Cypermethrin (0.06 μg g^{-1}), chlorpyriphos (Tr), and quinalphos (Tr) each were detected in only one sample of cottonseed.

Cottonseed Aflatoxin Contamination

Aflatoxins are primarily produced by the fungi *A. flavus* Link and *A. parasiticus*. Optimal thermal conditions for fungal growth are 36–38 °C, whereas maximum toxin production occurs at 25–27 °C. Growth in storage facilities is favored by humidity above 85%. Because suitable conditions for its growth and toxin production occur in most areas, aflatoxin contamination of food is a universal problem across the world.

Transgenic Cotton

There are concerns relating to the safety of transgenic food for human consumption. Worldwide, most transgenic crops are grown in developed countries (76% of total area) and 24% in the developing countries. Four countries, the USA, Argentina, Canada, and China, grew 99% of the global total of transgenic crops in 2000. Most of this area is divided among four crops: soybean (58%), maize (23%), cotton (12%), and oilseed rape (7%). China, where some 7.5 million small farmers are growing IR cotton, represents the most successful case so far in terms of productivity, farmer incomes, equity, and sustainability.

Legumes

Legumes are plants in the family Fabaceae (or Leguminosae), or fruits of these specific plants. Farmed legumes can belong to

many agricultural classes, including forage, grain, blooms, pharmaceutical/industrial, fallow/green manure, and timber species. Well-known legumes include alfalfa, clover, peas, beans, lentils, Mesquite, soy, and peanuts.

Pea

Risk Assessment for GM Pea

GM field peas underwent a number of tests during development: (1) laboratory and glasshouse tests; (2) performance studies in the field; (3) feeding trials; and (4) immune response tests. Scientists and their collaborators modified the gene that produces the protective protein. Using gene technology they then introduced the gene into the pea. Field trials showed that the GM peas were 99.5% resistant to pea weevils. Results showed the alpha-amylase inhibitor GM peas provided 99.5% protection against the pea weevil with yields comparable to non-GM field peas.

Feeding Trials Test of GM Pea

The bean alpha-amylase inhibitor protein has been studied extensively over many years and has shown no health risk to humans or animals. However, as part of its risk assessment, Commonwealth Scientific and Industrial Research Organization (CSIRO) worked with other research groups to conduct feeding trials in chickens and pigs. In two feeding trials, chickens were fed GM and non-GM field peas incorporated into a maize–soybean diet. In the first trial, birds were fed the diet from 3 to 17 days posthatching. In the second trial, the birds were fed the diet for 40 days. In another trial, pigs were fed wheat mixed with either non-GM or GM field peas for 15 days. Results of each study showed that whereas protein digestion was the same in pigs and chickens fed GM or non-GM field peas, starch digestion was reduced in animals eating the GM field peas. This indicated that the alpha-amylase inhibitor protein also affected digestion of starch. Mice fed alpha-amylase inhibitor GM-peas showed evidence of an immune response after 2 weeks, with the response increasing at 4 weeks. The reaction in mice was inflammation in the lungs and increased serum antibody levels. The reaction to the pea alpha-amylase inhibitor protein was compared to bean alpha-amylase inhibitor protein when administered to the mice lungs.

Gene Flow from GM Plant to Wild Plant

Peas are self-pollinating and it is unlikely that gene flow would occur between GM and non-GM peas. However, CSIRO conducted gene flow studies to test this assumption. The results of the work showed that gene flow did not occur between GM and non-GM field peas. According to these results, CSIRO made the decision to discontinue developing the alpha-amylase inhibitor GM peas.

Bean

Food Allergy to Bean

As a member of the legume family, the green bean frequently associated with food allergy. However, allergic reactions caused by skin contact or by inhalation of vapors from boiling legumes are rare. Test results indicate that the patient has type I hypersensitivity to raw green bean antigen(s). This case is of interest because it demonstrates that a food allergen, when inhaled, can induce respiratory symptoms in sensitized patients and may even be the source of primary sensitization.

A bean allergy is an adverse reaction by the body's immune system to beans or food containing beans. This type of allergy is rare and serious reactions are very rare. The body's immune system produces immunoglobulin E (an antibody) and histamine in response to contact with the allergen. The specific symptoms that can result vary considerably among patients, for example, skin, respiratory, and behavioral symptoms.

Occupational allergy to castor bean has been found in workers in a felt-manufacturing plant. Of the workers, 37% complained that they were affected by the felt. Of these, 50% were considered to have occupational allergy. The presence of castor bean allergens in the felt was suggested by the correlation between the radioallergosorbent test (RAST) scores to the felt and castor bean and confirmed by RAST inhibition experiments. The RAST results correlated well with the results of skin prick tests to felt and castor bean extracts.

Bean Seedborne Fungi

The average percentages of seedborne fungi in the bean is approximately 50%. The most-frequently isolated fungi are *Alternaria*, *Aspergillus*, *Eurotium*, *Fusarium*, *Rhizoctonia*, *Penicillium*, *Rhizopus*, *Sclerotinia*, *Gliocladium*, and *Curvularia*. Based on these profiles, *Fusarium* and *Aspergillus* were identified as the most-probable mycotoxin-producing fungi in the bean. The infected beans contained the *Fusarium* toxins diacetoxyscripenol (DAS), DON, T-2 toxin, and fumonisin B1, aflatoxins B1, B2, G1, and G2. *F. avenaceum*, *F. culmorum*, *F. graminearum*, *F. moniliforme*, *F. oxysporum*, and *F. solani* were isolated from moldy bean. The incidences of mycotoxin contamination have a correlation to seed discoloration. Several mycotoxins were detected in naturally infected moldy navy beans (*Phaseolus vulgaris* L.) with distinct whitish gray to pink discoloration. Three types of bean samples were analyzed for mycotoxins: (1) healthy beans without any apparent discoloration; (2) beans with pink discoloration; and (3) a mixture of beans with whitish gray and pink discoloration. The results indicated that DAS, DON, T-2 toxin (T-2), and fumonisin B1 (FB1) were present in type B and C samples but not in the healthy type A samples.

Chickpea

The Effect of Food Processing on Pesticide Residue

The effect of food processing on pesticide residues on dry chickpeas has been studied in a supervised trial. Food processing offers a suitable approach to deal with the current scenario of poor quality and unsafe food prevalent in the developing countries. Food legumes are widely consumed over the world on account of their nutritive value. The effects of common domestic processing techniques like soaking and germination on pesticide residue showed germination (day 1) resulting in almost complete elimination of chlorpyrifos and its metabolites in chickpea, hence germination of legumes is a simple, cost-effective, suitable process for addressing the

concerns of food quality and safety especially for rural populace of developing countries. The residue of triadimefon and triadimenol 2 weeks after the last application, were at or about the limit of determination.

Mycoflora and Mycotoxigenic Fungi in Chickpea

High production of crops requires using high quality of seeds. However, seedborne fungi play an important role in deterioration of seed quality, which leads to high economic losses in crop yield. Poor harvesting practices, improper storage, and less than optimal conditions during transportation, marketing, and processing can also contribute to fungal growth and increase the risk of mycotoxin production. Many fungal species such as, *A. porri*, *A. alternata*, *A. amstelodami*, *A. flavus*, *A. fumigatus*, *A. nidulans*, *A. niger*, *A. sydowi*, *A. wentii*, *Botrytis cinerea*, *Cladosporium macrocarpum*, *Curvularia lunata*, *F. equiseti*, *F. moniliforme*, *F. oxysporum*, *F. semitectum*, *Macrophomina phaseolina*, *Myrothecium roridum*, *Penicillium notatum*, *Rhizoctonia* sp., and *Rhizopus arrhizus* have been reported from chickpea.

Mycotoxins attract worldwide attention because of the significant economic losses associated with their impact on human health, animal productivity and trade. *Aspergillus*, the most common genus, emerged from 100% of Fabaceae seed samples tested; *A. flavus*, *A. niger*, and *A. fumigatus* were the most prevalent; and *A. parasiticus*, *A. flavus* var. *columnaris*, and *A. ficuum* emerged in moderate or low frequency of occurrence in Fabaceae. Mycotoxin with different toxins and varying degrees of toxicity were found in 26.7% of the tested samples. No mycotoxins tested were detected in any chickpea seed samples investigated. Aflatoxins (B_1, B_2, G_1, and G_2), ochratoxin A, sterigmatocystin, simple microcyclic trichothecenes (DAS, T-2 toxin, and HT-2 toxin), patulin, fumigillin, and zearalenone could not be detected in most of roasted chickpea seed samples tested, but unfortunately the isolated fungi exhibited potentially mycotoxin production in favorite conditions.

Lentil

The genus *Aspergillus* is the most prevalent genus in seed of lentil (*Lens esculenta*) followed by *Rhizopus*, *Penicillium*, *Fusarium*, and *Chaetomium*. Natural contamination with aflatoxins B1, B2, G1, and G2 (14.3 $\mu g\,kg^{-1}$) were reported.

Lentil Allergy

Peanuts and soybeans are the major legumes involved in human food allergy; however, scarce data exist on adverse reactions of lentils. Some people have symptomatic allergy to lentils. The most frequent symptoms were oropharyngeal symptoms and acute urticaria. Some people also have allergic symptoms when they were exposed to steam from cooked lentils. Allergic reactions to lentils started early in life, usually below 4 years of age. Allergic reaction to lentil frequently associated with allergic reaction to other legumes such as chickpeas, peas, and green beans; oropharyngeal symptoms and acute urticaria are the most common symptoms through ingestion.

Risk of Pollen Migration in Transgenic Alfalfa

Alfalfa (*Medicago sativa* L.) is a perennial legume widely cultivated to provide high-quality forage in the form of hay, silage, and to a lesser extent as a grazing crop, as well as for improving soil fertility. The availability of alfalfa lines that can be easily transformed with *Agrobacterium* and regenerated in tissue culture, makes this plant attractive for genetic engineering and provides the opportunity to develop new uses for alfalfa with value-added products of commercial interest. Alfalfa is the most important forage crop in North America. It is currently grown on approximately 26 million acres in the USA. Because alfalfa is easily genetically transformed, it is often considered as the ideal plant to use in large-scale production of transgenic products. Pollen can function as a vehicle to disseminate introduced genetically engineered genes throughout a plant population or into a related species. Concerns have been raised over the release of GE plants into the environment, because of the risk of inadvertent dispersal of engineered genes into the cultivated crop, or into related weed species. Factors germane to that risk include the rate of pollen-mediated gene spread, the maximum dispersion distance of pollen, and the spatial dynamics of pollen movement within seed production fields, none of which are known for alfalfa (*M. sativa* L.), an insect-pollinated species.

Hay

Hay is grass, legumes, or other herbaceous plants that have been cut, dried, and stored for use as animal fodder, particularly for grazing livestock, such as cattle, horses, goats, and sheep. Hay is also fed to pets, such as rabbits and guinea pigs. The long drying periods with high humidity allowed field growth of mold on the hay. Mold will grow on hay without preservative at moisture levels above 14–15%. Molds commonly found in hay include *Alternaria*, *Aspergillus*, *Cladosporum*, *Fusarium*, *Mucor*, *Penicillium*, and *Rhizopus*. These molds can produce spores that cause respiratory problems, especially in horses or other animals fed in poorly ventilated areas and, under some conditions, will produce mycotoxins. Mycotoxins affect animals and subsequently human life in the following ways: (1) intake reduction or feed refusal; (2) reduced nutrient absorption and impaired metabolism, including altered rumen fermentation and microbial growth, diarrhea, intestinal irritation, reduced production, lower fertility, lethargy, and increased morbidity; (3) alterations in the endocrine and exocrine systems; (4) suppression of the immune system, which predisposes livestock to many diseases and may increase milk somatic cell count. A suppressed immune system may also cause lack of response to medications and failure of vaccine programs; and (5) cellular death causing organ damage.

Mycotoxins may cause acute health or production problems, which are most common in horses and other nonruminants. In cattle, mycotoxins more likely will contribute to chronic problems including a higher incidence of disease, poor reproductive performance, or suboptimal milk production. Ruminants are somewhat protected from acute toxicity because the rumen destroys a large portion of most mycotoxins.

The mycotoxins of greatest concern are those produced by *Aspergillus* (aflatoxin, gliotoxin, fumitremorgens, and fumigaclavines), *Fusarium* (DON, zearalenone, and T-2 toxin), and *Penicillium* (PR toxin, mycophenolic acid, roquefortine C, and patulin), but other mycotoxins can be present. There are approximately 400 different known mycotoxins. Increased attention to field and storage management may help reduce the incidence and concentration of mycotoxins in forage. Heavily contaminated forage may need to be discarded. Lightly contaminated feed can be diluted and used for animals under less stress.

Another trend contributing to the frequency of mycotoxin contamination of feeds is improved global grain transportation systems and global trading of agricultural commodities. This allows more extensive shipping of grains and other feed components throughout the world. As a result, complete feeds are likely a more complex blend of feedstuffs with more widely varying geographic origins than was seen in the past. The potential for aflatoxins and mixtures of *Fusarium* mycotoxins to be cocontaminants in feeds is, therefore, enhanced.

Feed samples (alfalfa hay, wheat straw, shrubs, pasture, and concentrates) and milk were investigated for contamination with pesticide residues. The results showed that the summation operator endosulfan was the main pesticide residue that was detected in all the concentrate samples at a mean concentration of 5.36 mg kg^{-1}, which is much higher from the MRL. In addition, the summation operator endosulfan was also detected in all the alfalfa hay samples but at a mean concentration of 0.10 mg kg^{-1} which is lower than the MRL. In the wheat straw, shrubs, and pasture samples no pesticide residues were detected. No pesticide residues were also detected in milk samples of sheep and goats. Thus, this milk from the farms sampled presents no human health risks.

Introduction

The tree nut industry consists of almonds, brazil nuts, cashews, hazelnuts, macadamias, pecans, pinenuts, pistachios, and walnuts. Tree nuts are produced in more than 40 developed and less-developed countries (Tables 1 and 2) and consumed worldwide. Millions of hectares of land are devoted to tree nuts, providing economic livelihood for hundreds of thousands of producers and small families.

Table 1 Summary of global tree nut production and area harvested in 2010

Tree nut	*Area harvested (hectares)*	*Production quantity (metric tons)*
Almonds (in shell)[a]	1 675 284	15 007
Brazil nuts	–[b]	2 514 022
Cashews	4 404 105	3 585 807
Hazelnuts	620 383	888 328
Macadamias (kernel basis)	–[b]	28 714
Pecans	–[b]	91 861
Pinenuts (kernel basis)	–[b]	9 702
Pistachios	461 955	912 379
Walnuts	846 059	2 545 388

[a]Data are based on information gathered from producing country government statistics and industry sources and FAO production database (Brazil nut, pistachio, walnut, almond, hazelnut, and cashew data from FAO production database).
[b]There are no data.

Worldwide Tree Nut Consumption

Tree nuts are widely consumed in both raw and processed forms. Unlike groundnuts, which are predominantly used for oil and feeding stuff, tree nuts are primarily consumed as whole foods, as ingredients in foods, or in medicinal preparations. For example, in several Asian cultures, almonds play a significant role in Ayurvedic preparations, a philosophy which for thousands of years has promoted the interrelationship of nutrition/diet with healing, prevention, and longevity (Table 3).

Based on data contained in the 2007 FAO Food Balance Sheets, it is apparent that tree nut consumption varies both among and within the regions where there is tree nut production.

Sources of Nut Contamination

There are three main types of nut contaminants:

- Microbiological,
- chemical, and
- physical.

Nuts can become contaminated during growth and harvesting of raw materials, storage and transport to the factory, and processing into finished products. The final product may then become recontaminated during subsequent storage and transport to shops, and during storage and preparation by the consumer.

Pathogenic microorganisms are the major safety concern for the nut industry. The vast majority of outbreaks of nut-related illness are due to microbial pathogens, rather than to chemical or physical contaminants. As they are generally undetectable by the unaided human senses (i.e., they do not usually cause color changes or produce 'off'-flavors or taints in the food) and they are capable of rapid growth under favorable storage conditions, much time and effort are spent in controlling and/or eliminating them.

Pistachio

Pistachio (*Pistacia vera* L., Anacardiaceae) originates from Central Asia. Domestication occurred less than 2000 years ago and traders introduced them throughout the Middle East and the Mediterranean area. Today the major production areas are located in the Middle East, North America, and Europe. Iran is the world's largest pistachio producer and it accounts for 44% of world production.

Change in hull color is closely connected with shell splitting and so it is important to harvest nuts when they are fully mature to ensure maximum shell split.

Smaller shake and catch harvesters mostly operate with a catching frame not unlike an inverted umbrella that can be opened under the tree canopy when the tree is shaken and closed for transport to the next tree.

Whether the nuts are destined for the fresh or dried pistachio market they are harvested by the shake and catch method. In both cases, the harvested nuts must be quickly transported for processing. Fresh pistachios are sold in the hull and so do not need hulling. The fresh nuts are cooled immediately after harvest in a cool room.

Nuts that are destined for the dried pistachio market are quickly transported to the hulling and drying plant. If hulls are not removed within 24 h, the nuts generate heat and the shell can become stained. The sooner the nuts are hulled and dried, the better quality the nut will be.

The nuts are then slowly dried using ambient air to retain kernel quality.

Heat during drying can damage the kernel. The nuts are stable in storage when the moisture content is approximately 6%.

Depending on the conditions of production, processing, transport, and distribution, pistachios can become contaminated with different hazards. These range from chemicals such as pesticide residues, toxic metals (lead and cadmium), or microbial hazards such as *Salmonella*.

The biggest concern for pistachio has so far been contamination with toxigenic molds, for example, *Aspergillus flavus*, and growth of these and subsequent formation of aflatoxins (AFLs). Other mycotoxigenic fungi that are ochratoxin and fumonisin producers were identified from pistachio, but these toxins were not detected in pistachio fruit.

AFL in Pistachio

The Codex Alimentarius adopted standards for AFL in pistachios for ready-to-eat (RTE) and for further processing. In 2010, the European Union (EU) which previously had stringent regulation on AFL (2 and 4 ppb, respectively, for AFL B_1 and total AFLs) relaxed its requirements and aligned its requirement with that of Codex Alimentarius.

Codex Alimentarius has also adopted a sampling plan consisting of 2×10 kg of sample for RTE nuts (including pistachio, hazelnut, and almond) and 1×20 kg sample for pistachios for further processing. From February 2010, EU has adopted the sampling plan recommended by Codex Alimentarius.

Contamination of pistachio nut by *Aspergillus* species and their mycotoxins are the most serious challenge to pistachio production, consumption, and exportation in the world.

Factors influencing infection of pistachio nuts include: cracking of pistachio nuts (especially early hull splitting pistachios), environmental factors, cultural practices, frequency and time of irrigation, plant litter, animal manures, frequency of toxigenic strains, distribution of AFL in pistachio bulks, and harvesting date. These factors have been shown to be critical in infection especially in early splitting cultivars where the hull (pericarp) gets split exposing the kernel to molds and insects increasing chances of AFL production and contamination. Whereas the molds such as *Aspergillus* spp. may cause direct contamination resulting in AFL production, insects may play the role of spreading fungal spores, which in turn infect exposed kernels.

Pistachio nuts are characterized by a split in the shell at the calyx end of the nut. This split normally occurs on the tree about a month before harvest. The hull (mesocarp) of the pistachio usually encloses the shell and remains intact through harvest, serving as protection for the kernel. On normal nuts, there is space between the hull interior and shell exterior, so the shell can split open without splitting the hull. However, approximately 1–4% of the time, the hull will adhere tightly to the shell and the hull will split open along with the shell. These nuts are called 'early splits.' The split in the hull allows an unobstructed passage to the kernel for airborne mold spores and insects or other small animals, such as mites, that

might be carrying mold spores. Insects and small animal infestation rates on early split nuts are much higher because of the easy access to the kernel. The mold, *A. flavus*, has been found in pistachio nuts before harvest.

Salmonella in Pistachio

Salmonellosis is an infection with bacteria called *Salmonella*. Most persons infected with *Salmonella* develop diarrhea, fever, and abdominal cramps 12–72 h after infection. The illness usually lasts 4–7 days, and most persons recover without treatment. However, in some persons, the diarrhea may be so severe that the patient needs to be hospitalized. In these patients, the *Salmonella* infection may spread from the intestines to the blood stream, and then to other body sites and can cause death unless the person is treated promptly with antibiotics. The elderly, infants, and those with impaired immune systems are more likely to have a severe illness.

On March 26, 2009 the US Food and Drug Administration (FDA) informed Centers for Disease Control and Prevention (CDC) that multiple samples of pistachio nuts and pistachio-containing products collected over several months from a single company were contaminated with several serotypes of *Salmonella*, including Montevideo, Newport, and Senftenberg. Since that time, CDC has been actively investigating whether this contamination is linked to human illness. In addition to the pistachios, some of these deoxyribonucleic acid (DNA) fingerprints have been associated with other foods, and a fingerprint match does not mean that the illnesses are necessarily linked to pistachios. CDC is collaborating with state and local public health agencies to interview persons with *Salmonella* strains having DNA fingerprints that match those from the pistachio products to determine whether they had eaten pistachio nuts or pistachio-containing products before their illnesses. To date, one patient in Connecticut infected with a *Salmonella* strain with a matching DNA fingerprint has reported consuming a pistachio-containing product.

Salmonella that contaminates food, including nuts, can cause human illness and is a public health concern. CDC estimates that cases of salmonellosis reported to the public health system represent approximately 3% of the illnesses that actually occur, because many ill persons do not seek medical care or have a specimen cultured. Even if no reported illnesses are related to a contaminated product, it is possible that some illnesses might occur.

Pre and postharvest pistachios are exposed to environments that impose some level of risk of contamination with foodborne pathogens. Pistachios that have fallen to the ground several days preceding harvest may absorb water. The water may be contaminated with *Salmonella* or other pathogens originating from wild or domestic animal feces, inadequately composted manure, irrigation water, or run-off water. Cleaning pistachio may involve immersion in water and cross-contamination with foodborne pathogens. Wetting of inshell nuts may result from leaks in roofs or walls of storage facilities, thereby resulting in potential contamination or development of high-moisture environments that favor the growth of mycotoxigenic molds and foodborne pathogens. Conditioning pistachio also creates an environment that may result in cross contamination.

As with most horticultural crops, the implementation of appropriate good agricultural practices is considered important to reduce the opportunity for foodborne pathogens to contaminate the crop.

The potential to recontaminate a finished nut product is high if adequate good manufacturing practices are not in place. Facility design, product flow (separation of raw from finished product), equipment and facility maintenance, cleaning and sanitation, as well as human hygiene should be adequately controlled to prevent contamination. Cleaning and sanitation may be challenging in dry areas of the facility where moisture should usually be restricted; however, dry cleaning and sanitation programs are available and widely used in the food industry. The efficacy of the cleaning and sanitation program should be monitored through a robust environmental monitoring program that includes assessment for *Salmonella* or other pathogens, if appropriate.

Pistachio Allergies

Pistachios are relatively commonly reported tree nuts to cause food allergy symptoms, and are cross-reactive to cashews and mangoes. Hay fever to the pollen from the *Parietaria* weed, found in Europe, appears to predispose to pistachio allergy.

Pistacia vera, which likewise cause allergic reactions in sensitized individuals, have a major and several minor IgE-binding proteins. Pine nuts (*Pinus edulis*) contain at least three proteins that bind human IgE.

Almond

The almond tree grown today originated from wild almonds growing in deserts and low mountain forests of central and south-west Asia from northern Syria and Turkey to Iran and Iraq. From the bitter-seeded wild forms a sweet nut was selected and cultivated some 4000 years BC. Thousands of years later in the mid-1800s almonds were first cultivated as a commercial nut crop.

Today the US accounts for approximately 80% of world almond trade and produces more than half of the world almond supply. The next highest producer is Spain.

Harvesting is done by shaking the tree to ensure all nuts are down, allowing the nuts to dry, sweeping the nuts into windrows, and picking up the nuts with a harvester. In preparing the orchard for harvest, the floor is mown short or sprayed with a knockdown herbicide and cleared of branch debris and stones. Dry weather throughout the harvest operation is needed to avoid nut deterioration. When the hulls are splitting open and dry, the trees are ready for harvest.

Harvested crops are not safe to stockpile unless the moisture content is down to approximately 5%. At this stage t he kernel will snap in half. At moisture levels higher than this the nuts will deteriorate due to mold and spontaneous combustion can occur. The stockpile is left uncovered unless temporary covers are needed for rain protection. Almond crops are bulky because of the amount of hull in the har

vested crop. However, hulls are a marketable byproductand valued as a high-protein stock feed. Harvest is a dusty operation and when all is complete, the trees are irrigated.

Varieties that are marketed in shell are hulled and those marketed as kernel are hulled and cracked. After hulling, shear–roll machines crack the nuts and the shell is separated out and the kernel is then graded.

AFL in Almond

Insect-feeding damage is a principal factor leading to preharvest fungal infection of nut kernels of almonds, pistachios, and walnuts which may lead to subsequent AFL contamination. Wounds to the protective layers surrounding nut kernels (hull, shell, and seedcoat) provide avenues for infection by windborne spores of aflatoxigenic aspergilla. The principal insect pests of tree nuts are larvae of the navel orangeworm (NOW).

Amyelois transitella Walker (Lepidoptera: Pyralidae), which infests kernels of almonds, walnuts, and pistachios; the peach twig borer, *Anarsia lineatella* Zell. (Lepidoptera: Gelechiidae), which infests meristem leaf shoots, husks, and kernels of almonds.

There is considerable evidence that almonds, pistachios, and walnuts show a differential resistance to contamination by AFLs. For example, in 2005, no walnut shipments to the EU were the subject of alerts or notifications for AFLs, although one shipment was the subject of an alert for mold. In contrast, 28 almonds and 13 pistachio shipments were identified. Although this is circumstantial evidence, it reflects market realities and conforms to the position of the industry groups, in which walnut producers are primarily concerned with spoilage microorganisms such as *Rhizopus*, *Penicillium*, and *Aspergillus niger*, whereas almond and pistachio producers are greatly affected by the economic impact of AFL contamination.

Such differences cannot be accounted for merely by differences in physical protection of the nuts by the hulls or shells because both codling moth and NOW are major pests of almonds, pistachios, and walnuts, wounding the external tissues and providing many avenues for entry of fungal spores into the edible portion.

Salmonella in Almond

Nuts have been associated with *Salmonella* outbreaks in the USA and Canada several times over the past 10 years. Almonds were responsible for the first outbreaks, in 2001 and then again in 2004, when contamination with *Salmonella enterica* triggered a recall of 13 million pounds of California almonds. A requirement was implemented in 2007 that all almonds sold on the domestic market be pasteurized. A court recently upheld that requirement.

The rule is a response to two outbreaks of *Salmonella* poisoning, which sickened more than 100 people in Canada in 2001 and 29 people in the USA and Canada in 2004. One person died in the 2004 outbreak and a costly lawsuit against a major almond processor ensued. The *Salmonella* outbreak of 2004 was traced to Paramount Farms, the world's largest supplier of pistachios and almonds, with 9000 acres of nut crop production, although the source of the bacteria was never identified. (*Salmonella* is directly associated with manure and other fecal matter.) The most common method of sterilizing almonds is propylene oxide (PPO) fumigation. Other pasteurization methods include steam heating, oil roasting, and blanching. Organic 'raw' almonds will not be fumigated, but will undergo the steam pasteurization, so that they are no longer truly raw.

Both PPO and steam treatments kill bacteria with a 5-log reduction, meaning that if 100 000 harmful pathogens are present on an almond before treatment, only one will remain afterward.

Almond Allergies

Almonds are the most popular tree nut consumed in the US, and the third most common tree nut allergy. Almonds are commonly found in food processing, and are unexpected ingredients in breakfast cereals, granola bars, and baked goods. Almond allergy may predispose a person to other tree nut allergies, especially pistachio nuts.

Ingestion of tree nuts, the edible kernels of the seed of several trees, may also cause immunological illness. Sweet almonds (*Amygdalus communis*) and bitter almonds (*Prunus amygdalus*) comprise 22% protein and contain multiple IgE-binding proteins that may trigger severe allergic reactions.

Brazil Nut

Brazil nut '*Bertholletia excelsa*' is a member of the Lecythidaceae family and grows in the tropical forests of Amazonia. These Brazil nut forests are known as 'castanhais' and occur in the Guianas, Amazonian Brazil, south-eastern Colombia, southern Venezuela, eastern Peru, and northern Bolivia.

Most of the collected Brazil nuts are then subjected to minimal processing (selection, classification, cleaning, drying, and shell cracking among the main processing steps) for export either in shell or shelled (as a kernel), mainly to Europe and the USA. Bolivia is presently the largest Brazil nut producer and exporter, followed by Brazil and Peru.

Brazil nuts are harvested almost entirely from wild trees during a 5–6 month period in the rainy season. The fruits, which weigh from 0.5 to 2.5 kg and contain 10–25 seeds, are gathered immediately after they fall in order to minimize insect and fungal attack of the seeds, and to control the number of seeds carried away by animals. The number of capsules produced per tree ranges from 63 to 216.

After collecting the fruits from the forest floor, the gatherers carry them to local dealers then to peeling and bagging factories before export. The harvested fruits are split open, washed, and dried. In Brazil the nuts are dried in rotary driers, whereas in Bolivia and Peru nuts are dried on slatted floors. The nuts are shelled either by the autoclave process using steam to expand the shell and loosen the inner skin, or by soaking for 24 h to expand the shell to ease manual cracking. The nuts are graded and then oven dried or sundried before storage.

AFL in Brazil Nut

The highest levels of AFL occurred in nuts when the relative humidity of the storage environment approached 97% and

was accompanied by temperatures in the range of 25–30 °C. At 10 °C or at a relative humidity level below 75% toxin was not produced. Warm temperatures and a high relative humidity are characteristics of the production areas in the Amazon, especially during the harvesting season, which occurs from January to April, and reducing relative humidity and or temperature is not economically viable; however, reducing the moisture in the nuts to lower than 5.0% could prevent AFL production especially during storage. Therefore, air and or mechanical drying of the nuts following harvesting can be used to control mold growth, thereby limiting toxin formation. Despite that, when their shells are cracked either when pods fall on the ground or during pod opening for nut extraction (done by an axe) and exposed to high moisture and temperature of the tropical forest, fungi may grow leading to nut spoilage. If fungi are toxigenic, they may produce AFLs. Nevertheless, the Brazil nut production chain is confronted with problems of contamination by AFLs, which are toxic secondary metabolites produced by *A. flavus*, *Aspergillus parasiticus*, and *Aspergillus nomius* when the nuts are kept under conditions that favor the development of these fungi and toxin production.

Beside *A. flavus, A. nomius* is an important producer of AFLs in Brazil nuts and that its occurrence, and possibly other B and G AFL producers.

The higher selenium (Se) content present in the Brazil nuts leads to less fungi proliferation, growth rate in the plate, and AFL production that could be caused by its toxic effect to the fungus provoking stress and activating AFL production.

Selenium Toxicity and Radioactivity of Brazil Nut

Se is an essential micronutrient that, once incorporated into selenoproteins, performs important functions in the human body, participating in antioxidant defense, in the immune system, and in the regulation of thyroid function. Glutathione peroxidase is a selenoprotein that acts as an antioxidant enzyme in plasma and is associated with slowing the aging process, boosting the immune system, and protecting against heart disease and certain forms of cancer. However, at doses above the recommended daily intake of 55 μg per day, Se can be toxic. Brazil nut trees absorb the natural element Se from soil as along with radionuclides, such as 226Ra. The concentration of radioactive elements in Brazil nuts can reach quantities up to 1000 times greater than in other foods. Owing to the high concentration of radionuclides, studies report that Brazil nuts are radioactive.

Perhaps radiation is the most bizarre risk associated with Brazil nuts. The trees are so large, their extensive root systems bore deep into the ground and soak up unusual amounts of radium from the soil. This radium gets transferred into the nuts, making them radioactive. It is believed Brazil nuts have 1000 times more radium than the next most radioactive food. Although extensive studies are yet to be conducted, the amount of radiation in a Brazil nut is still small when compared to radiation encountered in everyday life, and it is not believed to pose any serious health risk, regardless of the quantities ingested. The occurrence of cancer is among the risks associated with the ingestion of radioactive foods, and monitoring is a form of health protection. The Brazil nut is native to the Amazon region and is economically important. It is collected in indigenous regions and in small communities during the rainy season, and transported to processing plants, to undergo treatment involving the following stages: sorting, drying, breaking, and sorting by size. The initial stage of manual/visual sorting is important to remove moldy and stained nuts, and precedes classification by size. At the end of the drying and cooling processes, the product is subjected to vacuum packaging and hot sealing.

Brazil Nut Allergies

Allergy to Brazil nut is uncommon, probably because these are not commonly eaten tree nuts. It is possible that allergy to Brazil nuts will increase in the future, because genetically modified soybeans accidentally have proteins similar to those found in Brazil nut allergen. People with Brazil nut allergy may also be allergic to walnuts.

Brazil nuts (*Bertholletia excelsa*, *Bertholletia myrtaceae*), ingestion of which has triggered allergic reactions in children and adults, contain 14% protein, including a methionine-rich protein (Ber e 1) that constitutes the major allergen.

Cashew

Cashew (*Anacardium occidentale*) belongs to the Anacardiaceae family. Pistachio and mango also belong to this family and the cashew tree foliage is very similar to pistachio foliage. Cashew trees are evergreen and grow rapidly to form a large much-branched tree of some 15 m in height.

The cashew or monkey nut is native to tropical America and north-eastern Brazil, in particular. Cashew trees thrive in warm humid climates where there is an annual rainfall greater than 1000 mm and they grow from sea level to an altitude of 1000 m. Cashew is cultivated primarily in India, Brazil, Vietnam, Tanzania, and Mozambique. Plantings have also been established in West Africa and Australia. Cashew trees are robust fast-growing evergreen trees that tolerate periods of drought. The nut that forms at the base of the cashew apple is highly valued as a roasted snack nut, in confectionery, and in cooking, but the apple also has value. Cashew apple juice is a popular drink in many communities and it can be fermented into a Madeira-like wine. The fruit pulp can be made into preserves, jelly, candied fruit, and syrup. However, the cashew apple harvested from commercial plantations is discarded when the nut is removed due to lack of markets for apple products. It has been reported that in India alone approximately 1.25 million tons of cashew apple is wasted each year.

The liquid enclosed in the shell is called cashew nut shell liquid (CNSL) and it is caustic. It contains cardol and anacardic acid and acts as a vesicant producing burn-like blisters when in contact with human skin. However, CNSL has many industrial uses because of its polymerizing and friction-reducing properties. It also has a use as a waterproofing agent and preservative. When distilled and polymerized, the oil is used in varnishes, cements, tiles, lubricants, and inks. It has also been used in tropical medicine.

Dry weather is essential before and during harvest. As mentioned above, fertilizer applications can be adjusted to

ensure fruit drop completes before the arrival of the wet season. In dry weather during nut drop, the apple remains firmly attached to the nut at harvest but if rain occurs during nut drop, the apple may rot on the ground before harvest.

The orchard floor is cleaned before nut drop. Traditionally cashew fruit is harvested by hand and the crop can lie on the ground to dry in fine weather, but it must be harvested if the weather is wet.

After harvesting, the cashew product is transported to a cleaning belt for removal of debris and it is then conveyed into driers. Ambient air is used in the drying process and drying can take a few days. The dried product is then stored in a dry atmosphere protected from vermin, usually in silos, until it is processed to remove the nut from the cashew apple. The dried product will remain in good condition for a year under good conditions.

Cashew Allergies

Cashews are the second most common tree nuts to cause food allergies. The oil found in the nutshell of the cashew is known to cause contact dermatitis, and is related to the oils found in the leaves of poison oak and in the skin of mangoes. Cashew allergens are similar in structure to palm oil, *Macadamia* nuts, peas, soybean, and walnut. Therefore, people with a walnut allergy may experience allergic reactions to these other foods.

Tree nut allergies, including allergic reactions to cashews, affect 1.2% of the children. Although 9% of children outgrow this allergy by the time they reach 6 years of age, the reaction triggered by eating cashews may be severe. A study published in the August 2007 issue of the journal *Allergy* indicates that breathing and cardiovascular issues are common, especially when compared to the allergic reactions triggered by eating peanuts.

AFL in Cashew

There is limited information as to the degree of the suitability of cashew nut as a substrate for mycotoxin production, especially AFLs by *A. flavus*.

In a study, 12 samples of cashew were tested for AFL and mold. The incidence of molds in cashew nuts in the first testing period was between 91.67% and 31.25%, and in the second period it was between 89.58% and 62.5% for sales points 1, 2, 3, and 4. The incidence of *A. flavus* and *A. parasiticus* in cashew nuts was 5.74% and 0.49%, respectively, and the differences were not significant. The concentrations of AFLs recovered from cashew nuts were between 20.67 and 11.33 ppb, for all sales points.

Walnut

Walnuts belong to Juglandaceae, the same family as pecans. Although all temperate species are deciduous, subtropical species tend to be evergreen in their native habitat.

The species cultivated for its sweet nut is *Juglans regia*, commonly known as English walnut but it is also called Persian walnut and in years past, the royal nut of Jupiter. This species is believed to have originated near the Caspian Sea in Iran and the native habitat extends east from Turkey and Iran to valleys in western China and the eastern Himalayas. A distinctive characteristic of this walnut is that the hull separates readily from the shell.

Cultivars of English walnut are grown for commercial nut production in southern Europe (particularly France, Germany, Italy, and Turkey), in the USA (California and Oregon), and in China, India, South Africa, Australia, and New Zealand.

Walnuts are ready to harvest in autumn when the hull cracks to release the nut and the oil content of the kernel is high.

Tree shakers are the most valuable piece of harvest machinery to own because nut fall can occur at the optimum time and this makes pick-up most efficient and produces greatest nut quality. When approximately 80% of the hulls are cracking, trees to be harvested that day are shaken.

Walnuts must be picked up and dried as soon as possible after nut fall preferably within hours. Failure to do so will result in discolored shell and moldy kernel in moist weather, heat-affected nuts in hot weather, and potential vermin damage.

The moisture content of nuts at harvest can vary from 20% to 40% depending on the weather and locality. The aim is to reduce the moisture content down to approximately 8%. Large capacity driers heat the air pumped through the nuts to reduce the drying time, whereas small-scale operations may use ambient air and heat only when required to reduce humidity. The dried nuts are then stored in a cool room or cool, vermin-proof silo, or store room.

AFL in Walnut

There also are metabolites in walnuts, which have potential as endogenous constituents of tree nuts as inhibitors of growth of *A. flavus* or aflatoxigenesis. The primary barrier to attack by external organisms is the hull of the walnut, which is known to contain a structurally related series of naphthoquinones, including 1,4-naphthoquinone, juglone, 2-methyl-1,4-naphthoquinone, and plumbagin. All of the quinines can delay fungal spore germination at lower levels and can completely inhibit growth at higher levels. The most potent compounds were 2-methyl-1,4-naphthoquinone and plumbagin, which were similar to each other in activity, i.e., they delayed germination for 40 h at 20 $\mu g\, g^{-1}$ and inhibited growth at 50 $\mu g\, g^{-1}$, so that walnuts are considered at lower AFL risk. However, in a study of walnuts, 75% of the walnut samples contained AFL in the range of 15–25 $ng\, g^{-1}$.

Control of insect pests in walnut orchards is a major strategy to lower AFL contamination, because insect feeding damage can lead to fungal infection and subsequent mycotoxin contamination. Through breeding and genetic engineering, new varieties of walnuts have been developed which are resistant to insect attack.

Penitrems in Walnut

Penitrems are a group of six related tremorgenic mycotoxins produced by *Penicillium. crustosum*, of which penitrem A ($C_{37}H_{44}NO_6Cl$) is the most toxic and the most studied

member. At low doses it was found to cause tremors in several animals. Dogs were reported to be victims of poisoning via consumption of moldy foods, such as walnuts contaminated with *P. crustosum*.

Walnut Allergies

Walnuts are the most common tree nut allergy, especially English walnuts. Many people are allergic to walnut pollen, which causes symptoms of allergic rhinitis, but this does not mean that the person is also allergic to the tree nut. Walnut allergens are similar in structure to those allergens found in pecans, cashews, Brazil nuts, castor beans, cottonseed, and mustard. Therefore, people with a walnut allergy may experience allergic reactions to these other foods. *Juglans regia* have also been etiologically implicated in human anaphylaxis.

Pecan

Pecan trees are also known as hickory trees and they belong to the walnut family Juglandaceae. In fact, the pecan grown commercially for nuts was originally classified as a species of walnut, *Juglans illinoensis*, but was renamed *Hicoria pecan* and finally *Carya illinoensis*.

Pecan trees are native to North America, growing in woodlands in the Mississippi Valley from Indiana and Illinois to Kansas and Texas, and at higher altitudes south of central Mexico. Pecans are also grown commercially in Australia, Brazil, China, Israel, and South Africa.

Nut maturity coincides with a peak in kernel oil content. The first visual sign of nut maturity is when the husk or shuck begins to split open.

The sooner the nuts are harvested and dried after they fall from the shuck, the better the nut quality will be. Trees are shaken with a tree shaker and most harvesting machinery is fitted with trash removal equipment that separates out leaves, husks, and twigs from the nut crop. The nuts are then transported straight to the dryer. Efficient drying is critical to nut quality. Nuts that lie moist on the ground for days, or nuts that are dried too slowly or at too high a temperature may develop off-flavor, darkened color, mold, and may soon become rancid.

The moisture content of nuts at harvest may be approximately 20% and they are dried to approximately 8% moisture content. They may then be dried further down to 4.5% for long-term storage.

AFL in Pecan

Leaves of the pecan *C. illinoensis* (Wangenh) K. Koch, another member of the Juglandaceae but in a different subfamily from *Juglans*, contain the naphthoquinone juglone, which inhibits mycelial growth of *Cladosporium caryigenum* (Ellis & Langl.) Gottwald (*Fusicladium effusum* G. Winter), the causative agent of pecan scab.

The natural occurrence of alternariols was reported in pecans. However, their production was limited to discolored pecan kernels, which are removed from shelled pecans during processing, which led to the suggestion that such pecans would be rejected by buyers of inshell pecans.

In a study, 148 isolates of *A. flavus* and *A. parasiticus* were isolated from 5608 pecans obtained from Chicago and Georgia markets. The percentage of internal contamination by these species was 7.3% in the pecans in Chicago market and 1.7% in those from markets in Georgia. Of the 148 isolates, 93% of the *A. parasiticus*, but only 54% of the *A. flavus*, were capable of producing AFL. Overall, 57% of the isolates were potentially aflatoxigenic. *Aspergillus parasiticus* isolates generally produced a greater amount of AFLs than *A. flavus*.

Salmonella in Pecan

Pecans thought to be contaminated with *Salmonella* were recalled from the US market in 2009.

Pre- and postharvest pecans are exposed to environmentsthat impose some level of risk of contamination with foodborne pathogens. Pecans that have fallen to the ground several days preceding harvest may absorb water. This water may contain *Salmonella, Escherichia coli* O157:H7, or other pathogens originating from wild or domestic animal feces, inadequately composted manure, irrigation water, or run-off water. Cleaning pecans may involve immersion in water and cross-contamination with foodborne pathogens. Wetting of inshell nuts may result from leaks in roofs or walls of storage facilities, thereby resulting in potential contamination or development of high-moisture environments that favor the growth of mycotoxigenic molds and foodborne pathogens. Conditioning pecans also creates an environment that may result in cross contamination.

Studies showed that *Salmonella* can survive on dry inshell pecans and pecan halves for several weeks. Survival was enhanced by storing nuts at freezing or refrigeration temperatures. Studies also showed that aqueous extract of pecan shucks is toxic to *Salmonella*.

Escherichia coli Contamination of Pecan

Escherichia coli is a common shell contaminant, especially for nuts harvested in orchards where animal grazing is practiced. Contamination of nutmeats may occur if shells are broken during harvest or if shells are not properly sanitized by addition of chlorine to heated soak-water just before cracking. Because of high amounts of organic material on the surface of pecan shells, chlorine should be monitored and replenished as needed to maintain the desired concentration.

Pecan Allergies

Pecans are a common food in the southern USA, but less common elsewhere in the world. Pecan affects approximately 1 in 10 people with tree nut allergies. People with pecan allergy are at risk for allergies to walnut, given the similarities between the allergens in these tree nuts.

Hazelnut

The hazelnut trees planted in commercial orchards (*Corylus avellana* cvs.) are smallish deciduous trees growing to

approximately 3 m tall. Turkey is the world's main producer of hazelnuts with a 75% share of the total world production and 70–75% of the total world's export.

Hazelnuts mature from late summer to early autumn depending on the variety and the location. As the husks yellow, nuts begin to fall and are ready to harvest. Some varieties fall free of the husk and others fall in the husk and require dehusking.

To ensure best quality, hazelnuts should be harvested from clean dry ground and transported to the dryer as soon as possible. In dry weather, nuts can remain on the ground for some days without loss of quality; however, both kernel and shell deteriorate rapidly when left on the ground in moist conditions.

The harvested nuts are dehusked and cleaned by hand or mechanically using dehuskers, trommel tables, trash-removing drums, or hand work via a conveyor. Where possible, blank nuts and nuts with shriveled kernel are blown or floated off. The cleaned nuts are immediately placed in a dryer.

The moisture content of harvested nuts can be as high as 20% depending on the weather and locality, and the aim is to reduce moisture content down to 8%. The dried nuts are stored in a cool room or cool situation in a vermin-proof silo or store room.

AFL in Hazelnut

A limited survey for the presence of AFLs in tree nuts from local markets and supermarkets in Valencia was carried out. The samples containing AFLs were hazelnuts, with AFL B1 and G1 levels up to 0.42 and 0.52 mg kg^{-1}, respectively.

In another study of hazelnuts, 90% of the hazelnuts were AFL positive (25–175 ng g^{-1}). One sample was also contaminated with zearalenone. The dominant fungal flora during storage is *Penicillium* and *Aspergillus* spp. *Aspergillus flavus* capable of producing AFL has been isolated from hazelnuts in storage. Reduction of inshell moisture content to below 10%, and nutmeat moisture content to less than 6% is an effective means deterring mold growth. Sanitation with chlorine dips may also be effective in reducing the incidence of mold infestation by reducing the amount if innoculum is carried into postharvest storage. Because of the high amounts of organic material on the surface of shells, chlorine concentrations should be monitored and replenished as necessary to maintain chlorine at concentrations necessary to kill microorganisms.

Romularia in Hazelnut

The most common decay found in hazelnuts is molds, with *Romularia* spp. most prevalent throughout nut development and the major pathogen associated with kernel tip mold. Although *Romularia* spp. appears to infect hazelnuts during nut development and may be quiescent before maturity and storage, many molds require breakage of the shell to contaminate the nut and thus intactness of the shell offers some natural defense against mold infestation.

Hazelnut Allergies

Allergy to hazelnut is more common in Europe than in the US. Hazelnut pollen is a common cause of seasonal hay fever, and it appears that a person with hazelnut pollen allergy is at risk for food allergy to the tree nut itself. Hazelnut is also related to birch pollen, and therefore people with birch pollen allergy may experience oral allergy symptoms with eating hazelnuts. People with hazelnut allergy may also be allergic to coconut, cashews, peanuts, and soybean, given the similarity between the allergens in these foods.

Macadamia Nut

The family Proteaceae includes approximately 10 species of the genus *Macadamia*, two of which produce edible nuts: *Macadamia integrifolia* and *Macadamia tetraphylla* or hybrids of these. The major species of commerce is *M. integrifolia*. *Macadamia* nuts are native to Australia and are produced there as well as in Hawaii, Central and South America, and parts of Africa. Nearly all production consists of grafted trees of cultivars developed in Hawaii or Australia. The edible kernel is enclosed in a thick, hard shell that, in turn, is enclosed in a husk that separates from the tree at about the time the seed is mature. The kernel is nearly spherical, consisting of joined equal-sized halves, i.e., cotyledons.

Macadamia nuts should be husked within 24 h of harvest, after which the drying process should be initiated. Freshly fallen nuts contain approximately 25% kernel moisture, although nuts that have remained on the ground for extended periods may have as little as 10–15% moisture. Drying should begin with ambient air, followed by a gradual increase in temperature that will not exceed 60 °C (140 °F) in the final stage of drying. Drying may be completed in shell (to 1.5% kernel moisture) or the nuts can be partially dried in shell (to approximately 5–6% kernel moisture), followed by cracking and finish drying of kernels alone to 1.5% moisture. It is important to protect the dry kernels from moisture and O_2, so that packaging in a material that is impervious to moisture is important. Vacuum packaging or nitrogen flush offers protection from O_2. Exposure to moisture results in loss of crispness and shelf life. Likewise, prolonged exposure to O_2 results in rancidity. Cold storage is normally not necessary for short-term storage, but might be desirable for extended periods. Frozen storage (-18 °C, 0 °F) can be very effective in extending shelf life.

Extended harvest intervals may result in mold, yeast, or bacterial contamination in the field as well as insect damage. Southern green stinkbug (*Nezara viridula* (L.)), tropical nut borer (*Hypothenemus obscurus* (F.)), koa seed worm (*Cryptophlebia illepida* (Butler)), and litchi fruit moth (*Cryptophlebia ombrodelta*) are the major insect pests causing damage to *Macadamia* nuts in Hawaii, resulting in an unmarketable kernel. Delay in husking the nuts following harvest can also result in mold growth and fermentation. Husking should occur within 24 h of harvest. The thick shell provides considerable protection for the kernel, but cracked shells and open micropyles can provide entry of fungi and bacteria as well as ants. When the nuts fall from the tree, the kernels contain approximately 25% moisture. At harvest, moisture level can range from approximately 10% to 25%. Once the nuts have been dried to 1.5% kernel moisture, the water

activity is 0.3, which is insufficient to support the growth of mold or bacteria.

Macadamia nuts are common foods in Hawaii and the tropics, and are a novelty food elsewhere in the world. There is significant cross-reactivity between the allergens in *Macadamia* nuts and cashews, hence a person is likely to be allergic to both of these tree nuts.

Chemical Safety of Drinking Water

Minerals

Risk Associated with a Lack of Minerals

Minerals are essential for human life, being involved in a number of biochemical reactions, and as constituents used by the body. The drinking water, because of its essentiality, is one valuable source. The mineral content of water defines its hardness, and several studies have investigated its potential health effects: most of them were ecological epidemiological studies, which founded an inverse relationship between hardness and cardiovascular mortality.

In 2006, an expert meeting was organized by the World Health Organization (WHO) to address the possible role of drinking water containing calcium and/or magnesium as a contribution to the daily intake of those minerals. Indeed, the major source of micronutrients such as calcium and magnesium comes from the diet, but due to food habits, and the needs which can vary considerably among individuals and life periods, some people from various countries fail to reach the recommended intakes of these nutrients. Finally, a consensus was stood between the experts for the benefits linked to the calcium and magnesium intakes through the drinking water consumption. Regarding calcium, inadequate intakes are mainly associated with increased risks of osteoporosis and nephrolithiasis (kidney stones). Magnesium has also a significant impact on the health, with low magnesium levels being linked to endothelial dysfunction and hypertension.

Fluoride is another mineral found in most drinking waters. Demineralization and some other treatment processes will reduce its levels. However, where dental caries risk is high or increasing, authorities may consider addition of fluoride to the demineralized public water supply to between 0.5 and 1.0 mg l^{-1}, but other factors should also be considered. In countries where dental health awareness among the public is very high and alternative vehicles for fluoride, such as fluoridated toothpaste, are widely available and widely used, the absence of fluoridation would likely be of little consequence. However, in developing and developed countries where public dental health awareness might be much lower, addition of fluoride in drinking water would be important. The WHO drinking-water guideline value for fluoride is 1.5 mg l^{-1}.

Some treatments can have also a negative impact on the mineral wealth of drinking water. Point-of-entry ion exchange devices (water softener) are used in some households to remove hardness from water. Each divalent ion in the water is replaced by two monovalent sodium ions. Softening will not only have several esthetically beneficial effects inside the home, such as reducing scaling in pipes, fixtures, and water heaters and improving laundry and washing characteristics, but it also increases the sodium content of the drinking water. Point-of-use reverse osmosis and distilling devices remove virtually all the minerals from the input water, functioning as a final barrier against potential trace-level contaminants that may be present, as well as removing nutrients. The resultant drinking water is devoid of all minerals. Use of these devices may result in the reduction of the overall intake of nutrient minerals by the consumers.

Risk Associated with High Amount of Minerals

Nutrients are a good example of a risk – risk assessment: at low levels, there is a health risk linked to an inappropriate intake such as osteoporosis, cardiac malfunction, dental health, etc. However, at high doses, another health risk will occur: excessive intake of fluoride cause crippling skeletal fluorosis and possibly increased bone fracture risk. Ingestion of excess fluoride during tooth development, particularly at the maturation stage, may also result in dental fluorosis. These effects may be mitigated by coexposure to some minerals, such as calcium or magnesium.

Another example of nutrients that can lead to a negative health impact with high exposure is nitrates. They are widely encored in the nature, as part of the global nitrogen cycle. Moreover, they have been extensively used as fertilizers in agriculture, and as food additives (e.g., conservatives for meat and fish). Both groundwater and surface water can be contaminated by nitrates as a result of agricultural activities. Levels of nitrate contamination are usually significantly higher in groundwater, particularly in shallow wells, in which concentrations that exceed the current WHO guideline value of 50 mg l^{-1}, and exceptionally exceed 500 mg l^{-1}, have been reported in intensive agricultural regions. Nitrites are not frequently detected in drinking-water; when they are present, their concentrations rarely exceed 3 mg l^{-1}. Nitrates per se are relatively nontoxic, but their metabolites and reaction products, for example, nitrite, nitric oxide, and *N*-nitroso compounds, have raised concern because of implications for adverse health effects such as methemoglobinaemia and carcinogenesis. Dealing with methemoglobinaemia, infants are a critical subpopulation due to their higher gastric pH inducing

a higher rate of reduction of the nitrates to nitrites. Nitrites react with oxidized hemoglobin to form nitrates and methemoglobin.

Carcinogenicity is another worry on nitrates exposure: ingested nitrates and nitrites are classified into group 2A (probably carcinogenic to humans) by the International Agency for Research on Cancer (IARC) since 2006. Their toxicity comes from their reduction from nitrates to nitrites, and by endogenous nitrosation to *N*-nitroso compounds such as nitrosamines.

Current Issues

Environmental Contaminants

Heavy Metals

Heavy metals are ubiquitous and many foodstuffs are contaminated. Drinking water follows this rule, but heavy metals can come from anthropogenic or natural sources (soil, rocks crossed by water, etc.). The WHO sets guideline values for most of them, and both the US Environmental Protection Agency (EPA) and the European Commission also defined legal maximal limits for heavy metals.

Among them, lead is associated with some consumer products (e.g., paint, toys, and leaded fuel), and its exposure has dropped since the 1990s, especially thanks to the forbidden use of lead tetraethyl as fuel additive. Lead induces neurobehavioral and intellectual troubles, especially in young children, and recent studies discussed the relevance of a threshold level for its neurotoxic effects at low doses. Children are more sensitive to its health effects, due to a bigger water intake/mass weight ratio, a specifically sensitive window for neurobehavioral development, and a higher gastrointestinal absorption of lead (4–5 times more than adults). Currently, the US Centers for Disease Control and Prevention (CDC) set a maximal safe limit of the blood level to be at 10 $\mu g\,dl^{-1}$. Lead is very persistent in soil and can therefore leach in water by the erosion of natural deposits. However, its main origin in drinking water would come from pipes, solder and plumbing products. The leaching level varies depending on the several factors: presence of chloride and dissolved oxygen, pH, temperature, water softness, and standing time of water, soft, acidic water being the most plumbosolvent. Some focus was made in scientific journals, which summarize the recent overexposure to lead via drinking water in North America. Indeed, many water treatment plants now use disinfectants called chloramines, combinations of chlorine and ammonia. However, in some water systems this switch has coincided with an increase in lead in water, perhaps because chloramines cause lead to leach from pipes, fixtures, and solder. The US regulation of lead in drinking water is zero, with an action plan set at 15 $\mu g\,l^{-1}$, whereas the guideline value from the WHO for drinking water is 10 $\mu g\,l^{-1}$.

Arsenic, another heavy metal associated with drinking water safety, is known since antiquity as both a remedy and a poison. In the nineteenth century, the Fowler's solution was one famous tonic containing the arsenic derivate, and organoderivatives of arsenic were used to cure syphilis. Nevertheless, arsenic is even more known as one of the most toxic metals. Arsenic exists in oxidation states of -3, 0, 3, and 5, mainly in organic forms in food and inorganic form in drinking water, the latter showing the highest toxicity. It has been classified as evident carcinogen in humans by both the IARC and the National Toxicology Program for its ability to induce skin, bladder, and lung cancers following oral intake. Although there is substantial epidemiological data showing an association between skin cancers and arsenic exposure through drinking water, uncertainty of arsenic risk remains high for low doses. The available data on its mode of action cannot provide evidence for using linear or nonlinear extrapolation. Moreover, its toxicity is influenced by both endogenous and exogenous factors (genetics, malnutrition, etc.). Currently, neither the European Food Safety Authority nor the Joint FAO/WHO Expert Committee on Food Additives (JECFA) has determined a safe threshold value for inorganic arsenic. JECFA previously did it, but the Committee has recently considered that the previous provisional tolerable weekly intake is no longer appropriate. The maximum likelihood estimates, using a linear extrapolation, for bladder and lung cancer for the US populations exposed to 10 $\mu g\,l^{-1}$ of arsenic in drinking water are, respectively, 12 and 18 per 10 000 population for females and 23 and 14 per 10 000 population for males. The WHO has retained the level of 10 $\mu g\,l^{-1}$ as the arsenic guideline value. Unfortunately, its presence in drinking water is a daily reality for millions of persons living in West Bengal and in Bangladesh. It is estimated that of the 125 million inhabitants of Bangladesh between 35 and 77 millions are at risk of drinking contaminated water. According to a study conducted in 1998 by the British Geological Survey, 35% of the sampled tube-wells in Bangladesh showed arsenic concentration levels greater than 50 $\mu g\,l^{-1}$, and 8.4% showed greater than 300 $\mu g\,l^{-1}$, well above the WHO guideline value.

Others

Other chemical contaminants in drinking water, the presence of which express safety concern, are organic contaminants such as pesticides, dioxins and polychlorobiphenyls, polycyclic aromatic hydrocarbons, and so on. The phytosanitary product family encompasses a wide variety of chemicals, from agricultural activities and from the water treatment used for the control of disease-carrying insects in the drinking water. The third edition of the WHO guidelines for drinking water quality quotes five pesticides, all of them being planned to be used as a mosquito larvicide in containers in order to control the dengue fever. Even if the WHO considers that it is not appropriate to set a formal guideline value, the maximal dosage for each pesticide is specified as assessed by the WHO Pesticides Evaluation Scheme. Apart from these, the WHO sets guideline values for almost 40 active substances: for herbicides, such as alachlor (CAS number 15972-60-8), atrazine (CAS number 1912-24-9), and for insecticides like aldrin (CAS number 309-00-2), chlordane (CAS number 57-47-9), DDT (CAS number 107917-42-0), etc. In terms of comparison, the European regulation on drinking water (Council Directive 98/83/CE) does not consider pesticides individually but as a whole: the maximal limit per pesticide is 0.10 $\mu g\,l^{-1}$ and for the total pesticides 0.50 $\mu g\,l^{-1}$. Here the term pesticide means organic insecticides, herbicides, fungicides, nematocides,

acaricides, algicides, rodenticides, slimicides, related products (inter alia, growth regulators) and their relevant metabolites, degradation, and reaction products. In the case of aldrin, dieldrin, heptachlor, and heptachlor epoxide the parametric value is 0.030 $\mu g\,l^{-1}$.

Process Contaminants

Disinfection Byproducts (DBPs)

Although disinfection of drinking water is indisputably beneficial for human health, the chemical reactions between oxidative agents (chlorine, ozone, etc.) and natural organic matter lead to the formation of DBPs. Among the hundreds of DBPS, only half of them are known, even less with chloramine treatment. The best known are chloroform (CAS number 67-66-3), bromoform (CAS number 75-25-2), bromodichloromethane (CAS number 75-27-4), and dibromochloromethane (CAS number 124-48-1) from the family of the trihalomethanes (THMs), and mono-, di-, and trichlororacetic acids (CAS numbers 79-11-8, 79-43-6, and 76-03-9, respectively) and mono- and dibromoacetic acids of the haloacetics acids group (CAS numbers 79-08-3 and 631-64-1, respectively).

To date, the European Commission regulated the presence of four THMs, chlorite (CAS number 7758-19-2), and chlorate (CAS number 7775-09-0). The US EPA also included five haloacetic acids and bromate (CAS number 15541-45-4). The last edition of the WHO guidelines for drinking water includes other DBPs such as 3-chloro-4-dichloromethyl-5-hydroxy-2(5H)-furanone (MX, CAS number 77439-76-0) or *N*-nitrosodimethylamine (NDMA, CAS number 62-75-9). In parallel, recent studies performed on emerging DBPs highlighted that a classification for toxicity potential can be addressed with the following hierarchy: iodo-DBP > bromo-DBP > chloro-DBP. However, despite that the experimental toxicity data showed genotoxic and reprotoxic potentials, the epidemiological studies on the incidences of bladder cancer, colorectal cancer, or stillbirths and congenital malformations failed to find a strong relationship with the level of DBPs, always expressed by the concentration of THMs. New studies are planned in Europe to dig the link between the exposure to chlorinated water and the occurrence of pregnancy issues. In these studies, all sources of exposure should be assessed, including the inhalation one (during the shower), the oral exposure (both the water drank and the water used for the preparation of food), and the dermal way (during all recreational activities in swimming pool).

Ozonation is another good means to disinfect water and to eliminate the micropollutants. However, ozonation also generates toxic byproducts. In the presence of bromide ions, these are oxidated to hypobromous acid and further the hypobromite ion is oxidated into bromate. As the second step requires the ionic form, and does not proceed with the protonated form, the rate of reaction increases with increasing pH. In terms of toxicity, bromates are mutagenic and carcinogenic, and potassium bromate is classified into group 2B by IARC. In male rats, bromates induce multisite tumors in the kidneys, the thyroid gland, and in the peritoneum. Only renal adenomas and carcinomas were seen in female rats. For the WHO , the weight of evidence from the rat bioassays clearly indicates that bromate has the potential to be a human carcinogen. Owing to insufficient data on the mode of action for carcinogenicity of bromates, the International Programme on Chemical Safety developed both a threshold and a linear extrapolation model. Applying the multistage linearized model, the concentration of bromate in drinking water associated with an upper-bound excess lifetime cancer risk of 10^{-5} is 2 $\mu g\,l^{-1}$. The health-based value was raised from 2 to 10 $\mu g\,l^{-1}$ by the WHO for analytical and technological reasons. A provisional guideline value of 10 $\mu g\,l^{-1}$ is currently recommended.

Materials in Contact with Water

Conditioning of water, including central softening and stabilization, may be necessary to reduce corrosion of piping materials and/or scaling effects in installations and to improve consumer acceptability. Corrosion and scaling can be associated with adverse effects on health (from leachates such as lead) and the environment (from leachates such as copper if the water is not conditioned) and reduced the lifespan of the distribution network and appliances using water. Soft waters are aggressive and can corrode water pipes leading to matter release, but any new water treatment can enhance pipe corrosion. In several counties in the USA, the switch from chloride to chloramine treatment has been accompanied with a huge peak in lead concentration in drinking water. Indeed, the addition of chloramine in water modifies the configuration of lead, increasing its solubility in water.

The topic of packaging is also of particular concern for bottled waters. The polyethylene terephtalate (PET, CAS number 25038-59-9) is now extensively used for the bottling of water in small volume. It is known that the use of such material is associated with the migration of antimony trioxide (CAS number 1309-64-4), a catalyst used in its manufacture for nearly 30 years. However, the migration levels recorded in bottled water samples are very low. These levels are well below the health standards set by the US EPA (6 $\mu g\,l^{-1}$), by the European Food Safety Agency (40 $\mu g\,l^{-1}$), or by the WHO (18 $\mu g\,l^{-1}$). Now, the PET is under a new evolution with the increasing incorporation of a recycled PET with the virgin material to reduce the carbon footprint of bottled water.

The Home and Office Delivery service implies the reuse of bottles, which need to be built with a rigid, resistant, and crystal material for volumes of approximately 5 gal. Such bottles are made with polycarbonate, made with bisphenol A (CAS number 80-05-7), which can migrate from the packaging into the water. There is a strong scientific debate on toxicity of bisphenol A, with endocrine disruption effects observed at both high and low doses, following a U-curve. The reliability of tests, the endpoints observed and the extrapolation of experimental data to humans are the key points currently discussed by risk assessors for allowing the best risk management for public health.

Emerging Issues

Endocrine Disruptors

The WHO gave a definition of endocrine disruptors: "An endocrine disruptor is an exogenous substance or mixture that

alters function(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or its progeny, or (sub)populations.'' Their mode of action can be direct or indirect. For example, the pharmaceutical estrone (CAS number 53-16-7) and the industrial contaminant alkylphenols polyethoxylates are able to directly link the estrogen receptor and activate it. Traces of these substances have been detected in rivers, and then can be detected in the drinking water. Thankfully, water treatments (activated charcoal, ozonation, etc.) are efficient enough to remove most of these molecules. Another example of an endocrine disruptor chemical found in water is perchlorate (CAS number 14797-73-0). It exerts an antithyroid activity by an indirect mechanism. Thyroid gland produces hormones: triiodothyronine (T3) and thyroxine (T4), under the control of the thyroid-stimulating hormone, which is synthesized in the anterior pituitary gland. These hormones are essential for good biological development, and the role of iodine in their synthesis is primordial. In humans, perchlorate can interfere with iodine uptake by the thyroid gland, causing changes in the levels of the thyroid hormones. These changes can lead to problems in growth and development of the fetus and infant and may impair the function of many organs in humans of all ages.

Pharmaceuticals and Personal-Care Products

A recent research has focused on this class of contaminants with many articles published on it. The consumption of drugs is associated with a specific disease, and once cured, pharmaceuticals are often disposed of down toilets. In parallel, those absorbed are metabolized and eliminated by the body. The steps of metabolism, especially with the enzymes of the second phase, increase their aqueous solubility to enhance their natural elimination. Taken all together, both parent molecules and metabolites can be found in wastewater and then in the environment. The first difficulty the authorities faced was the definition of a limited list of pharmaceuticals to be looked for in the environment and the drinking water. The priorization was made to take into account the volume of production, the level of consumption, the biodegradability, and their physicochemical properties. Some classes of pharmaceuticals, with representative molecules, have been identified. Among them, the most often detected substances are carbamazepine (CAS number 298-46-4), an antiepileptic drug, diclofenac (CAS number 15307-86-5), ibuprofen (CAS number 15687-27-1), and other nonsteroid antiinflammatory medication. Caffeine (CAS number 58-08-2) and aspirin (CAS number 50-78-2) can also be detected but their origin is subject to caution: aspirin under the form of salicylic acid can be naturally found in the environment and analytical cross-contamination can occur for caffeine at low levels of quantification. Nevertheless, at the levels usually found, none of these compounds are susceptible to exert toxic effects. Two questions are now rising: What is the impact of these mixtures at low doses and what is their behavior in the environment (e.g., development of antibiotic resistance) and during the drinking water treatments. Indeed, triclosan (CAS number 3380-34-5), an antibacterial agent, can lead to the formation of dioxin under ozone oxidation.

Assessing the Risks

Principles

The level of contaminant in drinking water is usually expressed in milligrams per liter, even in micrograms per liter for the most toxic chemical hazards. In toxicological risk assessment, comparison is made with toxicological reference doses, expressed for oral toxicity in mass unit per body weight (in kg) and, for nonacute exposure, per exposure time (usually given by day). These toxicological reference doses are most often based on *in vivo* experimental data, with safety factors applied to extrapolate the experimental data to a safe exposure for humans. The risk results from the exposure to a hazard: indeed, the risk must be identified (what is the hazard) and characterized (what is the level of exposure to such hazard). To be able to compare contaminant concentrations in drinking water with toxicological reference doses, an assumption of the quantity of water drunk every day must be set. A global approach is to consider a drinking water consumption of 2 l per day for a 60 kg adult. This assumption is declined for toddler (1 l per day for a 20 kg child) and for infant (0.75 l per day for a 5 kg baby). It must be specified that this assumption can be adapted and modified by national agencies in order to be closer to the scope of their assessment. Thus, the US EPA considers in its assumption a 70 kg body weight as an average weight for American adults, whereas the WHO uses preferentially 60 kg body weight as the standard for worldwide adults.

This methodology is used for chemicals for which a toxicity threshold exists. This is not the case for substances which are both genotoxic and carcinogenic. For those, no safe dose can be established and the recommendation is to reduce the exposure as low as reasonably achievable. However, for risk management, a maximal level must be specified, and it is done through a linear extrapolation of the dose–effect relationship observed at high doses from the epidemiological data in humans or from the experimental data in animals. This is a conservative approach as it considers that the organism answers in a similar manner at low doses than at high doses. The linear extrapolation model gives a correlation factor between the additional cancer risk and the hazard concentration. An 'acceptable' risk corresponds to an additional risk of cancer for one million of individuals (10^{-6}).

Example

Benzene is an evident human carcinogen leading to acute nonlymphocytic leukemia and a variety of other blood-related disorders in humans following occupational exposure. Its oral carcinogenicity has been observed in experimental animals. Additionally, changes in blood and bone marrow consistent with hematotoxicity are recognized in humans and experimental animals. Although it is not mutagenic in standard bacterial assays *in vitro*, its genotoxicity (chromosomal aberrations) has be shown *in vivo*. Two different approaches were made by both the US EPA and the WHO.

The EPA states in 1998 that ''there is [currently] insufficient evidence to deviate from using an assumption of a linear dose-response curve for benzene, hence, the Agency's past approach of using a model with low dose linearity is

Table 1 Major outbreaks linked to the consumption of drinking water, bottled water, and ice

Germs involved	*Type of organism*	*Number of cases/ deaths*	*Year and localization*	*Water involved*	*Reference*
Cryptosporidium parvum	Parasites	403 000/0	1993 Milwaukee, USA	Public water supply	Mac Kenzie *et al.* (1994)
Escherichia coli O157 and *Campylobacter*	Bacteria	2000/7	2000 Walkerton, Canada	Public water supply	Holme (2003)
Hepatitis A	Viruses	107/0	2006 Sichuan Province, China	Ice snacks made with untreated well water	Zhang *et al.* (2008)
Legionella	Bacteria	449/9	2001 Murcia, Spain	Hospital cooling towers	Garcia-Fulgueiras *et al.* (2003)
Noroviruses (Calicivirus)	Viruses	41/0	2005 Pugia area, Italy	Ice?	Rizzo *et al.* (2007)
Salmonella	Bacteria	46/0	2006 Gran Canaria, Spain	Bottled water	Palmera-Suarez *et al.* (2007)
Campylobacter, *Giardia*, and enteric viruses	Parasite Bacteria Viruses	8453/0	2006 Nokia, Finland	Public water supply	Laine *et al.* (2007)

still recommended.'' In 2000, the EPA extrapolated data on cancer risk associated with inhalation exposure to oral risk. The inhalation unit risk range is first converted to unit of dose (μg per kg body weight per day). Then, assuming a 100% oral absorption and a standard intake of 2 l per day, the unit of risk is expressed in $\mu g\,l^{-1}$. The WHO built its assessment of the risk estimates on the basis of a 2-year oral study in rats and mice. As for the EPA, a robust linear extrapolation model was used, data having been unfit for the linearized multistage model. The estimated range of benzene level in drinking water corresponding to excess cancer risks in female mice and male rats are similar to those derived from the epidemiological data. Thus WHO and EPA found the same relationship between benzene concentration in drinking water and excess lifetime cancer risk: 10^{-4}, 10^{-5}, and 10^{-6} excess risk at 100, 10, and 1 $\mu g\,l^{-1}$, respectively. The US EPA set a maximal limit at 5 $\mu g\,l^{-1}$, whereas the WHO guideline value is 10 $\mu g\,l^{-1}$.

Microbial Safety of Drinking Water

Microbial contamination is one of the major risks drinking water suppliers have to face, in developing and developed countries as well. Outbreaks of waterborne diseases affecting thousands of people worldwide are reported from countries at all levels of development and from all types of water supply.

Impact of Drinking Water-Related Diseases

The global impact of waterborne and water-related diseases is difficult to assess. The main reasons are a global lack of data especially in developing countries, the difficulty to find the origin and the agent responsible for the infections, seasonal as well as geographical disparities, secondary transmissions from person to person, etc.

Gastroenteritis is the most frequent water-related outcome. The precise ratio of water-linked enteric illnesses is not precisely estimated but the WHO quotes 1.7 million deaths associated with unsafe water, sanitation, and hygiene mainly among young children under the age of 5 years and elderly.

In addition, the exact health impact of the microbiological quality of drinking water is also not easy to estimate. 'Drinking water' that ''should be suitable for human consumption and for all usual domestic purposes including personal hygiene'' according to WHO includes waters not only from piped sources, water from springs and wells but also packaged and bottled water and ice.

More complete epidemiological data have been reported by the US CDC and EPA. During 2007–08, 36 drinking water-related outbreaks were reported in the US leading to 3 deaths and 4128 infectious cases. Of these, 61.1% were gastrointestinal infections, 33.3% were linked to respiratory illness (Legionellosis), and others were related to skin injury or hepatitis. More than half of the described outbreaks were associated with untreated or inadequately treated groundwater.

Indeed, the microbial quality of water resources as well as the different types of disinfection applied are both essential to ensure the safety of drinking waters.

Surface waters and groundwaters under direct influence of surface waters are more 'vulnerable' to microbial contaminations from environmental or animal origins than well protected groundwaters. Disinfected waters – through physical and/or chemical processes – are also less susceptible to microbial contaminations than untreated, poorly protected drinking waters.

However, reports of major outbreaks linked to the consumption of drinking water, packaged water, and ice are well documented (Table 1), proving that microbiological safety of drinking water is a real challenge.

Waterborne Pathogens

Main Waterborne Pathogens

Unfortunately, germs potentially causing diseases and transmitted through water include a large range of organisms from viruses, bacteria, protozoa, and even helminthes.

It can be considered that mainly most of the enteric pathogens can be transmitted through water. Water as food is one of the common transmission ways of fecal–oral transmitted diseases.

However, waterborne pathogens are not strictly limited to enteric ones and other organisms, transmitted for instance through inhalation or contact (during bathing or washing) should not be omitted.

Microbial contamination can occur via introduction of human and animal fecal matter into drinking water but additionally organisms occurring in the environment such as *Legionella* spp. and *Acanthamoeba* spp. can lead to severe infectious diseases. Infections spectra is large from mild gastroenteritis to severe diseases targeting the intestinal tract as cholera or dysentery or hepatitis, to respiratory illness such as Legionellosis and skin or brain disorders (Table 2).

Usually, organisms are classified according to the epidemiological evidences of being water transmitted:

- Organisms for which clear epidemiological data of water transmission are available (such as *Vibrio cholerae*, *Cryptosporidium parvum*, noroviruses, etc.).
- Organisms for which water transmission is conceivable (such as *Helicobacter pylori*, *Isospora belli*, etc.) but not yet confirmed.
- Known pathogens for which there is no evidence of water transmission.

Toxin producers (e.g., cyanobacteria) are also to be included as waterborne pathogens.

Host–germ interactions play an important role in waterborne infections and diseases. For instance, asymptomatic infections are poorly reported and the precise part of water-related contaminations, i.e., with hepatitis A virus, are not easy to distinguish in large endemic areas.

Waterborne Pathogen's Behaviors in Water

The occurrence of an organism in drinking water cannot only justify its significance regarding human health. Indeed, the survival of the target organism in water (i.e., inactivation rate) as well as the infectious dose greatly impacts the probability of infection through water ingestion/inhalation.

Some pathogens can both survive and multiply in water. Most of them are from environmental origin as *Legionella pneumophila*. Others harbor long survival abilities in water keeping their infectiosity as parasites like *Cryptosporidium parvum*, *Giardia lamblia*, and also enteric viruses. Some seem to have a more limited survival in water as *Campylobacter* spp. Qualitative information on the survival of waterborne pathogens' in drinking water are available in Table 2.

Under certain living conditions as starvation, bacteria may enter into a viable but not cultivable (VBNC) state: cells are metabolically active, while being unable to grow on its usual growth medium. *Pseudomonas*, *Campylobacter*, and *Escherichia coli* are the known VBNC bacteria. VBNC cells could persist in the water and may keep growth capability and infectivity.

Influence of Industrial Processes on Waterborne Pathogens

Among 84 outbreaks occurred in Europe between 1990 and 2004, Smets *et al.* found that a large part of them was due to insufficient treatment or treatment failure irrespective of the origin of the water, whether surface or groundwater. Inadequate treatment to deal with rare events of high and punctual contaminations of the water source was also cited.

Drinking water treatments indeed are key for providing safe drinking water except in the case of natural mineral waters, where no microbiological treatment is allowed.

In addition to the process dedicated to remove organisms, some process mainly designed for particle removal can also have an impact on pathogenic organisms. The combination of all process steps has to be combined to assess the overall microbial reduction as shown with the multibarrier approach.

Monitoring drinking water storage and distribution (tanks, pipes, and bottles) is also required to protect water from postcontaminations and to guarantee its microbial safety until it reaches the consumer.

Disinfection

Chemical disinfection consists of adding a disinfectant (generally a strong oxidant) to the water, which reacts with the organic matter and microbial organisms. Most frequent chemical disinfection compounds are chlorine dioxide, chlorine, and chloramines on one hand and ozone on the other hand. Depending of the water, the chemical disinfection efficiency can be lowered, for instance, at higher pH when using chlorine or with high organic matter concentrations. Byproducts originating from oxidative reactions can also be generated by chemical disinfection. Some may have adverse health effects.

Microorganisms adsorbed on particles are more resistant to chemical disinfection than free living organisms. Chemical disinfection is generally used as the primary microbial removal step and can be completed by another disinfection to ensure microbial quality during the distribution.

Efficiency of disinfection is defined using the Ct value which is defined as the product of disinfectant concentration (milligram per liter) and the contact time (min). Temperature and pH both influence the Ct value.

Chlorine is a strong disinfectant regarding vegetative bacteria in a range from 0.05 to 200 mg-min l^{-1} depending on the organic matter load. Chlorine dioxide is also a strong oxidant and disinfectant more effective than free chlorine at basic pH. Ct values for chlorine dioxide are less than 1 mg-min l^{-1} for most vegetative bacteria and viruses (Table 3).

However, some parasites as Cryptosporidium are known to show high resistance to chlorine-based oxidation with Ct values of approximately 15 mg-min l^{-1} for *Giardia* cysts.

Table 2 General overview of the main waterborne organisms that can cause or be suspected of causing illnesses

Organism	*Reservoir*	*Transmission route*	*Clinical features*	*Infectious dose*	*Survival in water*
Campylobacter	Animals	Fecal–oral	Gastroenteritis Guillain–Barré syndrome Meningitis	Low	Moderate (VBNC)
Pathogenic *Escherichia coli*	Animals Humans	Fecal–oral	Bloody diarrhea Hemolytic uremic syndrome	Low	Low to moderate (Biofilms?)
Legionella	Environment (surface waters)	Inhalation Ingestion	Legionellosis Pontiac disease	Moderate	High (Amoebae)
Salmonella typhi/ paratyphi	Humans	Fecal–oral	Typhoid	Low	ND
Other Salmonella	Humans Animals	Fecal–oral	Acute gastroenteritis	Moderate	Low to moderate (VBNC)
Shigella	Humans	Fecal–oral	Dysentry Acute gastroenteritis	Low	Low (VBNC, amoebae?)
Vibrio cholerae	Environment Humans	Fecal–oral	Cholera gastroenteritis	Low	High (water temperature $>20\ ^{\circ}C$)
Yersinia enterocolitica *Yersinia. pseudotuberculosis*	Animals (swine and rodents)	Fecal–oral	Gastroenteritis Mesenteric adenitis	High	Unknown
Aeromonas	Environment (surface waters)	Inhalation Ingestion	Respiratory tract infections Gastrointestinal illness	Unknown	High (regrowth)
Burkholderia pseudomallei	Environment Animals (sheep, goats, and swine)	Inhalation, ingestion, person-to-person?	Melioidosis Acute respiratory infections	Unknown	Moderate? Regrowth?
Cyanobacteria	Environment (surface waters)	Ingestion of cyanotoxins Skin contact	Gastrointestinal and, respiratory disorders, liver damage, neurotoxic reactions	$1\ \mu g\ l^{-1}$ for microcystin LR	High (regrowth)
Helicobacter pylori	Humans, Environment?	Person to person Fecal–oral	Gastritis, stomach ulcers	Unknown	Low to moderate (VBNC)
Nontuberculosis mycobacteria	Environment Animals	Inhalation Ingestion Contact	Pulmonary and gastrointestinal diseases Lymphadenitis Skin infections	Unknown	High (regrowth)
Pseudomonas aeruginosa	Environment	Inhalation Contact Ingestion?	Acute respiratory infections	Unknown	High (regrowth)
Adenovirus	Humans	Fecal–oral Inhalation Contact	Gastroenteritis Respiratory infection and conjunctivitis	Low	High
Calicivirus (Norovirus)	Humans	Fecal–oral	Gastroenteritis	Low	Moderate to high
Enterovirus	Humans	Fecal–oral	Poliomyelitis Encephalitis Meningitis Myocarditis	Low	Moderate to high
Hepatitis A	Humans	Fecal–oral	Gastroenteritis	Low	Moderate to high
Hepatitis E	Humans Animals	Fecal–oral	Gastroenteritis	Low	Moderate
Rotavirus	Humans	Fecal–oral	Gastroenteritis	Low	Moderate to high
Cryptosporidium	Humans Animals	Fecal–oral	Cryptosporidiosis	Low	High
Giardia	Humans Animals	Fecal–oral	Giardiosis	Low	High
Cyclospora	Humans	Fecal–oral	Cyclosporiasis	Low	High
Acanthamoeba	Environmental	Inhalation Contact	Encephalitis Keratitis	Unknown	High

Abbreviations: ND, not detected; VBNC, viable but not cultivable.

Ultraviolet light (UV) is also widely used for water treatment. UV lamps are placed in a flow-through contact compartment that is continuously operated. UV fluence corresponding to the UV light intensity and the contact time (function of water flow rate) directly impacts the disinfection efficiency.

Both flow patterns and the type of lamp (medium to low pressure mercury lamps) influence the removal of organisms. Inactivation of adenoviruses by UV treatment requires higher fluencies than that for other organisms (Table 4).

In addition to disinfection, special attention should be paid to ensure the absence of recontamination posttreatment. Chlorine, for instance, is widely used to protect drinking water safety along the water supply to the point of use.

Filtration

Filtration covers a wide range of processes from microfiltration to nanofiltration and reverse osmosis. Removing not only the particles but also organic compounds and colloids that can be present in water is the main aim of filtration. Nevertheless, depending on the membrane porosity and/or molecular weight cut-off, filtration can offer an alternative process to disinfection (Table 5).

There are mainly two classes of membrane treatment systems:

- The low pressure membrane systems, such as microfiltration and ultrafiltration (UF), are commonly used to remove particulate and microbial contaminants.
- The high pressure membrane systems, such as nanofiltration and reverse osmosis (RO), are typically applied for the removal of dissolved constituents.

Operating filtration devices with the aim of pathogen removal requires, however, application of good hygienic practices and strict maintenance conditions. Another drawback of such systems compared with disinfection treatment as UV or chlorine can be water losses that are generated especially for UF and RO filtrations.

Coagulation and Flocculation

Coagulation and flocculation first aim to remove organic matter and particles that can be present in source water as surface waters. Addition of chemical coagulants causes flocs to form that are further removed by sedimentation and clarification or filtration. Microbial germs, either as free living organisms or adsorbed on particles, can be partly embedded in coagulation flocs and/or naturally settle or be retained by filters.

Efficiency of coagulation and clarification depends obviously on water composition and pH; organic matter concentration; type of coagulants used and its concentration; process design including clarification, settling or filtration steps, and operating conditions (e.g., increased flow rates, increased turbidity, etc.).

Average microbial removal for coagulation/sedimentation/filtration processes ranges from

- 0.7–3.5 log for bacteria,
- 0.85–3.05 log for enteric viruses, and
- 0.2–3.5 log for parasites

depending on water turbidity (inlet and outlet), filter types, pH, and flow rates.

Bottling Process

Many different processes can be applied to packaged and bottled waters with the exception of natural mineral waters.

Disinfection treatments such as UV or ozonation are widely used as well as filtration systems depending on the source of the water (surface water and vulnerable groundwater). Maintaining the sanitary conditions of bottling operations are key to avoid microbial contaminations from catchment to bottle and especially postdisinfection. It implies, in addition to the

Table 5 Filtration systems and their potential removal of microbial organisms

Technology	*Operating pressure*	*Pore size*	*Primary applications*	*Microbes removal*
MF	1–2 bar	0.02–10 μm	Removal of particles and turbidity	Algae, protozoa and some bacteria (function of porosity)
UF	<5 bar	20–200 nm (5000–500000 Da)	Removal of dissolved nonionic solutes	Algae, protozoa, most bacteria, and viruses
NF	5 bar	1–10 nm (200–10000 Da)	Removal of divalent ions (softening) and dissolved organic matter	
RO	15–50 bar	<2 nm (50–300 Da)	Removal of monovalent ions (desalination)	

Abbreviations: MF, microfiltration; NF, nanofiltration; RO, reverse osmosis; and UF, ultrafiltration.

protection of the borehole, strict hygiene from plant environment to the design of tanks, pipes, pumps, and other process equipments. Filling area is of particular concern regarding potential microbial contamination. Air as well as operators can be possible vectors of microorganisms.

Packaging materials, bottles, containers, and caps are additional ways of contamination. Dedicated cleaning and disinfecting processes are usually applied for packs more than ever for glass bottles and reused jars (home delivery service). The Codex Alimentarius code of hygienic practice for packaged drinking waters CAC/RCP 48-2001 defined the minimal requirements to be applied by bottled water manufacturers.

In spite of packaged treated waters, natural mineral waters are not allowed to be disinfected (in line with the European Standards) as they originate from well protected groundwaters. At source, natural mineral waters must be free of any pathogenic organism. Specific recommendations have been provided by Codex Alimentarius in its code of practice for collecting, processing and marketing of natural mineral waters (CAC/RCP 33-1985).

Freezing

Freezing is considered to have a low impact on microbial survival. Avian Influenza viruses remained infectious in frozen environmental waters and a large outbreak of viral gastroenteritis was reported in 1987 by CDC due to ice made with water originated in wells that had been flooded by a creek during heavy rains.

Microbial Indicators

The Role of Indicators

As in food industry, the management of microbial risks in drinking water relies on both 'index organisms' and 'indicators.' Index organisms indicate the presence of ecologically similar pathogens (potential health risk) whereas indicator presence shows inadequate processing for safety (process failure). Basically, indicators must be present when pathogens are present and must be easy and fast to detect and quantify.

The detection of each pathogenic organism cannot be associated with the indicator concept as the presence of one pathogen does not mean the presence of others (e.g., there is no link between the presence of Legionella and Cryptosporidium) and its absence the absence of other contaminants. Moreover, some pathogens may be poorly detectable because of lack of reliable and sensitive methods or because of their physiological state in drinking water (VBNC for instance).

No indicators, however, can indicate the presence of environmental pathogens as Legionella and mycobacteria.

Fecal and Quality Indicators

Microbial indicators are commonly classified as fecal indicators and quality indicators.

- *Escherichia coli* is a well recognized bacterial indicator of fecal contamination being directly linked with the feces of warm-blooded animals. As such, it shows the potential presence of other enteric pathogens and a potential health risk.
- Coliforms can be of fecal origin (as *E. coli* which belongs to the coliforms group) or of telluric origin (soil and environment). Their presence in drinking water must at least be considered as indicative of microbiological quality weakening: treatment failure, loss of disinfectant products, addition of contaminated water into the water supply or the resource, etc.
- Enterococci (previously fecal streptococci) belongs to the fecal indicators group too as they originate from the gut of animals. They are widely used for recreational waters due to their resistance into the environment.
- Sulfite-reducing anaerobes (clostridia) are organisms that form spores that are environmentally resistant and their presence may indicate soil contamination, although some species may be associated with corrosion of distribution pipes. *Clostridium perfringens* is associated with fecal contamination. Their presence postdisinfection treatment may indicate a failure of efficiency as spores are more resistant than other vegetative bacteria as the *E. coli*.
- *Pseudomonas aeruginosa* is a ubiquitous environmental organism. Its presence is constant in surface waters and it can

easily grow in all types of freshwaters, even in pure water. As it is an opportunistic pathogen, its presence can either show a vulnerability of resources to surface waters/environmental contaminations or a vulnerability of the process environment. *Pseudomonas aeruginosa* is widely used in bottled water industry as a process indicator.

Enteric Viruses

Among waterborne pathogens, enteric viruses play an important role. Their detection remains uneasy as some are still uncultivable. Genomic techniques (deoxyribonucleic acid (DNA)/ribonucleic acid (RNA)) allow detection of viral genomes in waters but do not indicate if the detected viruses are infectious or not. Usual bacterial indicators (*E. coli*) seem not to be reliable for monitoring viral contamination because of

- a lack of correlation between the presence of fecal indicators and enteric viruses;
- enteric viruses are naturally more resistant to disinfection; and
- viral particles transfer through soil and even filters are totally different from bacteria.

Bacteriophages, which are viruses that infect bacteria, and especially somatic and F-RNA coliphages, seem good candidates as they harbor the same structure and size, surface charges and to a less extent similar resistance toward treatments.

Heterotrophic Plate Count (HPC)

HPC bacteria represent microbes isolated by a particular method that may vary regarding growth medium, time, and temperature incubation. Other names are used such as ' total viable count,' 'total flora,' and 'autochtonous flora.' The detection method largely impacts the number of cultivable bacteria and the species types that are isolated.

The number of HPC bacteria in drinking water varies widely depending on the source water, the applied treatments, disinfection residuals, condition of storage (even in distribution system), etc and, of course, on the HPC method that is used.

Even if, "there is insufficient clinical evidence that the addition of a maximum limit on HPC populations would provide a higher level of public health protection" as stated by Allen *et al.*, HPC counts are useful tools to monitor disinfection efficiency, defining adequate storage and distribution conditions, monitoring bacterial regrowth and for natural mineral waters assessing the stability and protection of the resources.

Assessing Microbiological Risks

Principles and Examples

Risk assessment is the first component of the risk analysis process (recent information is available on the US Department of Agriculture guideline for food and water, 2012). It is based on a four-step framework which includes

- hazard identification,
- hazard characterization,
- exposure assessment, and
- risk characterization

as described in the 'Principles and Guidelines for the Conduct of Microbiological Risk Assessment, from Codex Alimentarius.

Quantitative Microbial Risk Assessment (QMRA) is now largely applied in drinking water field.

Identifying water-related microbial hazards consists of prioritizing for each waterborne pathogen the range of potential human health outcomes associated with exposure. The occurrence and severity of disease have to be considered and also the host characteristics (age, immune status).

Assessing exposure is a complex task. The amount of the targeted microorganism in the drinking water, the volume ingested, the frequency and duration of exposure (e.g., every day) have to be included. The survival of the germ in water and its resistance toward treatments and the inactivation rates are key components of exposure assessment.

Dose–response mathematical models are widely used to define the probability of developing an illness (or infection) depending on the concentration of the pathogen. Data from clinical studies using volunteers are sometimes available but can be limited depending on the germ. The two main models – exponential and beta-Poisson – define the probability of infection function of the dose–response curve and the number of ingested (or inhalated) pathogenic organism.

The last step, characterizing the risk, integrates all the previous data to have an estimation of the potential risk toward a population. Simulation using Monte-Carlo tools are always needed in order to include the distribution of probabilities among all situations from worst case scenario to realistic situations. Assumptions as percentage of infectious organisms, removal of the target organisms by water treatments, water intakes (usually 2 l per day per person) may have also an impact on the risk estimate.

Quantitative microbial risk assessment focuses mainly on exposure assessment and as such continuously evolves thanks to new epidemiological data, new detection methods, better knowledge on microbial survival and resistance to drinking water treatments. QMRA processes are involved in risk management strategies defined either by health authorities as well as by drinking water suppliers.

Water Safety Plans (WSPs)

The WSP approach is applicable throughout the whole water supply from catchment to the consumer to ensure safe drinking water. It has been largely described in the WHO Guidelines for Drinking Water Quality and relies on the classical principles of microbial risk assessment. WSP relies on five related steps.

- Health-based targets based on public health protection and disease prevention.
- System assessment to determine if the water supply chain (up to the point of consumption) as a whole can deliver water of a quality that meets the defined targets.
- Monitoring the steps in the supply chain that are of particular importance in securing safe drinking water.

- Management plans documenting the system assessment and monitoring extreme events, including documentation and communication.
- Systematic independent surveillance that verifies that the above are operating properly.

Besides risk assessment, WSP takes account of each specific drinking water supply including its operational design and monitoring. It should also contain emergency action plans to ensure that the water supply is safeguarded even in case of rare events.

Concluding Remarks

Microbial safety of drinking water remains a public health concern, not only in developing countries, and should remain as a priority for water and health community. Future challenges should address better monitoring of water resources, especially regarding climate changes and water scarcity, as well as better monitoring and prevention of rare contamination events.

SAFETY OF FOOD AND BEVERAGES

Soft Drinks and Fruit Juices

R Ryan, Institute of Food Science and Technology of Ireland, Dublin, Ireland

Glossary

Brix The sugar content in aqueous solution. (One degree Brix is 1 g of sucrose in 100 g of solution and represents the strength of the solution as percentage by weight (% w/w). If the solution contains dissolved solids other than pure sucrose, then the °Bx only approximates the dissolved solid content.

Fruit juice The unfermented product obtained from fruit which is sound and ripe, fresh or preserved by chilling, of one or more kinds mixed together, having the characteristic color, flavor, and taste typical of the juice of the fruit from which it comes.

Soft drink A beverage that may be made from natural and artificial flavors and sweeteners, carbonated and noncarbonated water, vegetable and fruit juice extracts, and other ingredients, but which contains no alcohol.

Introduction

Perhaps the most widely consumed beverages in the world (outside of water) are soft drinks and fruit juices. These two categories of beverages include a variety of products but do not include alcoholic beverages (wine, spirits, beer, cider, etc.) and natural mineral and bottled drinking water, which are covered in other articles.

What Constitutes a Soft Drink?

For the purpose of this article, a soft drink is defined as water-based flavored drink usually with added carbon dioxide (CO_2) and with nutritive, nonnutritive, and/or intense sweeteners with other permitted food additives. This definition also includes gaseosa (water-based drinks with added CO_2, sweetener, and flavor), and sodas such as colas, pepper types, root beer, lemon–lime, and citrus types, both diet/light and regular types. These beverages may be clear, cloudy, or may contain particulate matter (e.g., fruit pieces). Soft drinks also include so-called 'energy' drinks that are carbonated and contain high levels of nutrients and other ingredients (e.g., caffeine, taurine, and carnitine).

Recipes for soft drinks can be formulated so that their composition is controlled and be maintained as a trade secret. Most recipes contain an extract, sugar, water, and various additives, such as acidity regulators, colors, and citric acid. Some additives are prohibited by specific legal regulation.

Categories of Soft Drinks

The most important categories of soft drinks are:

1. *Ready-to-drink essence-flavored beverages*: These are practically always carbonated. The essences used in them may be of natural or of synthetic origin and the sweetener used may be nutritive, nonnutritive, and/or intense.
2. *Ready-to-drink beverages containing fruit or fruit juice*: These can be made from fruit juice or concentrated fruit juice with the addition of sweetening agents, citric acid, and water. The normal juice content is not generally sufficient to impart sufficient flavor, and therefore, essences are added.
   a. This class is not therefore entirely distinct from class (1), as soft drinks are made with many differing ratios of fruit juice to essence. Ready-to-drink beverages can also be made by macerating whole fruit producing a fruit comminute. These beverages are composed of fruit juice and tissue with natural peel oil emulsion, thoroughly homogenized (i.e., with uniform dispersion of the solid matter throughout the drink).
   b. This class includes both carbonated and noncarbonated beverages. Similar in some ways to these are the so-called 'nonalcoholic wines' and other fermented beverages similar to alcoholic ones, but with a very low alcohol content.
3. *Concentrates of beverages intended for drinking after dilution with water at home*: These fountain syrups (e.g., cola syrup), fruit syrups for soft drinks, frozen or powdered concentrate for lemonade and iced tea mixes. These are noncarbonated and usually have a fruit base, though flavoring essences may be added as well. They include citrus 'squashes' containing fruit juice with cells, sugar syrup, essences, and citric acid, and intended to be diluted four or five times by volume before consumption. This also includes concentrated comminuted citrus drinks, similar to those described in class (2). This class also includes cordials containing noncitrus juices and flavored cordials, as well as syrups.

 doi:10.1016/B978-0-12-378612-8.00296-1

The largest single ingredient of soft drinks is water, and their manufacture depends on a supply of safe, good quality water. In addition to the water and the fruit juice or flavoring, most soft drinks require sweetening agents. Nutritive, nonnutritive, and/or intense sweeteners can be used for this purpose. There is a certain demand, from diabetics and consumers wishing to achieve weight control, for soft drinks that contain nonnutritive sweeteners.

Soft drinks, *per se*, are not of great importance in international trade. Their bulk is large due to their water content, and most countries have their needs for soft drinks supplied by local manufacturers. Consequently, there is a considerable trade in concentrates, particularly those used for the cola-type drinks, fruit juice-based and comminuted fruit drinks. Similarly many countries import considerable quantities of fruit juices for manufacture into soft drinks. National trade statistics in general do not distinguish between these various classes.

The typical soft drink of the US is known as soda water. This phrase is to some extent, a misbranding, it is so called because originally the CO_2 gas with which it is carbonated was derived from the carbonate or the bicarbonate of soda. The name has become so firmly attached to waters of this kind that it probably will be accepted in the future as distinctive. Water is mixed with syrup which contains the sugar. A flavoring material is included to give it the character of the drink. For example, quinine is added to produce tonic water.

Manufacture of Soft Drinks

The most important element in the manufacture of a soft drink is the formulation of the syrup. The syrup is made to a predetermined strength using extracts, flavors, colors, sweeteners, and additives, such as preservatives, according to the recipe, which is usually considered a trade secret. As noted above, this syrup is made at a central location and is then shipped to distributors who add water in a fixed proportion to produce the drink. The drink is then is cooled, carbonated and filled into containers, the lid or cap is applied, sealed, check weighed, and packed off.

In addition to the fruity flavor, taste, and aroma imparted by the product, the worldwide acceptance of carbonated beverages is also due in part to the taste and sparkle imparted by CO_2. CO_2 derives from three sources, namely, fermentation, heating limestone, and burning carbon.

In the manufacture of carbonated drinks, CO_2 also destroys or inhibits growth of bacteria. This preservative action increases in line with the level of carbonation specified in the soft drink. In some beverages, such as ginger ale and tonic water, higher levels of carbonation are present so that the product can be used as a mixer with noncarbonated components, such as whiskey or gin.

The level of carbonation is normally described as the gas content or degree of carbonation or the volume(s) of CO_2. Depending on the form in which it is supplied and stored, the CO_2 should be sited convenient to its delivery area for reasons of safety and convenience. All the pipework in the case of liquid CO_2 must be able to withstand high pressure and be of stainless steel and preferably jointed seamlessly.

In typical practice, the syrup is pumped from the syrup tank across to a 'carbo cooler,' which is designed to produce a final product with a consistent brix and level of carbonation. To incorporate the CO_2 into the finished drink a large surface area of liquid is required and this will be reflected in the diameter of the carbonating vessel or container which must also be designed to withstand high pressure. In the carbocooler the chosen brix of a product is achieved by use of a specific orifice design to allow a small amount of syrup to be added to a designated quantity of water on a continuous basis. The resultant beverage is pumped across to a filler. In the filling of cans, the product is filled down the internal sides of the can allowing air to escape at the top of the filling valve. The cans are discharged from the filler and immediately enter the can seamer where the lid is seamed on to the can. As the can contains cooled beverage, it next passes into a can warmer to bring the product to ambient temperature. The can is then passed under an X-ray detection device to ensure correct fill. Finished cans are then conveyed to the packing unit for tray forming, can collation, shrink wrapping, and palletization.

Health – Negative Effects of Consumption

Because of the carbonation, soft drinks are generally considered safe from a microbiological perspective. In fact the World Health Organization recommends soft drinks when travelers are in locations where the quality of the drinking water is suspect. Most of the negative health effects associated with most soft drinks relate to their sugar content. Consumption of sugar has been shown to increase dental carries and excessive consumption of sugar has been linked to obesity. However, high-energy drinks have been associated with insomnia, headache, agitation, rapid heartbeat, and seizures. The US Substance Abuse and Mental Health Services Administration report found that the number of people who attended at the hospital emergency room after consuming energy drinks had more than doubled from just over 10 000 in 2007 to nearly 21 000 in 2011. In 42% of the cases, people reported consuming the energy drinks in combination with other drugs. Health Canada has proposed new regulations to limit the amount of caffeine in a single serving of an energy drink to 180 mg from more than 500 mg. A 237 ml cup of coffee contains about 135 mg of caffeine.

What Constitutes a Fruit Juice?

Fruit Juice is the unfermented but fermentable product obtained from fruit which is sound and ripe; fresh or preserved by chilling; of one or more kinds mixed together; and having the characteristic color, flavor, and taste typical of the juice of the fruit from which it comes. Fruit juices are expressed from fruits, which are among nature's most bountiful and healthy foods.

Fruits are pleasing to the senses of sight, taste, and smell. Their color, texture, and tartness add to their enjoyment as fruits. There are hundreds of different kinds of fruits. Some like apples and berries grow in temperate climates whereas others, such as citrus and exotic fruits, grow in tropical climates. Many

fruits have prominent roles in culture and religion and many have been used for their 'medicinal' value. This is not surprising because they are rich in health-sustaining vitamins and minerals, energy-giving fruit sugars, and health-protecting components such as antioxidants. With modern day technology, their juices give the same pleasure and benefits.

Categories of Fruits

Fruits can be divided into a number of main categories. For each category, a few examples of the possibilities are given below:

1. Citrus fruits: oranges, mandarins, grapefruit, lemons, and limes.
2. Soft fruits: strawberries; raspberries; gooseberries; blackberries; and white, red, and black currants.
3. Stone fruits: peaches, apricots, plums, and cherries.
4. Pome fruits: apples, pear, and quinces.
5. Exotic fruits: comprise a disparate group of fruits which do not form part of the other main categories including bananas, pineapples, pomegranates, melons, mango, kiwis, passion fruits, and figs.
6. Mixed fruit juices: combinations of the above. Note that rhubarb though a vegetable is often blended with fruit juices.

Primary Processing of Single Strength Juice

During processing, the juice is separated from flavor components, pulp and cells, but these may be restored to the juice in the final formulation. In the case of citrus fruits, the fruit juice must come from the interior fleshy portion (endocarp). Lime juice, however, may be obtained from the whole fruit, by suitable production processes whereby the proportion of constituents of the outer part of the fruit is reduced to a minimum.

Fruit juices may be considered in various categories depending on market requirements. For example, fruit from which the juice is extracted just before consumption is the only juice that may be classified as both pure and fresh. In the EU, only physical treatments are allowed for this juice. In the case of freshly squeezed juice, chilling is optional but is not regarded as a process. All other juices undergo processing to a greater or lesser extent.

Primary Processing of Concentrated Juice

Fruit juice from concentrate may be defined as the product obtained by replacing the water in the concentrated fruit juice that was extracted from that juice during concentration. If appropriate, pulp and cells that were removed during the process of producing the fruit juice, may be added back. In the reconstitution process, the water used must possess appropriate characteristics, particularly from the chemical, microbiological, and organoleptic viewpoints, to guarantee the safety and essential qualities of the juice. The final product obtained must display the basic organoleptic and analytical characteristics at least equivalent to those of its fresh counterpart.

Primary Processing of Nectars

Fruit nectar is the unfermented but fermentable product obtained by adding water with or without the addition of sugar, honey, syrups, and/or sweeteners to fruit juice, concentrated fruit juice, fruit purees or concentrated fruit purees, or a mixture of those products. Aromatic substances, volatile flavor components, pulp, and cells, all of which must have been recovered from the same kind of fruit and obtained by suitable physical means, may be added. Products may be based on a single fruit or fruit blend. Fruit nectars typically contain 25% to 50% fruit. Under the requirements of Annex IV of the EU Fruit Juice Directive, the addition of sugars and/or honey is permitted up to 20% of the total weight of the finished product. Where fruit nectars are manufactured without added sugar or with low energy value, sugars may be replaced wholly or partially by sweeteners, in accordance with Directive 94/35/EC of the European Parliament and of the Council of 30 June 1994 on sweeteners for use in foodstuffs.

Secondary Packing of Juice and Juice Products

Juices may be packed in cartons, polyethylene terephthalate (PET) bottles, glass, or cans. The carton, however, dominates the market worldwide and is based on the form, fill, and seal principle. Juices packed in the carton system are generally packed aseptically. The carton consists of a seven layer wall with polyethylene on the inside in contact with the juice. There normally are few issues with regard to shelf life. The biggest offender is damage caused by handling abuse.

Tetra Pak and Elopak are two of the major suppliers of form, fill, and seal packaging systems. To pack juices using either of these systems the heat exchanger and filler are presterilized. Juice is subsequently pasteurized in the presterilized heat exchanger and fed directly into the presterilized filler. Asepsis is maintained throughout the system.

A typical juice from concentrate preprocessing line consists of a drum dumper feeding juice concentrate to a juice/water proportioner automatic in line brix controller, juice tankage in which the juice is thoroughly mixed; pumped or gravity fed to a pasteurizer; then optionally fed to a deaerator; and from there it is fed to the carton packing machine.

The individual cartons are conveyed from the filler to case packers or in the case of smaller cartons to the drinking stray applicator, multicarton, packer. The larger 1 l packs go directly to the case packers where they are subsequently shrink wrapped and placed on pallets for despatch to warehousing.

Forms Under which Juice is Marketed

Citrus fruit juice and in particular orange juice dominates the fruit juice market. According to the United Nations Commodity Trade Statistics Database, international trade in orange juice exceeds US$16 billion a year. This trade involves orange juice in various forms. Single strength orange juice should have a brix value of at least 10% (or 10°Bx) measured at the time of picking. This juice is known as 'Not from Concentrate (NFC)' in the trade because it has not been concentrated and reconstituted with water. NFC juice may be pasteurized, chilled, or frozen before shipment to the packing house.

Juice from concentrate, however, is initially concentrated by evaporating the water resulting in a concentrate of 60° or 65°Bx. Concentration may be achieved using a thermally accelerated short time evaporator (TASTE). This type of evaporator is mainly used in the large citrus plantations of Brazil and USA. An important parameter in regard to process fruit juice is the degrees brix, which is the sugar content of in the aqueous portion of the juice. One degree brix is equivalent to 1 g of sucrose in 100 g of juice. If the solution contains dissolved solids other than pure sucrose, then the degrees brix only approximates the dissolved solid content.

Unlike NFC, citrus juice concentrate has a minimum value of 11.2°Bx because the concentrate plants mix concentrates from early, mid, and late seasons together to give the concentrate and subsequently its reconstituted juice the flavor, texture, and taste that meet the preferences of the market that the company is targeting. Certain food additives may be used to enhance the juice. For example, ascorbic or citric acid may be added to that which is naturally present in orange juice to give it more tartness. Ascorbic acid may also be added to improve the vitamin C content. Other nutrients, such as calcium, vitamin D, and omega-3 fatty acids may also be added. In addition, the producers of reconstituted orange juice may add a mixture of compounds derived from orange peels to give the juice the aroma of fresh-squeezed juice as these are lost during the concentration process.

Health – Benefits of Juice Products

As the consumption of fruits and vegetables have been shown in many studies to be associated with reduced risk of many cancer types, stroke, and Alzheimer's disease, the consumption of fruit juices has increased significantly in recent years. Most consumers believe that the health benefits of fruit juice are equal to fresh fruit, but some nutritionists have noted that juice lacks fiber of fresh fruit.

Health – Negative Effects of Consumption

Juice may naturally contain high levels of sugar, which poses the same risks of dental carries and obesity as refined sugar. In this regard, juices may contain added sugars, including high-fructose corn syrup.

Fruits can frequently be contaminated with biological hazards, such as viruses and bacteria. As a consequence, processed fruit juices are pasteurized to minimize this potential problem. However, fresh-squeezed juices are typically not and may present a health risk unless the fruit is decontaminated and sanitation of the equipment is maintained. In addition, fruit can contain residues of pesticides, which may be transferred to the juice. Controls should be directed at the source of the fruit to assure that levels do not exceed those allowed by regulation.

SAFETY OF FOOD AND BEVERAGES

Alcoholic Beverages

R Ryan, Institute of Food Science and Technology of Ireland, Dublin, Ireland

Glossary

Alcohol by volume (ABV) The percent of alcohol in a beverage based on the volume of alcohol present.
Bead Size of bubbles.
Brut Very common sparkling wine term – literally 'dry' but in practice not bone dry.
Cru Vinyard.
Distillation The technique of extracting alcohol from a fermented liquid by heating it and condensing the vapor, which is enriched in alcohol.
Fermentation yeasts The microorganisms used to convert sugar into alcohol and carbon dioxide.
Fusel oils The undesirable higher order alcohols and related compounds formed during the fermentation.
Malt The product produced when grain, usually barley, has been stimulated artificially into germination and then halted by drying.
Mash The sweet liquid after hot water has been flushed through the grist.
Nose The aroma of a wine or spirit.
Rose A wine made by blending red and white wines.

Introduction

The production of alcoholic (ethanol containing) beverages, namely, beers, wines, and spirits has provided mankind with sustenance and refreshment since prehistoric times. The experience of drinking alcoholic beverages is made all the more satisfying when consumed with foods. There has always been a close relationship with bread making and fermentation of alcoholic drinks owing to their common ingredients, namely, grain, water, and yeast. The Sumerians baked barley loaves called bappir that could be either eaten as bread or mixed with malted barley to form a mash for brewing. Some have speculated that bread and beer increased prosperity to a level that allowed time for development of other technology and contributed to the building of civilizations.

As with the discovery of other foods, it can be assumed that alcoholic beverages were discovered by accident. Indeed, from the earliest times the art of preparing alcoholic beverages depended on local ingredients, such as grapes, barley, or honey, and on traditional fermentation methods. Over the centuries these beverages became rooted in the physical environment and culture. In Europe, for example, some vineyards have been cultivated for over 2000 years. In many cases, the great traditional beers, wines, and spirits have assumed national identities that draw their characters from the melding of environmental and cultural landscapes.

In achieving an appreciation of beers, wines, and spirits, it is necessary to understand the industrial processes and technology involved in their manufacture. Of obvious importance is the alcohol content. The percent of alcohol by volume (ABV) is now the harmonized measurement for alcoholic content. In the USA, the strength of a spirit was previously expressed as 'proof,' which was equivalent to 7/4 the alcohol content. According to US Federal regulations, the required labeling of alcohol content of wines and spirits is now ABV. However, the alcohol content of malt beverages, including beer, is optional unless required by State regulations.

Beer

Beers are alcoholic beverages brewed from germinated barley (malt), hops, yeast, and water. Examples include ale, brown beer, weiss beer, pilsner, lager beer, oud bruin beer, Obergariges Einfachbier, light beer, table beer, malt liquor, porter, stout, and barleywine. Beer is truly international probably because it is the oldest alcoholic beverage. Almost any substance containing sugar can naturally undergo alcoholic fermentation. It is likely that many cultures, on observing that a sweet liquid could be obtained from a source of starch, independently invented beer.

Historical Development of Beer

Beer is one of the world's oldest prepared beverages, possibly dating back to approximately 9500 BC, when cereals such as barley and wheat were first grown. Beer production is recorded in the written history of ancient Egypt and Mesopotamia. The available evidence suggests that barley beer or cervisia was made and consumed over many millennia. Barley beer was

 doi:10.1016/B978-0-12-378612-8.00432-7

initially made domestically by women who were described as 'brewsters.' Besides sources of nutrients, beer might have also been purer than water in some regions.

The Ebla Tablets, discovered in 1974 in Ebla, Syria, and dating back to 2500 BC, reveal that the city produced a range of beers, including one that appears to be named 'Ebla' after the city. A fermented beverage using rice and fruit was made in China approximately 7000 BC. Barley beer, however, is not the true ancestor of the beer which is consumed today. The difference between barley beer and beer brewed from the fifteenth century is that what is today referred to as beer contains hops as an integral ingredient in the recipe.

Some of the earliest Sumerian writings found in the north African/Middle East region contain references to a type of beer; one such example, a prayer to the goddess Ninkasi known as 'The Hymn to Ninkasi,' served as both a prayer and a method of remembering the recipe for beer in a culture with few literate people. Much later monks in monasteries took up the brewing of beers and some monasteries continue that tradition today.

In 1516, William IV, Duke of Bavaria, adopted Reinheitsgebot (purity law), perhaps the oldest food-quality regulation still in use in the twenty-first century, according to which the only allowed ingredients of beer are water, hops, and barley malt. The development of thermometers and hydrometers changed brewing by allowing the brewer more control of the process and greater knowledge of the results.

It is interesting to note that in the case of Guinness, which was founded in 1759 that the head brewer did not have a scientific qualification until 1902. The art of brewing had been mastered by thousands of brew masters down the centuries and that art had been intuitively crafted to produce excellent beers since the dawn of civilization. Although the chemistry and microbiology were not articulated in modern scientific terms, the brewers had always followed a method that enabled them to achieve the required result time and time again. It was not until the mid-nineteenth century that the work of Louis Pasteur unlocked the secrets of fermentation.

Brewing of Beer

Brewing is the process by which beer is made from the recipe ingredients including malted barley, water, hops, and yeast. Initially the wort is made by mixing the crushed malted barley, also known as grist, in a mash tun with hot water, also known as liquor. This takes approximately 2 h. In a process called 'sparging,' the sweet wort is separated from the grist or grains by washing and collecting the maximum wort. In separating the wort from the grains, the grains themselves form the filter bed and this part of the process is called 'lautering.' Filter frames may also be used depending on how many 'runnings' are needed to give paler beers.

The sweet wort is then transferred to a kettle known as the 'copper' and boiled for approximately an hour. Hops are then added as a source of bitterness, flavor, and aroma. The longer the wort containing the hops is boiled the greater the bitterness but the less flavor and aroma because these volatiles are flashed off.

The hopped wort is then cooled and is ready for the addition of yeast. The yeast ferments the hopped sweet wort and produces beer after approximately a week. The length of time may be longer depending on the type of yeast used and the strength of beer required. During this time fine particulate matter and the yeast in the wort settles out leaving a clear beer. A secondary fermentation may be undertaken depending on the storage requirements, whether stored in casks or kegs, cans, or bottles. In addition to barley, other sources of starch, maize or rice may be used and these are termed adjuncts.

The chemical quality of the water gives beers a distinctive character. Hard water suits the production of stouts, such as Guinness, whereas soft water in Plzen suits the production of pale lagers, such as Pilsner Urquell. The initial stages of beer production are similar to spirits production. Different roasting times and temperatures are used to produce different colors of malt from the same grain.

Brewer's yeast is mainly *Saccharomyces cerevisiae*, which is a top-fermenting yeast. However, *Saccharomyces uvarum* is a bottom-fermenting yeast used in the production of lagers and grows best at lower temperatures.

Brewers may add clarifying agents to beer to give the beer a bright and clean appearance. Particulate matter and proteins are precipitated out, removing the cloudy appearance, especially in beers made from wheat.

Although there are many types of beer brewed, the basics of brewing beer are shared across national and cultural boundaries. The traditional European brewing regions – Germany, Belgium, England, and the Czech Republic – have local varieties of beer. Top-fermented beers are most commonly produced using *S. cerevisiae* at temperatures between 15 and 23 °C. At these temperatures, the yeast produces significant amounts of esters and other flavor and aroma products, and the result is often a beer with a slight 'fruity' taste.

'Pale Ale' is a beer, which uses a top-fermenting yeast and a predominantly pale malt. It is one of the world's major beer styles. Mild ale has a predominantly malty palate. It is usually dark colored with an alcohol content of 3.0–3.6% ABV, although there are lighter hued milds as well as stronger examples reaching 6% ABV.

Lager is the English name for cool fermenting beers of Central European origin. Pale lagers are the most commonly consumed beers in the world. The name 'lager' comes from the German 'lagern' for 'to store,' as brewers around Bavaria stored beer in cool cellars and caves during the warm summer months. These brewers noticed that the beers continued to ferment and to also clear off sediment when stored in cool conditions.

Lager yeast is a cool bottom-fermenting yeast *S. uvarum* and typically undergoes primary fermentation at 7–12 °C and then is given a long secondary fermentation at 0–4 °C (called the lagering phase). During the secondary stage, the lager clears and mellows. The cooler conditions also inhibit the natural production of esters and other byproducts, resulting in a cleaner tasting beer.

Assessment of Beer

Bitterness of Beer

Beer is measured and assessed by its bitterness, strength, and color. Bitterness is due to the inclusion of hops in the recipe.

Hops are used as a flavor and as a preservation agent by eliminating undesirable bacteria. The bitterness balances the sweetness of the malt and aids in the retention of the head in a poured glass of beer. Perceived bitterness is measured by the International Bitterness Unit, defined in cooperation between the American Society of Brewing Chemists and the European Brewing Convention.

Color of Beer

Beer color is determined by the quality of the malt and its roasting. The most common color is a pale amber produced from using pale malts. Pale lager and pale ale are terms used for beers made from malt dried with coke. Coke was first used for roasting malt in 1642, but it was not until approximately1703 that the term pale ale was used.

Strength of Beer

Beer ranges from less than 3% ABV to approximately 14% ABV. The alcohol content of beer varies by local practice or beer style. The pale lagers that most consumers are familiar with fall in the range of 4–6% ABV. Some beers, such as table beers, are of low alcohol content (1–4% ABV). Exceptionally strong beers with very high alcohol content are also made.

Consumption – Positive and Negative Effects on Health

The moderate consumption of alcohol, including beer, is associated with a decreased risk of cardiac disease, stroke, and cognitive decline, including accidental injuries. However, excessive consumption can lead to addiction, cancer of various organs, neurologic problems, social problems, diseases of the liver, including alcoholic hepatitis and cirrhosis. In the USA, an estimated 80 000 deaths are caused by excessive alcohol consumption with an estimated cost of US$223.5 billion in 2006.

In particular, pregnant women or women who are trying to become pregnant should not drink any alcohol. Alcohol can cause miscarriage and stillbirth among pregnant women, and a combination of physical and mental birth defects among children that last throughout life. In addition, any person who is driving, planning to drive, or participating in other activities requiring skill, coordination, and alertness should avoid alcohol. Also people who have certain medical conditions or who are taking medications should also avoid alcohol.

Brewer yeast is known to be a rich source of nutrients; therefore, as expected, beer can contain significant amounts of nutrients, including magnesium, selenium, potassium, phosphorus, biotin, chromium, and B vitamins.

Wine

Wines are alcoholic beverages obtained exclusively from the partial or complete alcoholic fermentation of fresh grapes, whether crushed or not, or grape must. Wines can also be made from fruits other than grapes such as apples and pears and from other agricultural products, including grain as in the case of sake made from rice. However, the production of wine from grapes is by far the largest. Consequently, this section only addresses wine made from grapes. Finished bottled wine can be still or sparkling and can be red, white, or rose. The color of red wine is due to contact with grape skin, which also enriches the wine with tannins and antioxidants.

Varieties

The common varieties of the European species *Vitis vinifera* are Pinot Noir, Chardonnay, Cabernet Sauvignon, Gamay, and Merlot. When one of these varieties used is the predominant grape (usually at a level of 75–85%), the resultant wine is said to be a 'varietal' as opposed to a 'blended' wine. Blended wines are not considered inferior to varietal wines but they utilize a different style of winemaking; some of the world's most highly regarded wines that come from regions such as Bordeaux or the Rhone Valley are blended from different grape varieties.

Wines are made from a single variety or from a blend of varieties. In 'Old World' countries, wine laws prescribe and proscribe certain varieties for each of their designated quality wine areas based on what grows best there. Consequently, only certain grape varieties or blends of grapes may be used to produce the wine in a particular area with its specific appellation control.

Sometimes flavor differences in freshly picked grapes, such as Reisling or Gewurztraminer, are more pronounced in the resultant wines. Some varieties perform best when used as single varieties, such as Burgundy, Pinot Noir, and Chardonnay. Most varieties are ensemble players and are usually found in blends principally Cabernet Sauvignon, Merlot, and Cabernet Franc.

In the 'New World,' wine production rules such as these are almost nonexistent. The advantage of this system is that the winemaker is free to experiment, but it could also be the case that little-known grapes such as Gros and Petit Manseng, which are used to make the traditional and little-known wine of Jurancon, in France, could disappear. Some form of appellation control is desirable irrespective of the country of origin.

It should be noted that most varieties of European grapes have been grafted onto the North American species' rootstock due to their resistance to phylloxera, a root louse that eventually kills the vine plants. In the late nineteenth century, most of Europe's vineyards were destroyed by this infestation.

Soils

Grapes grow well in a variety of soils such as gravel, granite, chalk, and slate to mention but a few. A large number of vineyards are situated on the sides of river valleys in well-drained gravel deposits ('graves' means gravel). Some vines grow better in poor well-drained soils. This makes the vine roots extend deeper to source water, trace elements, and other plant nutrients. The Bordeaux region has gravelly soils, which are responsible for the fame of the wines of this region and it particularly suits growth of the Cabernet Sauvignon grape variety. Other soil types that underlay the gravel can also have an effect. Where the soil is clay, the wine will have less acidity than it would if it were limestone, for example.

Châteauneuf-du-Pape and Tavel rose are produced in the southern Rhone in granite country. This area is littered with

'pudding stones' making cultivation almost impossible. Once the stock has taken root, the granite stones reflect heat back onto the vine. This results in the production of big, high in alcohol, reds, and France's most famous rose. In Beaujolais, granite suits the Gamay variety in which its chemical properties reduce the wine's natural acidity.

Slate is another soil type and is typical of the alluvial deposits on the banks of the Rhine and Mosel rivers, which suit some vines in particular. This soil is responsible for the delicate fragrance of the fruity local wines. The great advantage of slate is that it retains heat during the colder days, which compensates for the cooler day temperatures in which the grapes have to ripen.

Another soil type is chalk, which provides very good drainage. This alkaline soil suits predominantly white grape varieties. The Chardonnay forms part of the inimitable blend for Champagne. Grapes grown on this type of soil are characteristic for their acidity and this is what links the Champagne, Chablis, and Sancerre.

Winemaking

Winemaking can be a simple operation. The grape is the basis of the global wine industry, although there are separate categories of wines made from fruits such as apples. All the ingredients necessary to make wine are contained in or on the surface of grapes, namely, the fruit sugars and the yeast. If grapes are crushed in a vessel, after a few days in a warm place the mixture will turn into an alcoholic liquid. This process called fermentation is due to the action of the yeasts. There are millions of yeast cells on the skins of grapes, which can ferment the natural sugars in the grapes. Although the resultant liquid can be described as wine, it may not look or taste good. Open vat fermentation is an unpredictable process, which can produce aldehydes and ketones that can taste bad and cause adverse reactions. To deal with this problem, the Romans often sweetened their wine with lead acetate, which had even more serious health effects.

Winemaking can also be complex when one considers the variety of grapes available, the viticulture, soil types, and climate. Soil types must have the ability to retain or reflect heat as well as providing nutrients for growth of the vines. Harvesting, fermenting, and maturing practices are also extremely important in producing a fine wine.

In winemaking, there are several stages commencing with the picking operation in the vineyard. Picking, sorting, stem removal is undertaken before transfer to fermentation vats. At this point, the type of wine to be made, that is, red or white, will determine whether skins are separated or allowed to remain in contact with the wine as is the case for making red wine. Cultured yeasts may be added in dried form to aid fermentation, although normally wild yeast either from the vineyard or the winery itself is sufficient to enable the fermentation to proceed to success. If cultured yeast is used, the wine is first treated with sodium sulfite to destroy the wild yeast.

As with all raw materials, however, the quality of the grapes is extremely important. In the vineyard the grapes on the vine must be picked when they have reached the optimal stage of ripeness. Grapes that are not ripe enough, or are overripe will affect the quality of the resultant wine. The grapes as they are harvested contain the potential of the wine. You can make a bad wine from good grapes, but not a good wine from bad grapes.

Harvesting of Grapes

Depending on the nature and size of the vineyard, the picking operation will normally be done by either hand or machine, ideally in good weather conditions. In the case of hand picking, the pickers pick bunches of grapes that are loaded into bins for transfer to the winery. In the case of mechanically harvested grapes, the operation results in individual grapes being harvested. Increasingly, grapes are being machine harvested. This is more cost-effective, and in warm regions quality can be preserved by picking at night, when it is cooler for improved quality. Hand-picked or machine-harvested grapes are sorted for quality. Sorting grapes enables rotten or 'raisined' grapes, leaves, and petioles to be removed. Sorted grapes go to the de-stemmer, which removes the stems. They may then be crushed.

Differences in Making Reds, Whites and Rose

This is where red winemaking differs from whites. Red wines are pressed and fermented in their skins, whereas white wines are pressed, separating juice from skins, before fermentation. The fermentation vessel may be a shallow stone lagar. The grapes are foot trodden, so that the juice can extract color and other components from the skins or in other wineries the grapes are loaded and taken by conveyor to a tank, from where they are being pumped into the fermentation vessel depending on whether the winery uses traditional methods. Fermentation begins naturally after the grapes have been foot trodden. Skins and juice are mixed by hand and this process is repeated many times a day to help with extraction, and also to prevent bacteria from growing on the cap of grape skins that naturally would float to the surface.

Sometimes red grapes are fermented in stainless steel tanks. During fermentation, carbon dioxide is released so the surface can be exposed. On other occasions, however, fermentation takes place in vented closed tanks to facilitate carbon dioxide escape.

Smaller tanks are used in which the skins can be punched down using a robotic cap plunger. In some wineries this is done by hand, using poles. An alternative to punch downs is to pump wine from the bottom of the tank back over the skins. Here, fermenting red wine is being pumped out of the tank, and then pumped back in again. The idea is to introduce oxygen in the wine to help the yeasts in their growth. At other stages in winemaking, care is taken to protect wine from oxygen, but at this stage it is needed. White wines are fermented in stainless steel containers.

Once fermentation has finished, most red wines are then moved to barrels to complete their maturation. Barrels come in all shapes and sizes. The most common size is 225–250 l. The source of the oak, and whether or not the barrel has been used previously, is important in the effect it has on the developing wine. Sometimes much larger, older oak barrels are utilized, imparting virtually no oak character to the wine. This suits some wine styles better than smaller barrels.

Once fermentation has completed and the young wine has been drained of the skins, the remaining skins and stems are pressed to extract the last of the wine that they contain. This is termed a bladder press, used for some reds and almost all whites. A large bladder fills with air, pressing the contents gently and evenly, with gradually increasing pressure. In smaller wineries, basket presses are employed. The marc is what is left at the end and is usually used to make compost. Red wines are generally matured in oak barrels.

As the wine industry developed, the science of enology came to the fore and which in turn augments the art of winemaking. Enologists are trained to classify wines by appearance, taste, and aroma. Once the wine has fermented and matured for its specified period of time, an enologist will sample it to determine if it is ready for bottling. After a wine is bottled and labeled, it is then aged for a designated period of time to reach its peak taste. Certain wines may be fine to sell immediately, whereas others are aged for a considerable period of time. Enology is generally concerned with winemaking and it can also include wine marketing. Enologists often meet with buyers to promote their wines. Those who work in the marketing aspect also arrange wine tastings for potential customers.

Vintage Wine

A 'vintage wine' is made from exceptional quality grapes that were grown in a particular year, and labeled as such. Some countries allow a recognized vintage wine to include a small portion that is not from the vintage year. Variations in a wine's character can include subtle differences in color, palate, nose or bouquet, body, and development. High-quality wines can improve in flavor with age if correctly stored. It is not unusual for wine enthusiasts and traders to save bottles of an especially good vintage wine for future consumption. For consistency, some nonvintage wines can be blended from more than one vintage to assist winemakers sustain a reliable market image and maintain sales even in nonvintage years.

Positive and Negative Effects on Health

Consumption of wine, especially red wine, is good because it is rich in antioxidants. The main active ingredient of wine is alcohol and therefore, the health effects of alcohol mentioned in the above section Consumption – Positive and Negative Effects on Health for beer also apply to wine.

White wines have been adulterated with ethylene glycol, a toxic chemical found in antifreeze. High levels of lead were found on wine that had lead casks covering the cork. Although the industry no longer uses lead, old bottles of wine with lead casks should be carefully cleaned before removing the cork.

In 2008, researchers in the UK reported finding high levels of toxic metals in wine. The sources of the contamination was not identified, but the researchers called for a study of wine production, including grape variety, soil type, geographic region, insecticides, containment vessels and equipment, and seasonal variations that may have an impact on metal ion uptake.

Beneficial cardiovascular effects from the consumption of one glass of red wine (but not white wine) have been reported. However, a recent study of beer consumption indicated that moderate consumption of beer resulted in a similar decline in cardiovascular risk as red wine. This raises questions about the nature of the beneficial agent because wine and beer are quite different in composition.

Spirits

Spirits includes all distilled spirituous beverages derived from grain (e.g., corn, barley, rye, and wheat), tubers (e.g., potato), fruit (e.g., grapes and berries), or sugar cane that contain greater than 15% alcohol. Spirits are produced in many countries and are often referred to as the national drink. Examples include bagaceira belha from Portugal made from pressed skins, seeds, and stalks of the grapes; grappa from Italian made from the residues of pressed wine; schnapps from Germany usually derived from rye; mistelle from France; jeropico from South Africa; ouzo from Greek and flavored with aniseed; rum from the Caribbean; and cachaça from Brazil made from fermented distilled sugar cane juice; vodka from Russia made from potatoes; and whiskey from Ireland and Scotland derived from barley. Whiskey is an excellent example of a spirit beverage in that it encompasses all the processes necessary to make alcohol, all of which need not necessarily occur on the same manufacturing site. Whiskey undergoes several processes such as malting, mashing, fermentation, distillation, maturation, and blending in its manufacture. Consequently, the following relates to the production of whiskey because it would not be possible to discuss every spirit.

History of Distillation

Distillation of fermented brews for alcoholic consumption is thought to have been introduced to Ireland and Scotland in the sixth century by missionary monks returning from the Mesopotamia regions of the Middle East and Egypt where they observed the distillation of perfume using the Alembic Still. The monks modified the Alembic Still to create a Pot Still designed to make 'aqua vita' (Latin for water of life), which is known today as whiskey. The first written record of whiskey comes from 1405 in Ireland. The production of whiskey from malted barley is first mentioned in Scotland in an entry on the 1494 Exchequer Rolls, which reads "Eight bolls of malt to Friar John Cor, by order of the King, wherewith to make aqua vita." The first license to produce whiskey was granted to Bushmills distillery in 1608 in the reign of James I of England. The Pot Still, which is basically a batch still, was used until continuous stills were introduced in the nineteenth century to increase economies of scale and meet commercial demand. The monks in other European countries created many different spirits, such as gin, brandy, vodka, and rum, as well as spirit-fortified wines, beers, and stout/porter, which survive in production to this day.

Barley as a Crop

Barley is a cereal crop that grows well in the more temperate regions of the world. It is one of the most widely distributed of all cereals. Barley grows well in cool and semi-arid climates and on fertile well-drained soils. It prefers higher soil pH but is

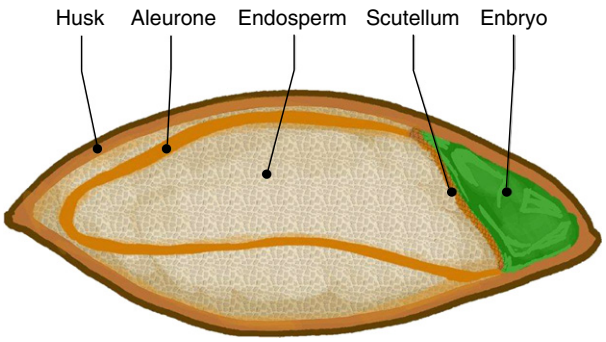

Figure 1 The mature barley grain.

most susceptible to fungal attack of all the cereals. There are two types of barley, two-rowed and six-rowed, with the six-rowed the most commonly grown. Barley can form part of a crop rotation, sometimes after a cultivated crop such as potatoes or sugar beet. Barley also makes an excellent cover crop planted with a legume to help with weed control. The requirements, however, for malting barley are very ridged, and special management and environmental control are necessary for the production of good malting barley.

Barley as Raw Material

In the normal crop life cycle of barley, as the temperature rises barley seeds are planted and over time the crop sprouts, develops roots, and grows to maturity. In the production of alcohol, man learned how to simulate the germination of barley under controlled but artificial conditions to make alcohol.

To appreciate the process of germination, it is essential to understand the nature and composition of the barley kernel (Figure 1). Barley, after harvesting, is dried to approximately 14% moisture so that it can be stored without risk of deterioration until it is required for use.

The mature barley grain comprises the embryo and endosperm, which provides a store of carbohydrates, mainly starch and protein to support the initial growth of the germinating embryo. The endosperm is a nonliving storage tissue, surrounded by a living nonstarch cell layer called aleurone. The grain is protected by an outer husk.

A grain or kernel of barley contains within it two main parts, namely, the embryo and endosperm. The embryo is the most important part of the grain as it contains all the organs necessary to enable the kernel to germinate and develop into a plant. The embryo is made up of three parts, the cotyledon or seedleaf, epicotyl or shoot, and radicle or root. The barley kernel is classified as a monocot because it consists of only one cotyledon. The endosperm contains the food source needed for germination by the embryo, that is, starch and protein.

Starch exists in two forms in the endosperm, amylose and amylopectin. The following enzymes degrade the starch into smaller polysaccharides: α-amalyse, β-amalyse, α-glucosidase, and phosphorylase.

The most significant enzymes are α-amalyse and β-amalyse. α-Amalyse is synthesized once germination begins, whereas β-amalyse is present in the grain in an inactive form, which subsequently becomes active during germination. α-Amalyse is involved in modifying the starch, cleaving it into polysaccharides known as dextrins. Maltose is produced by the action of β-amalyse on the starch.

Malting

Malting begins by soaking the barley in water. In this process, the raw barley is transferred into tanks filled with sufficient warm water where it remains for 2–3 days soaking up the water. The source of the water in this and subsequent stages is very important. The mineral and chemical properties of the water ultimately help to define the nature of the whiskey. Soft water is best. Soaked barley is then transferred to a huge room where it is spread out evenly on the floor over the heating source. This floor has ducts in it through which the air is circulated sometimes with the assistance of a fan. It is thus aerated and held at approximately 15 °C. It is regularly turned to prevent the temperature from rising too high and to ensure even germination. The grain continues to sprout but turning prevents the grain from putting down roots. This continues for approximately 5 days or so. At this stage it is termed 'green' malt. When the sprouts have reached a certain length, it is ready for drying and is transferred to a malt kiln. Drying stops germination due to denaturing the β-amalyse enzyme.

Mashing

When the malt is dried, it is then ground by rollers to form grist. The grist is then transferred to the mash tun, a large tank, and hot water added to dissolve the sugars and starches to produce a sweet liquid called wort. The wort is then drawn off, and this process cycle is repeated two more times. The water from the third mashing produces 'watery' wort, which is used to begin the mashing of the next batch. The grist itself, once it has gone through this process three times is removed from the mash tun and sold to farmers as a nutritious cattle feed.

Fermentation

Once the liquid wort has cooled, yeast is added to convert the sugars into alcohol. This is called the fermentation process. Yeast, similar to most organisms, can break down monosaccharides, such as glucose and fructose, and disaccharides, such as sucrose and maltose, because they are water soluble. It also develops other enzymes, such as proteases, which break down the proteins in the grain into forms that can be used by yeast. When fermentation is completed, a liquid called wash is produced, ready for distilling. It has an alcoholic content approximately the same as beer.

Distilliation

The alcohol from the fermented liquid is separated by boiling the wash in a large copper pot still or continuous still. The shape and size of the still determines the final character of the whiskey. Alcohol boils or vaporizes at a lower temperature than water and so is drawn off first leaving much of the water and other impurities behind. Although the resulting spirit is

much purer and higher in alcohol, the process is repeated a second time before the 'middle cut' or final spirit is collected by the operator of the still who decides on the exact moment to begin and end drawing off the precious 'middle cut.' At this stage, typically the colorless spirit is approximately 70% ABV.

Aging or Maturation in Casks

The spirit from the distillation process is diluted with water, invariably from the same source used in earlier stages, until its alcohol content is approximately 64%, then decanted into casks to begin the long, slow process of aging. Unlike wine, whiskey does not continue to mature in the bottle. The alcohol commences to draw flavors and color from the casks, which are made of oak. How it does this is not fully understood but over a minimum of 3 years, the colorless alcohol becomes a golden amber color and the taste becomes mellow. During this aging process/maturation, approximately 2% of the whiskey evaporates. This suggests that the oak casks or barrels 'breathe' and this loss of alcohol is termed the 'Angels share.'

In Ireland, the casks used have already been used in the making of sherry, although other casks used in winemaking are more recently being used as the distillers create new whiskeys to differentiate the market. In Scotland, the distillers use American oak casks that have already been used in the making of bourbon. The US law expressly requires several types of American whiskey, especially all American whiskey labeled as malt, rye malt, rye, wheat, bourbon, or straight whiskey to be aged in new oak casks. The selection of casks can affect the character of the final whiskey. To ensure continuity of supply of used oak casks, some Scottish distilling groups own oak forests in the USA and rent the new barrels to the US Bourbon producers for first fill use. Bourbon casks impart a characteristic vanilla flavor to the whiskey.

The spirit must be aged for at least 3 years in Ireland and in Scotland before it can be called whiskey. However, most distillers allow much longer times and part of the reason these whiskeys cost more is that they lose more of the 'Angels share' over time.

Whiskey may be produced as a single-malt whiskey or as a blend of different malt whiskeys. Single-malt whiskeys are generally made using pot stills and blends may combine the output of two or more different pot stills or by using continuous distillation. Single malts are typically associated with single-malt Scotch, although they are also produced in various other countries. Under the UK Scotch Whisky Regulations, a 'Single-Malt Scotch Whisky' must be made exclusively from malted barley, must be distilled using a pot still, and must be aged for at least 3 years in oak casks of a capacity not exceeding 700 l (150 imperial gallons; 180 US gallons).

Negative Effects of Over-Consumption of Whiskey

Because whiskey contains a large amount of alcohol, the health effects are a particular concern.

Whiskeys may also contain fusel oils. The term fusel comes from the German meaning 'bad liquor' or 'potato oil' in Europe. These are higher order alcohols, that is, alcohols with more than two carbon atoms, formed during fermentation. These fusel oils can also be present in other fermentations, such as cider, mead, beer, wine, and other spirits to varying degrees.

Alcoholic beverages can also contain ethyl carbamate (urethane), which is genotoxic and carcinogenic. The highest levels are found in stone-fruit brandies.

It is also vital that the compounds used in the sealing disks in the caps used in the bottling process or the sealing compounds do not introduce contaminants. For example, traditional Chinese spirits were reported to have high levels of phthalate esters from contact with certain plastic materials.

Spirits are also adulterated with other alcohols, but especially methanol, which can cause blindness and even death.

Glossary

Conching A process carried out under temperature, which permits the removal of volatiles and aids the even coating of sugar crystals in fat.
Enrobing The coating of a confectionery product in a thin film of chocolate.
Hazard analysis critical control point (HACCP) A systematic and science-based approach to the identification, assessment, and control of food safety hazards.
Prerequisite programs (PRPs) These programs are defined as basic conditions and activities that are necessary to maintain a hygienic environment throughout the food chain suitable for the production, handling, and provision of safe products.
Quenching A process (water or air) used to cool down the coffee beans after roasting.
Tempering A process of heating and cooling chocolate to ensure that the cocoa butter in chocolate forms stable crystals that are able to harden in a uniform crystal structure.
Winnowing A separation of cocoa shells from the cocoa nib.

Introduction

Coffee is one of the most popular beverages consumed worldwide, with a global production output of *ca*. 7 million tons in 2010, compared to 6.7 million tons in 1998–2000. Coffee plants belong to the family Rubiaceae and develop a pulpy fruit known as the 'cherry,' which contains two seeds otherwise termed coffee beans. Two coffee species are used successfully in commercial cultivation, namely *Coffea arabica* (Arabica) and *Coffea canephora robusta* (Robusta). The former accounts for *ca*. 64%, whereas Robusta accounts for *ca*. 35% of the world coffee production. Both species are chemically distinct and characterized by different amounts of minerals, polyphenols, and caffeine.

Arabica or Robusta beans are used either alone or as blends to impart to the finished product its unique organoleptic properties and sensory attributes. In fact, the botanical origin is frequently stipulated on the product label. Moreover, the sensory properties are not only influenced by the coffee species but also, within the same species, by the coffee variety. In essence, a coffee manufacturers' main aim is to deliver to the consumer a product of high quality and continuously superior in-cup taste and aroma. The latter are clearly influenced by the geographic and botanical origin, as well as the quality of the green beans.

Manufacture

Green Coffee Bean

Green coffee is processed by either the dry method (natural) or the wet (washing) method. In the dry method, where water is scarce, the ripe cherries containing the beans are shaken from the tree and laid on trays and sundried. They are then hulled (or shelled) and the beans washed. In the wet method, the cherries are passed in a flow of water into a pulping machine. The machine removes the outer skins, leaving the mucilage surrounding the bean exposed. After being fermented for approximately 1.5 days, the mucilage is then easily washed away, revealing the parchment covering the beans. In this state, still in water, the beans are divided into first and second quality, depending on their weight. They are then removed from the water, thoroughly dried, hulled, and graded by size.

An important factor to control for quality and safety is the green coffee bean moisture that in most cases ranges between 8% and 12.5%. The moisture content of the bean affects several parameters such as the roasting characteristics, sensory attributes of the finished product, susceptibility to insect attack, mold growth, and economical aspects.

Coffee arrives at the factory or facility for further processing either in smaller units, such as jute sacks, or in bulk via containers (train and truck), or one ton big bags. All arrivals should be subject to initial inspection, for example, evidence of moldy beans, integrity of the bags, signs of infestations, and wet damage. Quality approval of incoming lots is a key process before releasing the material for production. Coffee consignments are first sampled following a predefined sampling plan and then subject to physical testing and sensorial analysis. These tests enable a grading of the coffee (confirmation that delivery complies with a specification) and include quality characteristics such as defects, moisture (according to the International Organization for Standardization's (ISO's) standard ISO 6673), and, if specified, screen size. In the case of decaffeinated coffee,

 doi:10.1016/B978-0-12-378612-8.00288-2

the caffeine content in the green beans may be checked periodically, depending on the level of supplier confidence.

Roasting and Grinding

Green coffee beans are heated between 180 and 240 °C for *ca*. 6 to 15 min, depending on the degree of roast required. The longer the coffee bean is roasted, the darker it becomes. The roasting process can be described in different phases, i.e., preheating, endothermic and exothermic reactions, and finally a cooling stage. A multitude of chemical, in particular pyrolytic reactions take place during roasting and lead to changes in the cellular structure of the bean that expands considerably. Roasting is also characterized by bean dry matter losses of approximately 10% but is dependent on the thermal input. At higher temperatures and toward the end of the roast cycle, the reaction becomes exothermic that contributes to further raising the temperature of the roaster. Time–temperature conditions (roasting profile) are decisive for the generation of aroma compounds during coffee roasting. Many different roaster designs are in the present day commercially available, and the majority used in industry are hot air fluidized bed roasters with varying features (e.g., batch or continuous) and load capacity. At the same degree of roast, physical properties and concentrations of aroma compounds can differ considerably as a function of the applied time–temperature combinations. When coffees with different initial water content are roasted, differences in the evolution of the degree of roast and aroma formation are observed in light roasts because of the slower temperature increase in coffees with high moisture content.

At the end of the roasting process, water is usually sprayed on the beans (quenching water) to enable cooling. Quenching of coffee can also be carried out with air. When coffee is water quenched, water uptake is possible. In turn, the increased moisture content affects bean firmness and grinding behavior, accelerates degassing in whole coffee beans, and influences loss and degradation of aroma compounds. Roasting in commercial plants is typically followed by storage of the roasted whole beans of up to several hours before grinding – with the maximum tolerable storage time depending on individual quality criteria.

European roast coffees cover a broad range of flavor profiles according to different regional preferences and are designed to meet specific consumer groups' acceptances. The individual flavor profiles are controlled by specifying the green coffee blend, the degree of roast (typically measured by light reflectance or color measurements), and roast time.

To ensure a consistent brew performance and extractability, the roast whole beans are ground to controlled mean particle sizes. This increases the surface area and facilitates the extraction of soluble materials. The grinding process opens the cell structures of the beans, and it is known that grinding potentially causes significant losses of volatile aroma compounds. Very fine grinds may impact taste and facilitate extraction of carbohydrates and oils into the brew. The level of aroma loss depends on specific process conditions. Typical European drip filter grind sizes are in the range of 350–500 mm.

Carbon dioxide is generated in coffee beans as part of the roasting reactions. Roast and ground coffees intended for vacuum packs need to be degassed 2–6 h before packing. This is to allow carbon dioxide to escape from the beans in order to avoid this taking place inside the vacuum bag, which would result in a buildup of pressure and softening of the pack. The required degassing times are mainly dependent on bean type, roast conditions, moisture, and particle size. The amount of time depends on the grind.

Filling and Packing

Coffee is usually packed in a material that provides a gas (oxygen) and moisture barrier (metalized film or flexible laminate) that serves as a preservation of aroma and product characteristics. Packing is ideally under vacuum to maintain freshness and ensure an extended shelf life. In the present day, there exist a number of different packaging possibilities for roasted coffee beans and roast and ground coffee, such as simple pouches, sachets, vacuum packs, foil lined cartons, cans, glass jars, pods, and capsules, the latter for placement in an extraction chamber of a coffee dispensing machine.

Hazards and Control Measures

To help explain the system of managing safety, reference will be made to prerequisite programs (PRPs) and critical control points (CCPs) as defined by the Codex Alimentarius Commission. A food safety study must also consider primary production practices, manufacturing, utilities, transport, storage, and the distribution chain up to the consumption of the final product. In this section, only the significant hazards identified at the raw material and manufacturing stages will be addressed. These are usually defined as hazards that must be considered in a Hazard analysis critical control point (HACCP) plan, independent of the processes or set up of the manufacturing lines. It is assumed that the potential hazards, but nonsignificant are controlled through the PRPs.

Physical Hazards

Before further processing (roasting and grinding), the green beans are passed through a magnet to not only remove metallic contaminants but also as a protection of the coffee grinder at a later stage of processing. Other foreign matters, such as pieces of string (from bags), stones, wood, glass, plastic, etc. are removed with a bean cleaner and the green coffee conveyed to the intermediate storage silos.

Control Measures

Contamination of product with foreign bodies such as glass or metal is serious and can lead to product withdrawals or even public recalls. This may occur even in the presence of metal detectors and magnets and relying solely on detection systems, which does not suffice. In many cases, foreign bodies originate from process equipment and installations, and to mitigate contamination, appropriate measures at factory level must be in place to eliminate all potential sources of foreign bodies.

Important sources of foreign body issues are contact points along the line, for example, metal-to-metal friction and glass jars in case of glass filling lines. Points to consider are, for example, tote bins – lids, latches, and lid holders, tank or mixers with metal blender shafts, screw feeds, sieves, and fluid bed parts. In fact, anywhere in equipment where there is a risk of metal-to-metal friction and where there is mechanical movement, there is a risk of creating metal particles.

Depending on the final packaging, different physical hazards may need to be considered. In the case of filling in glass jars, an efficient procedure to avoid as far as possible glass breakage must be in place. In case of deviations or breakage, root cause analyses must be conducted and measures identified and implemented to avoid reoccurrence. It is important to emphasize that detection/rejection systems (e.g., X-ray and metal detector) have their limitations and will not solve issues without a solid foreign body prevention program in place. Detection systems need to be carefully maintained and fully validated, understanding their limitations in detecting a defect, and of course keeping the number of false rejects to a minimum.

Chemical Hazards

Green coffee may be treated with pesticides and fumigants, the hazard being the presence of unacceptable amounts of residues in the green beans and hence potentially the final roasted product. The European Commission has established a comprehensive database per crop and pesticide and lists >440 compounds and maximum residue limits (MRLs) for coffee, albeit the majority at the lower limit of analytical determination (Table 1).

The possible contamination of coffee beans with mineral oil was raised at the beginning of the 1990s. Investigations showed that jute and sisal fibers were softened with mineral oils before spinning and weaving. Hydrocarbon residues containing a high proportion of polycyclic aromatic hydrocarbons (PAHs) were found in commodities transported in such bags. This contamination was due to the use of low-grade mineral oils. Hydrocarbon residues were found in green beans and in the roasted coffees at 230 and 10–150 mg kg^{-1}, respectively.

However, PAHs have also been reported to be formed adventitiously during the roasting process and are present particularly in dark roasted coffee, albeit at the very low part-per-billion level. Further, analyses showed that PAHs were not released in both home brewing and industrial extraction. The evidence to date confirms that the risk of PAH formation in coffee is negligible.

Other food processing contaminants that have recently received much attention are acrylamide and furan. Coffee is considered a major contributor to both acrylamide and furan exposure via the diet. Several studies have been reported on the formation of acrylamide in coffee, and some have summarized the challenges of finding appropriate mitigation options. The content of acrylamide in coffee reaches a peak early in the roasting process, and toward the end acrylamide drops off sharply and consequently darker roasted coffees contain relatively lower amounts of acrylamide. However, the Maillard reaction also leads to the production of melanoidins, compounds with potent antioxidant activity. Coffee is said to contribute 64% of an average Norwegian's antioxidant intake and has been linked to a reduced risk of certain disease, especially liver disease and diabetes. More intense roasting to obtain darker colored beans not only reduces acrylamide levels but also negatively affects the ability of the brew to scavenge free radicals.

Another factor that affects the level of acrylamide in roasted coffee is the Arabica/Robusta ratio, with Robusta on average giving relatively higher levels. Studies on roast and ground coffees have also shown that the storage condition and time have an impact on acrylamide, with clear reduction at ambient storage. The acrylamide in roasted coffee is largely extracted into the brew and stable within the usual time of consumption. As these main factors also substantially affect the organoleptic properties of the brew and as modifications of the process have to comply with the consumer-accepted boundaries of taste profiles, only small effects in terms of acrylamide reduction are expected to be achievable. Laboratory and pilot studies employing the enzyme asparaginase, that converts the precursor asparagine into aspartic acid, have been reported, albeit with only marginal reductions ranging from 10% to 30% and characterized by a major impact on the sensorial properties of the final product. Further work with asparaginase, for example, using steam treated or water extracted beans, is ongoing, and data are expected to be published in the near future. Recently, the European Commission (EC) issued a recommendation on acrylamide in different foodstuffs and has set 'Indicative Values,' stipulated for roast and ground coffee and soluble coffee at 450 ppb and 900 μg kg^{-1}, respectively. Certain light roast coffees will be above this level, and currently there are no mitigation options available to reduce levels in coffee, without negatively impacting the organoleptic properties of the brew.

Several studies have been reported on the formation of furan, including coffee. The reduction of furan formation in food seems to be more challenging compared to, for example, acrylamide, particularly because the formation is based on multiple precursors and different reactions mechanisms. Recently, the 'European Coffee Cooperation Task Force' published a pilot study on the different stages in coffee manufacture that may contribute to the formation (or loss) of furan, including the consumer handling aspect. In the case of furan, which is highly volatile, accurate intake assessments are lacking, and the brewing technique has a major impact on the final furan exposure. Health authorities are also extending furan studies to include as well alkylfurans (2- and 3-methylfuran) that may exhibit similar toxicity profiles. For adults, coffee clearly tops the range with an average intake assessment of 0.43 μg per kg bodyweight per day for total furans, with the methylated furan analogs contributing considerably to the overall exposure. As recently stated by the European Food Safety Authority (EFSA), before considering remediation recommendations, there is a need not only for more detailed exposure assessment data but also for better toxicological information on which to base a comprehensive risk assessment.

Coffee consumption, in particular boiled coffee (Scandinavian, Turkish, and French press types), has been associated with elevated blood cholesterol and increased

Table 1 Example of a plan for the management of hazards in green coffee

Ingredient/step	*Hazard(s)*	*Control measure(s)*	*Acceptable level*	*Monitoring*	*Corrective action(s)*	*Verification*
Green coffee	Pathogenic bacteria, for example, *Salmonella*	No control measure necessary for green coffee with regards to pathogens. High heat treatment (roasting) in subsequent step (see **Table 2**)	No existing norms Not necessary to establish 'acceptable level in end product' due to high heat treatment in subsequent step	Roasting time and temperature	N/A	Quality monitoring system in place (process control)
Green coffee	Foreign bodies (sharp and hard, for example, metallic)	Foreign bodies management procedure at tipping station	$<$2 mm diameter of stainless steel (spherical) or approximately 4.2 mm^3 volume	Foreign body prevention system (magnet) and P2 cleaning	Block lot; Inform QA/production	Metal detector specifications, validation, and online testing
Green coffee	Mycotoxin: Ochratoxin A (OTA)	GAP and goods transportation – Build good relationship with suppliers – Specification addressed to supplier with moisture limit – Release of incoming bulk green coffee based on moisture content result and bean quality attributes	No OTA limits for green coffee established to date (limits have been set for R&G/soluble coffee) Limits set for moisture (12%, reject at 13%) and incoming bean quality (e.g., number of defects)	Moisture content measurement of each lot and quality control (defects, broken beans, moldy, etc.) following incoming inspection	Reject lot, Inform supplier	Sampling and OTA measurement according to sampling procedures
Green coffee	Fumigant Methyl bromide and inorganic bromide	Notification to all exporters/ traders/suppliers that commodities containing residues will be rejected Methyl bromide is being phased out in most countries and fumigation replaced with phosphine	25–50 mg kg^{-1} maximum residue tolerance levels	Material specification	Reject lot	Sampling and analysis
Green coffee	Pesticides	Notification to all exporters/ traders/suppliers that commodities containing residues above legislative levels will be rejected	EU: (EC) No. 149/2008 US: 40 CFR §180.225	Material specification	Reject lot	Sampling and analysis
Decaffeinated green coffee	Caffeine Presence of a high level of caffeine	Decaffeination process: online or at line measurement (e.g., NIR)	Caffeine $<$0.065% - for use in R&G	Material specification	Reject lot	Sampling and analysis

Note: Additional verification measures are discussed in the text.

Abbrevations: CFR, Code of Federal Regulations; EU, European Union; GAP, good agricultural practice; NIR, near infrared; R&G, roast & ground.

cardiovascular risk. The diterpenes cafestol and kahweol are attributed to the hypercholesterolemic effect of boiled coffee, and are extracted during the brewing process. However, the compounds are removed to a large extent by paper filters, and in the case of espresso coffees, the exposure is limited due to the relatively small serving size. As stipulated in Table 2, smaller grinds increase the surface to volume ratio, thereby enabling a better extraction of surface lipids and consequently more diterpenes in the cup. The scientific evidence in the literature in the present day makes it difficult to establish safety limits for total diterpenes, and average coffee consumption is considered unlikely to result in an appreciable increased risk of cardiovascular disease.

Coffee is a rich source of caffeine that provides mild stimulant effects but may be undesired by certain consumers. To cater for this need, manufacturers have developed processes to decaffeinate coffee, applied to the green bean and which remove caffeine to a large degree.

Caffeine, known chemically as 1,3,7-trimethylxanthine, is the major pharmacologically active ingredient in coffee and a central nervous system stimulant. The amount of caffeine consumed through beverages varies considerably and is dependent, for example, on how strong the coffee is prepared, and how much of it is consumed. Robusta is known to contain more caffeine than Arabica coffees.

There are four main methods of decaffeination, according to which substance is used to extract the caffeine: water, ethyl acetate, supercritical or liquid carbon dioxide, and methylene chloride. When organic solvents are employed, residues may be present in the coffee beans. Although the amount of residual solvent in green coffee is very small and no particular legislation has been adopted, there is a need to limit their presence to a minimum. Therefore, the measuring of caffeine as a verification of the decaffeination operation is encouraged. According to legislation within the EC, decaffeinated coffee is a coffee with a caffeine content reduced to 0.1% or less in roasted coffee beans and to 0.3% or less in soluble/instant coffee.

There is ample evidence in the scientific literature that the presence of caffeine above legislative limits in a 'decaffeinated' declared beverage is not a health concern but rather a legislative issue. Therefore, the decaffeination step is identified as a PRP but will nevertheless be carefully controlled to ensure each lot meets regulatory and/or internally set norms.

Control Measures

To effectively manage chemical contaminants such as pesticides and mycotoxins, a clear specification to material suppliers is mandatory. Further, elements that strengthen a control system is the supplier confidence, management at field/crop and transport/storage (warehouse) stages. Generally, the level of pesticide residues found in green coffee is very low. However, analysis of each lot according to the coffee-pesticide profile is simply impossible from a practical as well as economic point of view. It is well documented that if present, their concentration is substantially reduced during storage, roasting, and brewing. The harsh processing conditions (i.e., roasting at temperatures in the range of 180–240 °C) as well as high temperature extraction in the case of soluble coffee manufacture will in most cases lead to a significant reduction of residues should these be present at levels of concern. However, this should not be an incentive for manufacturers to accept lots that contain residues above MRLs. Good agricultural practice (GAP) and existing legislation must be respected at all times. Control measures for pesticides/fumigants (e.g., phosphine, and in some countries methyl bromide) upstream at the supplier level are therefore mandatory and must be firmly embedded in the supplier/grower contract and identified within the HACCP study as a PRP (Table 1). Verification through spot checks or monitoring is highly recommended, the frequency of such checks depending on the supplier confidence level and origins of the green beans. Monitoring should also take into account active substances that are not permitted for use in the commodity (potential abuse), as well as targeted analysis using knowledge of compounds actually applied at farm level to ensure that the commodity complies with National or International Standards and to ensure the safety of the product.

To avoid issues with PAHs, the International Jute Organization has issued specifications for the manufacture of jute bags that limit the amount of unsaponifiable matter to a maximum of 1250 mg kg^{-1}. Some manufacturers have developed a hydrocarbon-free oil, based on vegetable oils, to soften the fibers. Mineral oils in jute sacks should be part of a annual monitoring scheme, to ensure compliance and the safety of the product.

Water, steam, and air circuits are all to be considered within the HACCP study. Potential contamination of quenching water (e.g., microbiological load and absence of pathogens), or air circuits in contact with the roast and ground coffee (e.g., nonfood grade mineral oil from air compressors), may lead to unacceptable amounts of contaminants/residues. The use of food grade mineral hydrocarbons/lubricants at food contact areas is a point that warrants particular attention. In the case of lubricants used in food processing machines, these need to meet the requirements of the European hygiene standard for food processing machines. In the USA, United States Department of Agriculture (USDA)-H1 lubricants can be applied to all friction points where there may be accidental, technically unavoidable contact of lubricant and food product. H2 class lubricants can also be used in food processing but contact with food must be excluded. Manufacturers are encouraged to establish and maintain a lubricant management program, subject to periodical internal review/audit.

Microbiological Hazards

At the typical temperatures of roast, a plethora of thermally driven reactions take place within the coffee bean. The roast temperatures are well above those known to destroy microorganisms and even to large extent decompose mycotoxins. Consequently, the presence of pathogenic bacteria are not considered a hazard for pure roasted coffee as the control of the heat treatment is directed toward delivering sensorial attributes and any deviation will be detected by the sensorial evaluation of the final product (Table 2).

However, a major hazard for coffee is the presence of ochratoxin A (OTA), a nephrotoxic carcinogen produced by the two genera of fungi: *Penicillium* and *Aspergillus*. In fact,

Table 2 Example of a plan for the management of hazards in roasted coffee

Ingredient/step	*Hazard(s)*	*Control measure(s)*	*Acceptable level*	*Monitoring*	*Corrective action(s)*	*Verification/comments*
			No existing norms			Quality monitoring system in place (process control)
Roasting and quenching	Pathogenic bacteria, for example, *Salmonella*	No specific control measure necessary for roasted coffee with regards to pathogens	Not necessary to establish 'acceptable level in end product' due to high heat treatment	Roasting time and temperature	N/A	Control of heat treatment is not necessary as the roasting is driven by quality and any deviation is identified by sensory evaluation of the final product
Roasting and quenching	Acrylamide	None identified to date. Maillard reaction product from asparagine and reducing sugars. Roasting profile not severe enough to degrade acrylamide to a sufficient extent	ALARA. Where valid, 'official' guidance or indicative levels are to be considered	Roasting time and temperature	N/A	Particularly light roasted coffees have relatively high amounts of acrylamide
Roasting and quenching	Furan	None identified to date. Highly volatile compound formed from lipid degradation and sugar fragmentation	ALARA. Where valid, 'official' guidance or signal levels are to be considered	Roasting time and temperature	N/A	Furan has to be considered in changes related to roasting and grinding. Dark roast coffee tends to exhibit relatively higher amounts of furan versus light roasted beans
Grinding	Foreign bodies (sharp and hard, for example, metallic). Hard foreign bodies which have passed through foreign body prevention system may damage the grinder	Foreign bodies management procedure at tipping station	<2 mm diameter of stainless steel (spherical) or approximately 4.2 mm^3 volume	Metal detector specifications, validation, and online testing	Block lot; Inform QA/production	Once a year (depending on factory) the grinder is changed due to wear and tear
Grinding	Presence of high amounts of diterpenes (cafestol and kahweol)	Depending of grinding size diterpenes would be more available for extraction. Control grinding size according to QMS	Coffee oil is more prone to be extracted at finer grind size	Grind size analysis	Block lot; Inform QA/production	Quality monitoring system in place (process control)
Filling and packing	Foreign bodies (sharp and hard, for example, metallic)	Foreign bodies management procedure at filling	<2 mm diameter of stainless steel (spherical) or approximately 4.2 mm^3 volume	Check sensitivity with test pieces and that reject mechanism is working correctly	Hold product; Investigate source; Inform QA	Metal detector specifications, validation, and online testing

Note: Additional verification measures are discussed in the text.

Abbrevations: ALARA, As low as reasonably achievable; N/A, not applicable; QA, quality assurance; QMS, quality monitoring scheme.

coffee has been identified as one of the significant contributors to OTA exposure in the European Community and the Codex Committee on Contaminants in Foods has prepared a draft code of practice for the prevention and reduction of OTA in coffee. Mold contamination of coffee beans can be indirectly controlled through checks that should encompass three main criteria:

1. Dried cherries/pods/husks.
2. Visual damage.
3. Earthy/moldy smell.

The skin of the cherry normally protects the coffee bean itself from contamination with spores. This protection is lost if either cherries or skins and husks are not removed from the green coffee or if the skin is broken, of which broken beans or insect-damaged beans are indicative. An earthy/moldy smell or cup is an indicator for mold damage, and coffees without an earthy/moldy smell showed less than 1% risk to contain more than 10 $\mu g\ kg^{-1}$ of OTA.

Control Measures

In terms of controlling OTA, green bean moisture has been shown to be the main risk factor for OTA formation after the first processing stage. Moisture is regulated within International Coffee Organization (ICO) Resolution 420 and provides for a quality standard for exported green coffee, specifying a maximum moisture level at 12.5%. However, to cater for an additional margin of safety in terms of quality/risk of mold contamination, as well as possible fluctuation due to further storage/transport, manufacturers may choose an internal limit, for example, 12% (Table 1).

Consignments that exceed 13% are rejected, and those between 12% and 13% may lead to compensation claims made to the supplier, dependent on the supplier contract. Within a HACCP study, OTA may be considered a potential hazard. The likelihood of its occurrence depends on the supplier confidence level and the relative risk of exceeding limits due to the coffee origin. GAP and due diligence is the inclusion of verification measures, ideally defined as a surveillance or annual monitoring program of green bean origins (e.g., annual or biannual). Within the European Community, maximum limits have been established for roast and ground coffee and soluble coffees of 5 and 10 ppb, respectively. Notably, some countries have set individual national levels that may be more stringent and/or are based on green coffee beans. Therefore, mold contamination at the green coffee stage must be controlled, i.e., follow defined storage/warehousing and transport procedures and must be part of the manufacturers HACCP system.

Tea and Herbals

Introduction

Tea is the most widely consumed beverage in the world with an estimated daily consumption of 15–20 billions cups. This is due to its refreshing, mild stimulant properties, and also to its medicinal and general health-promoting purposes. In 2008, the world tea production was 3.8 million tons (International Tea Committee). The most commonly found varieties of tea, which are all originating from the same tea plant *Camellia sinensis*, are white, yellow, green, black teas, and oolong. The way in which the fresh leaves of the tea plant are processed and their levels of contact with oxygen determine the different varieties of tea. During the enzymatic oxidation process, tea leaves undergo natural chemical reactions that result in distinctive color and taste characteristics.

Besides traditional teas, there is a growing interest in other plant products termed herbal and fruit infusion (HFI) as they are recognized for their very diverse sensory properties as well as for their potential health beneficial properties. HFI may contain just one or two ingredients or are as minor ingredient blended with teas prepared from *C. sinensis*. Raw materials for herbal infusions are typically parts of plants, fruits, spices, herbs, etc., which do not originate from *C. sinensis*. Plants and parts of plants commonly used in HFI are listed in the European Herbal Infusions Association (EHIA) 'Inventory List of Herbals Considered as Food' in its current version. Other teas can be flavored by the addition of aromas.

Tea and Herbals Manufacture

Although each type of tea has different taste, smell, and visual appearance, tea processing for all traditional teas consists in a similar set of methods with some variations. The most popular teas are green and black. The manufacturing process of the latter involves the following main steps: growing, leaf harvesting, withering (wilting) under hot air stream, sifting, mechanical rolling, fermentation/oxidation for 2–4 h done at high humidity usually at 20–30 °C converting much of the catechins of the leaves into complex tannin, drying to a moisture content below 3% w/w, and finally grading and packing.

In comparison to black tea, the main difference in the processing of green tea is the blocking of the fermentation by heat inactivation of oxidative enzymes either with steam (Japanese method), or by dry cooking in hot pans (traditional Chinese method). Oolong tea falls somewhere between green and black teas as the leaves are only partly oxidized.

The graded tea is packed into containers for shipment from the countries of origin. Different packaging possibilities exist for dried and graded teas, such as wooden tea chests, paper laminate sacks, polythene bags in gunny sacks, polythene bags in cardboard cartons, and vacuum packed cartons/sacks.

In the case of HFI, a plethora of different ingredients originating from various plants or parts of the plants are being used such as roots, tree barks, leaves, flowers, fruits or seeds, and spices. In the EHIA inventory list of herbals, a wide spectrum of different ingredients with more than 400 foodstuffs is listed. Many of these raw materials are not grown in cultivated crops but wild and are then, after harvest, rather sundried than dried industrially at high temperatures.

The manufacturing process of ingredients used for HFI varies a lot due to the broad spectrum of used raw materials but comprises the major steps: growing, harvesting, transport to collection point, cleaning, drying either in the sun or in hot air drying chambers, packing, and storage/transport. HFI may contain just one or two ingredients, for example, ginger,

lemon, or chamomile or are as minor ingredient blended with traditional teas prepared from *C. sinensis*, for example, lemon balm blend and black tea with bergamot (equal to earl gray tea).

When mechanical dryers are being used, both time and temperature of drying should be controlled as well as the moisture of the dried products. A uniform drying of the material should be achieved.

Insects at all stages of their life cycle may be present in teas and HFI. Rigorous inspection and control procedures must be put in place at different levels to detect any sign of infestation in the country of origin, and at the processing plant, the blender/packer level as teas and HFI are submitted to long transportation and are stored for certain periods of time before further processing. Fumigation for the control and elimination of insects should only be applied when necessary with authorized fumigants (note, ethylene oxide is banned in the European Union (EU)) and fumigant residues must be below MRLs.

Hazards and Control Measures

The main food safety risks specific to teas and HFI are foreign bodies, pesticides, and presence of pathogenic microbiological contaminants such as *Salmonella* spp. and mycotoxins.

Physical Hazards and Control Measures

A wide variety of foreign bodies may be introduced in teas and HFI during harvest, postharvest process, transport, and blending/packing and are typically stones, glass, metal, wood, packaging or bag materials, etc.

Various methods such as sieves of different sizes, ferrous material with magnets and air separation to remove efficiently foreign bodies at the country of origin and upstream at the blender and/or packer plants do exist. Presence of foreign bodies represents a low food safety risk in teas and HFI as long as methods to remove them are integral part of the processing operations. Detection and rejection systems (metal detector and magnets) should be installed also downstream at the level of the blender and/or packer as a final verification measure so that all control measures at the countries of origin, during transport, were effective.

Chemical Hazards and Control Measures

At the stage of primary production, pesticide residues usually represent the main chemical hazard. Commonly detected residues in teas and herbals based on the European Tea Committee (ETC) surveillance reports (2001–04) in Indian teas are, for example, dicofol, cypermethrin, deltamethrin, fenvalerate, ethion, and endosulfan. The application of pesticides, if not appropriately controlled, may represent a potential food safety concern, particularly if residues exceed the acute reference dose. The surface area of tea leaves is indeed generally higher than in other types of crops, and thereby the absorption of the pesticides may be quite abundant and depends also on the spraying dose. Not only the tea leaves absorb pesticides but also the soil; some pesticides are known to persist in the soil for many years and may be assimilated by the tea and herbal plants.

Drying at high temperatures of teas and herbal teas will obviously concentrate pesticides present on tea shoots (also called drying factor), but at the same time, it is likely that a reduction of pesticides residues will take place due to the drying process, the heating process specific to green tea and subsequent preparation with hot/boiling water by consumers as reported by some authors.

The use of approved pesticides applied under GAP results in pesticide residues below the stipulated MRLs. This point, however, is not straightforward as MRLs are not aligned, and in some countries such as the USA only very few compounds have designated MRLs for tea ($n=8$). Only 11 MRLs are currently set at the Codex Alimentarius level, whereas Japan has listed >70 compounds and the EU approximately 60 compounds. Such inconsistencies may impact trade, and efforts need to focus on harmonized legislation to avoid trade barriers. In the case of ingredients used for HFI, the multitude of local farmers and the fact that HFI are usually not cultivated make the application of GAP much more challenging mainly for practical reasons, compared with the larger and well-structured traditional tea plantations.

Clear specification to material suppliers is mandatory to manage chemical and also microbiological contaminants. Furthermore, long-term and solid relationships with tea and herbal tea farmers are essential to prevent potential pesticide issues upstream of the supply chain. This is also valid for most of the other food safety concerns (pathogens, mycotoxins, etc.). In addition, monitoring or verification through spot checks is an essential element of the HACCP process and needs to be conducted at a frequency that should be adapted depending on the origin of the teas/HFI and on the supplier confidence level. In this respect, the ETC recommends a list of specific pesticides in teas that should be regularly monitored and sampling plans (2009). In ISO 1839, 'tea-sampling' is specified. The list of pesticides needs to be regularly updated based on the latest food safety information available such as emerging issues, rapid alert system for food and feed (RASFF), regulatory developments, etc.

Most foods contain some aluminum as it occurs ubiquitously in the environment. Beverages (tea, coffee, and soft drinks) and also cereals are the main sources of aluminum from foods. Tea and some spices and herbs contain particularly high levels. Studies showed that high aluminum availability in tea garden soil is the major contributing factors for the enhanced aluminum accumulation in tea leaves and HFI. Teas and herbal materials should not be cultivated in soils contaminated high levels of metals, pesticides, and other environmental contaminants.

In most of different teas and HFI, PAH content is low and does not represent a food safety concern, with perhaps the exception of 'smoked tea,' for example, Lapsang Souchong, which may contain residues of PAH.

Microbiological Hazards and Control Measures

Diverse microorganisms (bacteria/spore formers and fungi) may be present in teas and in HFI. They are indigenous to the

soil and plants in which they are grown. The sources of microbiological contamination may be dust, insects, fecal material from birds and rodents, etc.

The microbial load in teas and HFI is generally high but varies depending on the origin, on the variety of teas (microbial level in green tea is usually low due to the heat treatment), on the plants/part of plants used for HFI, on the process in particular the drying (sun drying versus industrial drying), on the moisture level at different stages, etc. Microbiological guidelines are proposed by the EHIA for herbal infusion raw materials and for finished product (consumer ready dry products), but stricter norms outlined in the specification can be applied if deemed necessary. This would encourage producers to improve hygienic conditions, minimize microbiological contamination, and avoid growth of microorganisms, notably molds and consequently potential mycotoxin formation.

If teas and HFI do not comply with the specification, application of an effective heat treatment (e.g., steam) must be envisaged. Nevertheless, teas and HFIs must not be accepted for heat treatments or other types of treatment if there is evidence of insect damage or/and mold growth because of risk of the presence of mycotoxins. Although reported cases of food outbreak related to tea and HFI are rare, there is evidence of microbial contamination. In 2002, a nationwide outbreak of salmonellosis occurred in Germany, which was traced to contaminated aniseeds. Infants below 13 years of age (42 cases) were principally affected. *Salmonella* agona was isolated from both aniseed containing herbal tea and patients. More recently, in 2007, 14 cases of *Salmonella* senftenberg infection were reported in Serbia and were linked to contaminated fennel seed tea. As teas and HFI (e.g., aniseed, caraway, and fennel seeds) are not only being drunk by healthy consumers but also by sensitive or more vulnerable population groups, such as infants and immune-depressed individuals, it is essential to follow strictly the brewing instructions during preparation. Contamination of tea with other pathogens such as verocytotoxin-producing *Escherichia coli* (VTEC) was also reported in RASFF between 2008 and 2010. It is well documented that *Salmonella* spp. can survive for long period of time in foods with low water activity and some of them are infective at low dose in dry foods. This must be borne in mind as some of these materials are blended as minor ingredient with teas.

During preparation of tea or herbal beverages at home, the brewing with hot/boiling water will ensure the elimination of vegetative pathogens (*Salmonella* spp. and VTEC) potentially present in the product. In this respect, brewing instruction on packages of tea and HFI must be followed by the consumer in order to guarantee the elimination of pathogens potentially present in teas and herbal/fruit infusions. In case an automatic beverage machine is being used, the temperature of the water prepared in the machine has to be high enough to ensure an effective pasteurization of the brewed tea or HFI. Verification that the machine is able to heat water at the desired temperature in the system precisely and over time must be checked by the machine developer through extended life cycle tests. This is particularly essential because tea is generally not perceived as a product at risk for contamination with enteric pathogens.

Inadequate processing and storage conditions, particularly when characterized by high humidity, can provide opportunities for microorganisms to grow, including molds. Growth can take place for the following main reasons: (1) prolonged time between harvest and drying; (2) insufficient drying; (3) insufficient protection from rain, overnight dew during sun drying; and (4) improper dry state during storage and transport contributing to humidity absorption.

One of the important characteristics of teas/HFI are their hygroscopicity, which means that if tea is not adequately protected by suitable packaging materials, they will absorb moisture quickly from the humid and hot ambient air in the countries of origin. Also, condensation under poor storage and transport conditions may occur leading to a localized increase of the water activity and potentially to the growth of microorganisms. The possibility of mycotoxin production by specific molds in high moisture teas and HFI has been reported. Only a minority of molds can generate mycotoxins, many of which are genotoxic carcinogens and may cause cancer. The risk was perceived as nonsignificant by some authors, albeit this subject has not been extensively investigated compared with numerous publications on the mycotoxin contamination of coffee by OTA or of other foods such as nuts or cereals.

In a recent study carried out in the Czech Republic, some 40 samples of green, black, and herbal teas from shops were analyzed. No mycotoxins were found in any of the samples, but some *Aspergillus* species able to synthesize OTA and aflatoxins were identified.

In spite of the long history and wide use of tea and HFI, there are few publications on their contamination with molds and mycotoxins compared with reports on the contamination of other foods such as cereals, nuts, and dried fruits. Liquorice and ginger are used as minor ingredient in some tea blends. Aflatoxins or OTA were identified in liquorice and ginger. Within the European Community, maximum limits for OTA of 20 ppb have been established for liquorice roots and 80 ppb for liquorice extract. Therefore, the tea/herbal tea industry should look at this potential problem in a wider context and possibly greater depth. Once mycotoxins are present, they can persist through processing into the final food product. In addition to the potential food safety issue of mycotoxin synthesis in teas and HFIs, growth of molds on the surface of teas and HFI is unacceptable from a visual and sensory point of view. Sensory properties of the brewed tea and herbal/fruit infusion will be negatively impacted, resulting in a moldy off flavors (musty taste).

To prevent microbiological growth, especially that of toxigenic molds, a safe moisture level must be achieved. The European Union's Scientific Committee on Food in 1997 specifies a maximum moisture level of 10%, which was considered to give an acceptable safety margin for the storage/warehousing of tea considering fluctuation during storage and transport. Generally, moisture content in black tea is largely below 10%. EHIA guidelines recommend a maximum moisture level of 12–13% for herbals, for example, camomile, fennel, lime, peppermint, etc. To determine moisture, ISO 1573 is recommended (103 °C for 6 h).

Cocoa and Derived Products

Introduction

The two distinguishing and pleasurable characteristics of chocolate are the flavor and texture. Chocolate is consumed by almost everyone globally and is considered an enjoyable food; it is generally sold at a price that means it is available to all. The key component of chocolate is cocoa liquor, which is obtained from cocoa. There are four main varieties of cocoa utilized for chocolate, cocoa powder, and cocoa butter production. The most common and widely used cocoa variety is Forastero, which grows largely in West Africa producing an estimated 70% of the world's crop. Criollo, Tinitario, and Nacional are produced in much smaller quantities and when combined make up approximately 10% of the world crop. The different species of cocoa trees (*Theobroma cacao* L.) can be differentiated by the color and shape of their pods, although this can be difficult due to cross-fertilization leading to copious hybrids between the species. Approximately, two-thirds of the cocoa crop is utilized in chocolate products, the remainder goes almost exclusively to beverage and bakery sources.

Manufacture

Cocoa Beans

Storage and Handling

The cacao tree produces pods containing pulp and raw beans. When pods ripen they are harvested from the tree. The pods are opened and the outer pod and placenta are removed, the separated beans are then fermented and dried, which is usually carried out on the farm. The bacteria involved in the fermentation process result in the production of acids and enzymes, which cause death of the beans and breakdown of proteins and sugars to produce cocoa flavor precursors, this ultimately provides the building blocks for the flavor of the cocoa liquor. The drying process then reduces the moisture content of the cocoa beans to between 6% and 8%, which allows the beans to be transported safely as well as removing the acids, which helps to improve the flavor of the cocoa liquor. The cocoa beans are then stored in jute sacks during shipment to manufacturers. On receipt, cocoa bean lots are subject to an intake inspection where checks are made for the presence of molds, damage to bags, signs of infestations, and wet damage. The quality approval of incoming lots is a key input before release of the material into production.

Cleaning and Winnowing

Cocoa bean cleaning is an essential step in the processing of cocoa and often includes air separation, vibration as well as a series of sieves and rotary magnets. The cocoa beans undergo a further processing step known as winnowing. Winnowing involves the predrying or heat treatment of the cocoa beans to allow for separation of the shells from the cocoa nib, the cocoa beans are then broken into large pieces to separate the shells from the nibs. A process known as variable aspiration is often used to remove the maximum quantity of shell without removing cocoa nib.

Roasting

The cocoa nibs are then roasted to bring out the chocolate flavor and color. The temperature and time of the roast depends on the moisture content, type of beans used, and the chocolate or product required from the process.

If the cocoa nibs are to be used to produce cocoa powder, then they must also undergo alkalization, usually with potassium carbonate, in order to develop the flavor and color and increase the solubility of the cocoa powder to be produced.

Milling

The roasted nibs are then milled to create cocoa liquor. Cocoa liquor consists of cocoa particles suspended in the cocoa butter. The temperature and degree of milling varies according to the type of nib used and the product required. Manufacturers commonly use more than one origin of bean in their products, and therefore the different liquors extracted from the different beans must be blended to the required formula.

The processing then takes one of two directions based on the final product required; the cocoa liquor can be used directly in the manufacture of chocolate, or it can undergo further processing involving pressing into two fractions – cocoa butter and cocoa press cake. Cocoa butter is utilized in the manufacture of chocolate whereas the cocoa press cake is further broken down to form cocoa powder, which is mainly utilized in beverages, baking, and desserts.

Chocolate Manufacture

Chocolate manufacture involves the mixing of several ingredients including cocoa liquor, cocoa butter, sugar, milk, emulsifying agents, and cocoa butter equivalents. The proportion of ingredients varies based on the type of chocolate require being manufactured.

Refining

The mixture undergoes a refining process by traveling through a series of rollers until the product becomes a fine flake. The refining process ensures that the particle size is adequately small resulting in the required mouth feel and viscosity of the chocolate.

Conching

Conching further develops the flavor and texture and is a process, which permits the removal of volatiles as well as the even coating of sugar crystals in fat. The conching process also allows flavor transfer into the sugar particles. The speed, duration, and temperature of the conching process influence the flavor of the chocolate.

Tempering

The mixture is then tempered, which involves heating, cooling, and reheating to give the characteristic melting profile of chocolate. The tempering process acts to delay fat bloom in the finished product.

Molding or Enrobing

The chocolate can then be molded or used to enrobe fillings. The molded or enrobed product is then cooled in a cooling chamber.

Distribution

Usually, the final stages of production include packaging and either the metal detection or X-ray of the product before distribution.

Hazards and Control Measures

The food safety hazards specific to cocoa mass production and chocolate manufacture include the potential presence and contamination with foreign bodies and the possible presence and/or contamination of *Salmonella*. These food safety hazards are controlled by a number of prerequisite programs as well as by performing processes that are considered critical to controlling the food safety of the cocoa mass or chocolate. In confectionery, chemical (e.g., presence of mycotoxins due to mold growth) and allergen (e.g., contamination by gluten) hazards are also frequently identified during the HACCP assessment; however, these hazards are not specific to cocoa production and chocolate manufacture and therefore will not be covered in this section. However, it is important to note that hazards will vary between confectionery processing facilities based on raw materials, suppliers, production equipment and processes, to name a few, therefore, in line with the HACCP approach, all hazards should be identified at each process step and suitable control measures effectively implemented.

Physical Hazards

Sources

Cocoa beans are a raw material of agricultural origin and therefore are a major potential source of foreign matter, for example, metal farming implements, pieces of bark, stones, glass, and pests in unprocessed cocoa beans. The fermenting and drying of the beans is nearly always performed directly on the farms, therefore, the likelihood of foreign matter contaminating the raw material is highly likely. In addition, the chocolate manufacturing process is complex in nature and, itself, can also be a major source of foreign body contamination – many pieces of equipment have moving metal parts, which have the capacity to come into direct contact with other parts resulting in metal-to-metal contact. Subsequently, this results in metal entering the process. Examples of such equipment include storage tanks with stirrers, conches, mixers, temperers, and depositors, to name a few. Additionally, polycarbonate molds are commonly utilized in the chocolate confectionery molding process, and these can be prone to breakage in the event of jams.

Control Measures

To control the risk of foreign bodies, an effective foreign body management system must be implemented by a cocoa mass and chocolate confectionery manufacturing establishment. For foreign matter, management in raw materials, auditing of the supplier's food safety practices is crucial as well as the building of a good relationship between supplier and manufacturer. Incoming raw materials must be adequately protected during transport and storage to ensure foreign body contamination is prevented. A check of the condition of raw materials on intake is necessary as well as rejection of damaged goods. Sieves and filters can be installed at the point of raw material intake as well as at other key points in the process as defined by the HACCP study, usually including the end of the chocolate-making process. An essential step in the processing of cocoa beans is cleaning where various methods are used to separate out foreign bodies, including air separation, vibration, sieving, and rotary magnets, although processes can vary greatly. Additionally, further removal of foreign material occurs after the beans have been broken – during winnowing, the shell is separated from the nib and at this point other hard residues such as dried pulp and loose shells are also removed. Ferrous metal contamination is often identified as a risk in the chocolate-making process, and in such a case magnets can be added to the process downstream from ferrous equipment with a possibility of failure. In molded products, a mold breakage procedure should be implemented and involve a thorough check of all potentially affected product. Metal detection is an important step of chocolate production that is purposefully designed into the process. It is usually found at the end of the process to allow for detection of metal hazards coming from all points in the process. It is important to note that such defenses have limitations, and therefore, foreign body prevention should be managed largely through robust prerequisite programs, such as preventive maintenance. This is a key to ensuring a food safe product in preference to a reliance on foreign body detection systems.

Microbiological Hazards

The microbiological hazard of concern during chocolate manufacture and end-product use is *Salmonella*. The low water activity characterized by chocolate (typically approximately 0.4 and 0.5) means that *Salmonella* is unable to grow in chocolate. However, in 1994, Cordier *et al*. elucidated that *Salmonella* has the ability to survive in chocolate products for up to several years. An overview of *Salmonella* food poisoning outbreaks in chocolate have been reported by Werber *et al*., in 2005 (Table 3), and these incidents all involved very low numbers of *Salmonella* cells. It has been hypothesized that the fatty matrix of chocolate actually preserves the *Salmonella* cells from the acidic conditions of the stomach allowing *Salmonella* to survive and ultimately colonize the lower gastrointestinal tract, resulting in the manifestation of clinical symptoms.

Sources

Salmonella can be introduced into chocolate through incoming cocoa beans. Cocoa beans are a known potential source of *Salmonella*, due to poor hygiene conditions during harvesting, fermenting, and drying. The pulp and beans are contaminated during and after breaking of the pod by several sources, some of which include the harvesters, the tools utilized during the harvesting process, soil, leaves, and pests. Following

Table 3 Overview of published chocolate outbreaks due to *Salmonella* contamination

Year	*Country*	*Serovar*	*Vehicle*	*Contamination source*	*Number of affected persons*
1970	Sweden	*Salmonella* Durham	Chocolate products	Cocoa powder	110
1973–74	USA and Canada	*Salmonella* Eastbourne	Chocolate balls: Canada	Cocoa beans	200
1982	England and Wales	*Salmonella* Napoli	Chocolate bars: Italy	Unknown	272
1985–86	Canada	*Salmonella* Nima	Chocolate coins: Belgium	Unknown	–
1987	Norway and Finland	*Salmonella* Typhimurium	Chocolate products: Norway	Avian contamination speculated	349
2001–02	Germany and other European countries	*Salmonella* Oranienburg	Chocolate brands (2): Germany	Unknown	439

fermentation the beans are dried, often on the floor in the sun, and there is virtually no environmental control, and as a result microbes can contaminate the beans. As a consequence, raw cocoa beans have high microbial levels and the presence of *Salmonella* is a well-recognized hazard. Other raw materials utilized in the chocolate-manufacturing process also need to be controlled because they too could introduce *Salmonella*. Milk powder has been implicated in a large number of salmonellosis outbreaks and heat treatment and cross-contamination controls in the milk powder manufacturing process must be strictly followed. Similarly to cocoa beans, raw nuts may become contaminated with *Salmonella* if they are exposed to poor hygiene conditions. The presence of *Salmonella* has also been linked to other common confectionery raw materials including egg products, flours and starches, lecithin, and coconut.

Inadequate hygiene practices in the cocoa and chocolate manufacturing and processing environment should also be considered as possible sources of microbiological contamination including *Salmonella*. Additionally, another source of *Salmonella* contamination from water includes leaks coming from insufficiently managed equipment (e.g., jacketed water systems) and poorly maintained facilities (e.g., leaking water pipes).

Control Measures

Suppliers of raw materials to be utilized in the manufacture of chocolate should be carefully selected, and their food safety controls audited to ensure that all incoming ingredients are microbiologically safe for use in the chocolate-making process because the microbiological safety of chocolate products relies entirely on the use of safe ingredients and the control of cross contamination during processing and packing.

Roasting of beans or nibs is often a CCP in the destruction of *Salmonella* because temperatures of 70–80 °C achieved during milling, refining, and conching are not sufficient to destroy *Salmonella*. Similarly to cocoa beans, the roasting of raw nuts is a critical step. It is therefore essential that appropriate controls are applied at the roasting step to ensure sufficient temperatures, and roasting times are achieved.

Following the roasting step, there are no further processing stages that will effectively destroy *Salmonella*, therefore, hygienic processes and working practices are essential as preventive measures to avoid *Salmonella* cross contamination and include: Correct hygienic zoning of the cocoa bean process to ensure no possibility of cross contamination from the raw to roasted beans; segregation of raw bean storage and handling areas; dedicated personnel and equipment to potentially contaminated areas; minimization of movement between raw bean and roasted bean areas including hygiene barriers that incorporate a shoe and overall changing area for workers.

Another key element in *Salmonella* contamination prevention in chocolate processes is the control of water. Cleaning procedures used in chocolate manufacturing and processing should always be directed toward dry cleaning as much as possible with a visual inspection on completion. Dry cleaning involves the application of kinetic energy to a surface and often includes manual scraping, brushing, and vacuum cleaning. Additionally, a clear color coding system for cleaning utensils should be implemented ensuring there are dedicated cleaning tools for food contact and nonfood contact surfaces to prevent cross contamination from dirty to clean surfaces. Hygienically, designed equipment is a vital factor in ensuring the ability to effectively clean chocolate processing equipment. Hollow bodies should be avoided, multifaceted surfaces minimized, and it should be possible to easily disassemble and reassemble equipment. Condensates coming from cold water piping, refrigerator coils, and the arches of cooling tunnels, may also act as a potential source of moisture and therefore *Salmonella*. As a result, cool surfaces located in warm areas should be sufficiently insulated and line/environment temperatures carefully monitored. Water leaks coming from closed loop jacketed water systems are common, especially in older equipment. Over time, biofilms may accumulate if water systems are not correctly monitored and treated, and in the event of a microleak, product contamination with *Salmonella* can occur. A key element in controlling this is through a planned preventive maintenance program. Through the formation of a thorough assessment plus historical background of each installation a schedule of planned maintenance should be developed and implemented to control a potential risk before it develops into a hazard. The need to also consider causes of previous *Salmonella* outbreaks as a means of preventing reoccurrences must also be emphasized, for example, since the 2006 Cadbury outbreak a planned preventive facilities maintenance schedule including regular checks on water pipes have prevented further *Salmonella* outbreak recurrences

which, as previously mentioned, should form part of the prerequisite program.

Monitoring programs that consider the environment (e.g., environmental sampling of floors and walls), equipment (e.g., samples taken from various points on a line and closed loop water system sampling), and product (e.g., positive release of part-processed and finished products) are essential to verify the effectiveness of the microbiological control measures as outlined above. A sampling plan should be developed to test, at regularly defined intervals, for *Salmonella* and an appropriate hygiene indicator such as enterobacteriaceae. Sampling points should target susceptible areas. Additionally, investigative sampling will be required. Data should be routinely evaluated and trends identified before the safety of the product becomes compromised. If hygienic processes and practices are insufficient or are not adhered to, then results from the pathogen monitoring program will highlight this. Corrections and corrective actions should then be implemented to manage potential risks. It is important to note that monitoring programs are a means of verifying the effectiveness of the control measures put in place and are not a control measure in their own right.

Conclusion

Pure roast and ground coffee has an inherently low risk of contamination (chemical, microbial, and physical hazards) that may lead to a food safety issue and harm the consumer. In the case of pesticides and fumigants, excursions of chemical residues above the MRL are seldom, and exceptional violation of an MRL is not a health or safety issue as adequate safety margins are incorporated into the MRL to allow a lifetime exposure at or below the given level. Nevertheless, the monitoring of mycotoxins at the green bean stage is important, and the EU Rapid Alert System has identified relatively high OTA levels in some producing countries in Africa, leading to the requirement of stricter controls in these origins. In the case of tea, pesticides remain an ongoing concern, particularly challenging to manage upstream at the growers and farmers level. The risk of microbial contamination in herbals and teas is not to be underestimated, and control is usually managed by the consumer by adding hot or boiling water to the product. Microbial contamination and foreign body hazards are most important to manage in cocoa and chocolate manufacture, requiring the establishment of reliable and robust good manufacturing practices (GMPs) and implementing HACCP at all stages of the supply chain.

The risk of encountering foods in the coffee/tea/cocoa – chocolate categories contaminated with pathogens or other contaminants at an unacceptable level is highly unlikely, provided that manufacturers follow GMP have robust and validated food safety management systems well embedded in their operations.

Glossary

Atactic This term is related to the tacticity of a polymer, which concerns the relative stereochemistry of contiguous chiral repeating units on a macromolecule. In vinyl polymers (as is the case of polystyrene (PS)), tacticity refers to the order in which substituent groups (aromatic ring in the case of PS) are located on one of the two sides of the macromolecular backbone. In the case of an atactic polymer, the substituents are placed randomly on the two sides of the macromolecule. Actually, mostly atactic PS is used although also syndiotactic PS is commercially available.

Bisphenol A The common name for 2,2-(4,4′-dihydroxydiphenyl)propane, 4,4′-isopropylidenediphenol, or 2,2′-bis(4-hydroxyphenyl)propane.

Esterification A chemical reaction that involves an oxygen-containing acid group of a reactant and a hydroxyl group (OH) of another reactant to form a product containing an ester group.

Nanoclay Layered magnesium aluminum silicate platelets.

Shelf life A period of time after which a packaged food, under defined environmental conditions, is no more acceptable in terms of organoleptic properties, nutritional value, and safety.

Standard temperature and pressure Standard temperature and pressure conditions, i.e., a temperature equal to 0 °C and pressure equal to 1 atm.

Aim of Packaging and Required Features

Food packaging serves the following important functions: (1) containing the food, (2) protecting the food against the action of external biological, physical, and chemical factors in order to preserve the food quality, prolong the shelf life of food and insure its safety by slowing down the microbial spoilage, (3) providing convenience for the consumer, and (4) acting as a communicating interface between the producer and consumer.

Selection of a proper packaging material is based on these required functions and also should take into account the cost, weight, transport, esthetic, and processing issues.

Primary packaging, i.e., the one that forms a sales unit for the user or final consumer (e.g., a bottle of water, can of soft drink, and packet of pasta) and directly contains food was mainly focused by the authors.

Packaging Materials and Structures

Relevant Functional and Structural Properties

To protect and preserve the contents, the food packaging material should guarantee adequate barrier to gases, vapors, and aromas, and adequate mechanical, thermal, and electromagnetic properties, depending on the properties of the food and required shelf life.

Barrier Properties

Depending on the material, low molecular weight (m.w.) compounds may or may not solubilize and diffuse through it. Although metallic and glassy materials are virtually impervious to low m.w. compounds, polymeric and cellulosic materials display finite permeability to gases and vapors, spanning a wide range of values. Packaging material should provide adequate 'barrier' to gases, vapors, and aromas, as determined by the preservation purposes. In particular, mass transport of oxygen, carbon dioxide, nitrogen, water vapor, and aromas is of paramount importance. The optimal barrier depends on the type of food and on the desired shelf life. Barrier to external oxygen from the environment to avoid or limit degradative oxidation of fats, barrier to internal carbon dioxide for carbonated beverages, and a proper ratio of the permeability of several gases to keep a desired 'modified atmosphere' in the package headspace are some relevant examples.

The main parameter describing barrier properties of a material is related to permeation. The higher the permeation of a low m.w. compound within a material, the lower is the barrier. It is important to notice that this property is referred to as the steady state condition. Measurements are performed by imposing a different partial pressure of the permeant on the two sides of the film or the sheet to be characterized, or between the external environment and internal part of a container. Either the pure permeant or the permeant present in a

 doi:10.1016/B978-0-12-378612-8.00297-3

mixture can be used. Different permeabilities are possibly measured in these two cases: As an example, pure oxygen permeation through a film is generally different (at equal partial pressure) from the case of oxygen permeation in the presence of water vapor.

There are several terms and units to describe permeation, which are as follows:

1. Permeation rate: Is referred to the overall package. It is defined as the permeated quantity per unit time. An example of adopted units is cm^3 (standard temperature and pressure (STP)) day^{-1}.
2. Transmission rate (TR): is defined as

$$TR = \frac{\text{Permeated quantity}}{\text{Area} \times \text{Time}}$$

Unit of TR is mol $(m^2\ s)^{-1}$ or, more commonly in the case of gases, cm^3 (STP) $(m^2\ day)^{-1}$. In this latter case, the term Gas TR is adopted.

3. Permeance (P), defined as:

$$P = \frac{TR}{\Delta p}$$

i.e., TR divided by the difference in the partial pressure (Δp) between the two sides of the film. Examples of units for P are mol $(m^2\ s\ Pa)^{-1}$ and g $(m^2\ s\ Pa)^{-1}$.

4. Permeability ($\overline{P}$) is different from the three previous properties, that can be defined for both heterogeneous and homogeneous films, in that permeability can be defined only for homogeneous films as:

$$\overline{P} = \frac{TR}{(\Delta P/l)}$$

i.e., TR divided by the 'driving force' for permeation (i.e., $\Delta p/l$, where l is the film thickness) between the two sides of the film. Examples of units for $\overline{P}$ are $(cm^3$ (STP) cm) $(cm^2\ s\ cm\ Hg)^{-1}$ or (g cm) $(cm^2\ s\ cm\ Hg)^{-1}$.

Mechanical Properties

Mechanical properties of packaging materials are of importance during packaging manufacture, during the operative life of packaging itself, in the production stages of packaged food, as well as during the distribution stages. Briefly, the most important mechanical properties of the packaging material are mentioned.

1. *Coefficient of friction (COF)*: It is related to the resistance to sliding between the two surfaces of two materials. It is of great importance to evaluate the machinability of a material in processes like printing or lamination. This property can be modified by the addition (mainly in polymeric packaging materials) of proper additives. Both static and dynamic COF are defined and expressed in terms of a ratio of forces.
2. *Mechanical moduli and strength*: A single material property cannot encompass the full complexity of mechanical behavior of a material. Some properties which are technologically relevant in the present context are:
   - Brittleness: It measures the attitude of a material to break under a load without a significant deformation, failing with little or no sign of plastic deformation.
   - Burst strength: It is related to the pressure that is required to bring about the bursting of the package.
   - Ductility: It measures the attitude of a material to deform plastically under a load before breakage.
   - Impact resistance: It is related to the resistance of a packaging material to impact and is measured as the energy (generally expressed in Joule, J) absorbed by a standardized specimen for breaking under a standardized impact.
   - Tear strength: It measures the tearing resistance of a (cellulosic or polymeric) packaging material as measured by the force (generally expressed in N) and absorbed energy (generally expressed in J) needed for the initiation and propagation of a tearing.
   - Tensile modulus: It describes the resistance of a material to deform uniaxially under a tensile load (typical units are MPa or GPa, where Pa stands for Pascal).
   - Tensile strength: It is the maximum tensile strength that a material can sustain before ultimate breakage (typical units are MPa or GPa).
   - Toughness: It is a measure of the energy a material is able to absorb by deforming under a load (typical units are those of energy per unit volume, i.e., MPa or GPa).
   - Creep/relaxation: These are properties related to the viscoelastic nature of a material. In fact, creep is a measure of time-dependent deformation occurring under a stress constant with time, whereas relaxation is a measure of stress reduction with time in the material submitted to a deformation constant with time.

Thermal Properties

The relevant thermal properties of materials for food packaging applications are those related to energy transport and thermal transitions.

1. *Thermal conductivity (k)*: It is defined as the amount of energy transferred in the form of heat per unit time, unit thickness, and unit temperature difference between the two sides of a slab of material of thickness l. Common units are kcal per (m h °C) or W per (m °C). This property is relevant in the processing stages of packaged food (e.g., sterilization) or packaging process of food (e.g., sealing). Thermal conductivity, among packaging materials, is the highest in metals (e.g., approximately 240 W per (m °C) for aluminum), the lowest for cellulosic and foamed polymeric materials (e.g., approximately 0.050 for expanded linear low density polyethylene (LDPE)), and intermediate for inorganic materials (e.g., approximately 1 for common inorganic glasses).
2. *Specific heat at constant pressure (C_p)*: It is defined as the amount of energy in the form of heat to be transferred per unit mass of material to increase its temperature by 1 °C. Common units are kcal $(kg\ °C)^{-1}$ or kJ $(kg\ °C)^{-1}$. This property is relevant in evaluating the degree of protection that the packaging provides against heat. Specific heat, among packaging materials, is the highest in cellulosic and polymeric materials (e.g., approximately 2.3 kJ $(kg\ °C)^{-1}$ for LDPE) and the lowest for metals and inorganic

materials (e.g., approximately 0.9 for aluminum and 0.84 for common inorganic glasses).
3. *Thermal expansion*: Linear (α) and volumetric (β) expansion coefficients are defined, respectively, as the relative change in length or volume per unit temperature change at a fixed pressure. Common units are $^{\circ}C^{-1}$. This property is relevant in evaluating possible breakages of package due to temperature changes. Thermal expansion is the highest in polymeric materials (e.g., approximately 110 $^{\circ}C^{-1}$ for polypropylene (PP)), intermediate for metals (e.g., approximately 25 $^{\circ}C^{-1}$ for aluminum), and the lowest for inorganic materials (e.g., approximately 6 $^{\circ}C^{-1}$ for common inorganic glasses).
4. *Transition temperatures*: The most important transition temperatures are the glass transition temperature (T_G) and melting temperature (T_M). T_G marks a substantial change in the mobility of amorphous regions of a material: below T_G the amorphous regions become much more brittle and rigid. The T_M corresponds to the phase change of the solid crystalline regions of a material into a liquid state. These transition temperatures are extremely important because they are related to the tolerable thermal range for the use of packaging materials, which define the lowest allowable temperature (at which the maximum allowable fragility occurs) and highest allowable temperature (at which unacceptable distortion or chemical modification occur). The highest temperatures among packaging materials are accessible with metals or inorganic glass materials (up to 600 $^{\circ}C$) and the lowest temperature are accessible with some polymeric materials (down to approximately -100 $^{\circ}C$ with fluoropolymers and high density polyethylene (HDPE)).

Electromagnetic Properties

Properties describing the interaction of the packaging materials with electromagnetic radiation are of great importance for protection against the action of light, for the interaction with microwaves, and for esthetic issues of a package.

1. *Refractive index*: It is related to the angles of incidence and refraction at the interfaces of the material surfaces for a radiation passing through the material itself.
2. *Transparency*: It measures the specular transmittance of a radiation through the material.
3. *Transmittance spectrum in ultraviolet (UV), Vis, and IR*: This property quantifies the transparency of the material at specific wavelengths. This is of particular relevance, for example, in quantifying the degree of protection provided by the packaging material against the photooxidation of lipids activated by UV radiation.
4. *Haze*: It measures the degree of opacity of the packaging material.
5. *Gloss*: It measures the shiny appearance of the surface of a packaging material.
6. *Effect of ionizing radiations*: Some radiations like β, γ, and X-radiation, can promote an alteration in some packaging materials. In particular, chain scission, oxidation, and cross-linking can occur in polymeric materials as a consequence of γ-radiation, which is frequently used for sterilizing the material surface to be placed in contact with food.
7. *Interaction with microwaves*: Depending on its structure, a material can interact with microwaves or be transparent to them. Polymeric materials and inorganic glasses are transparent, whereas metals are absorbing/reflective. This interaction behavior is relevant in the application of microwavable packaged food.

Chemical Structure and Morphology of Polymeric, Metallic, Ceramic, and Cellulosic Packaging Materials

Polymeric Materials

Polymers have been used increasingly in the last decades as packaging materials for numerous packaging applications. In fact, these materials can be processed in several forms like films, sheets, trays, bottles, and other types of containers. Polymer molecules, also referred to as macromolecules, have a very high m.w., up to the order of several million daltons. They are obtained by arranging together small repeating units.

Polymers can be classified into two main categories: thermoplastics and thermosets.

Thermoplastics, the most widely used type of polymers in food packaging, are made of independent macromolecules that could be linear or branched at different degrees. The chemical properties of thermoplastics are determined by the functional chemical groups present along the macromolecular chain. Properties of polymers can be finely tuned by changing the types of monomers used to build the polymer (the authors refer to a homopolymer or a copolymer, if, respectively, a single type of monomer or several types of monomers are used) or by blending different polymers. Depending on the chemical structure, the polymers can have a totally amorphous morphology or can be semicrystalline (it is not possible to have a totally crystalline thermoplastic polymer). The T_G involves only the amorphous phase of the material and T_M (higher than T_G) only involves crystalline domains. Properties of thermoplastics can also be tailored by the processing conditions. In fact, polymers can be stretched uni- or biaxially at a temperature between T_G and T_M, thus orienting both the amorphous and crystalline domains in preferential directions and thereby improving the mechanical and barrier properties.

Thermosets consist of a cross-linked network where polymer chains are all linked by chemical bonds. As opposed to thermoplastics, thermosets cannot be reprocessed and are more resistant to chemicals.

In general, polymers for packaging applications always contain additives, such as fillers, antioxidants, plasticizers, and other additives to improve the processing and mechanical properties, and resistance to environmental factors during service life.

The most widely used polymers in food packaging applications are mentioned as follows:

1. *Polyethylene (PE)*: There are actually thousands of types of PEs available commercially. These are rubbery (i.e., T_G is lower than room temperature) semicrystalline polymers. There are three main categories: LDPE, which, due to the branched structure of macromolecules, displays a limited crystallinity and, in turn, a lower density; HDPE, characterized by a more linear structure with few short side-chain branches displaying a higher crystallinity; linear LDPE (LLDPE), characterized by many and very short

side-chain branches. They are used as a heat-sealing layer and barrier to water vapor in the forms, among others, of blow-molded bottles, films, and containers.

2. *PP*: It is a rubbery semicrystalline polymer widely used in the form of nonoriented and oriented films and containers. It has good mechanical properties and high moisture barrier.
3. *PS*: It is the atactic PS used in food packaging applications, which is glassy (i.e., T_G is higher than room temperature) and totally amorphous with a low barrier to gases and water vapor. It is also used in its foamed form, known as Expanded PS, mainly for thermal and mechanical protection purposes, and blended with polybutadiene and grafted polybutadiene–polystyrene copolymer in the form of high impact PS displaying improved impact properties. Barrier properties to gases and moisture are quite low.
4. *Polyvinyl chloride (PVC)*: It is an amorphous glassy and rigid polymer used to produce films and containers. Barrier properties are moderate and it has a limited use due to environmental concerns related to the presence of organochlorine pollutants. Plasticized PVC, obtained by adding plasticizers (phthalates and adipates), is used to produce stretchable film (the so-called 'cling film'), but certain safety issues have been raised related to the migration of plasticizers into the food.
5. *PE terephthalate (PET)*: It is a glassy semicrystalline polymer with a moderate barrier to gases and water vapor. It is used to make films, trays, and bottles.
6. *Polyvinylidene chloride (PVdC)*: Also known as Saran™, it is a copolymer of vinylidene chloride (approximately 90%) and vinyl chloride monomers. It is used to make films and containers. Owing to its very high barrier to gases and water vapor, it is frequently used in the coating of more permeable films (e.g., PP) or as a barrier layer in multilayer packaging structures (films or thermoformable sheets).
7. *Ethylene vinyl alcohol (EVOH)*: It is a semicrystalline copolymer of vinyl alcohol and ethylene monomers (27–48%). It has an exceptional barrier to oxygen that tremendously decreases in the presence of moisture. The barrier to water vapor is low. It is mainly used as an oxygen barrier layer in multilayer laminated or coextruded films and containers.
8. *Ionomers*: They are copolymers made of ethylene and methacrylic acid (up to 15%) monomers. Methacrylic acid groups are partially or totally neutralized by zinc or sodium ions. Surlyn® is the trade name of a widely used class of ionomers. Their use in food packaging applications is related to the very good sealing properties and low melting temperature, which helps with temperature-sensitive foods.
9. *Ethylene vinyl acetate (EVA)*: It is a copolymer of ethylene and vinyl acetate monomers that is mainly used in hot melt formulations, as a sealing layer, and for bags t o package frozen foods.
10. *Polyamides (PAs)*: It is a class of generally semicrystalline polymers encompassing a wide range of glass transition temperatures. They derive their name by the presence of a chain of amide groups formed by the reaction of amine and carboxylic acid moieties of the starting monomers. Nylon 6 and Nylon 6,6 are important examples of PAs. They are used to produce films with high barrier properties.

Table 1 Physical properties of some polymeric materials widely used for food packaging applications

Polymer	*Density (kg m^{-3})*	*Mechanical property (qualitative)*	*Resistance to grease and oil*	*Transparency*	*Temperature range of use (°C)*
LDPE	910–925	Tough and flexible	Good	Poor/fair	−50 to 80
LLDPE	910–940	Tough and extensible	Good	Poor/fair	−30 to 100
HDPE	945–967	Tough and flexible	Good	Poor	−40 to 120
PP	900–915	Moderately stiff and strong	Good	Fair	−40 to 120
PS					
General	1040–1089	Stiff, strong, and brittle	Fair/good	Very good	−20 to 90
HiPS	1030–1100	Tough and strong	Fair/good	Poor	−20 to 90
PVC					
Plasticized	1350–1450	Soft and extensible	Good	Good	−2 to 80
Unplasticized	1160–1350	Stiff and strong	Good	Good	−2 to 80
PET	1380–1410	Stiff and strong	Good	Very good	−60 to 200
PVdC	1600–1700	Stiff and strong	Good	Good	−20 to 130
EVOH	1140–1410	Stiff and strong	Very good	Good	−20 to 150
Ionomers	940–960	Tough and extensible	Good	Very good	−40 to 65
EVA	920–940	Tough and extensible	Good	Very good	−75 to 65
Nylon	1130–1160	Strong and tough	Good	Fair/good	−2 to 120

Tables 1 and 2 present some important physical properties of polymers used in food packaging.

Inorganic, Nonmetallic Materials

This class of materials, referred to as ceramic materials, has been used for centuries to make food containers. Currently, glasses are in widespread use and are produced from molten inorganic nonmetallic materials. By proper cooling procedures, a noncrystalline solid is obtained. The main component of glasses is silicon oxide, but several other compounds are present, for example, oxides of alkaline earth elements (i.e., calcium, sodium, and magnesium) are added to guarantee a low temperature of melting and to lower the viscosity of the melt. Metal-based compounds are added as coloring ingredients.

Glasses are mainly used to make bottles and containers. These are fragile materials prone to brittle fracture, often initiated by the presence of surface scratches and flaws. For this reason, to strengthen the containers, surface coating is deposited on the surface and chemical or thermal toughening treatments are adopted. These materials are virtually impermeable to gases and vapors and can be used at elevated temperatures, of up to approximately 500 °C.

Glasses are quite inert to most of the substances with the exception of hydrofluoric acid, heated phosphoric acid, and hot alkalies. In acidic medium, a limited leaching of positive ions can occur. Glasses are instead prone to alkaline attack. In hot pressurized distilled water (121 °C), both ion leaching and alkaline attack can occur.

Metallic Materials

The metallic materials mainly used in food packaging applications are aluminum and steel, often coated with tin, chromium oxides, and varnishes. These metals are used to form cans (three- and two-piece cans), collapsible tubes, aerosol containers, and trays.

Aluminum: It is used not only in different forms like cans and foils, but also as a coating (typical thickness of the order of 0.01 μm) to manufacture metallized polymer films with improved barrier to light and low m.w. substances, as compared to the neat plastic substrate. Pure aluminum displays a rather high tensile modulus (approximately 70 GPa), high thermal conductivity, and a relatively low density ($2.71\ g\ cm^{-3}$). It is used in packaging applications either as pure aluminum or in the form of alloys containing manganese, magnesium, iron, silicon, copper, and chrome.

Steel: A steel is an alloy of iron and carbon. In food packaging applications, steel is prevalently used with up to 1% of carbon. Manganese, phosphorus, copper, silicon, and sulfur are also present as alloying elements. Density of steel ($7.85\ g\ cm^{-3}$) is much higher than that of aluminum as well as its tensile modulus (approximately 210 GPa). Because chemical inertness of steel toward foods can be a concern, steel is often coated with inorganic or organic coatings, in food packaging applications. A classic example of coated steel used for canned foods is 'tinplate' that consists of carbon steel coated with a layer of tin. Owing to the cost of tin, steel coated with metallic chromium and chromium oxide has been introduced.

Cellulosic Materials

Cellulosic packaging is based on raw materials containing cellulose fibers and includes corrugated boards and boxes, bags, folding cartons, and cans.

Paper and paperboard: Paper is produced starting from cellulose pulp which is obtained from the raw materials by mechanical/chemical processes. Apart from cellulose fibers, several noncellulosic additives are used in the process of paper

making ranging from fillers and coloring compounds to sizing and plasticizing additives, and many others. The suspension of cellulose fibers and additives is submitted to draining, pressing, and drying, gradually reducing its moisture content to obtain sheets of different densities (increasing the density yields paper, then cards, and finally boards). The amount of moisture determines the final mechanical and barrier properties.

The final properties of paper products to be used in food packaging applications are determined by coating, impregnating, laminating, and finishing steps. Paper is frequently used in multilayer structures with other materials, including aluminum foil and LDPE.

Cellulosic packaging takes the form of flexible films, bags, corrugated board boxes, wrappings, composite cans, and laminated cartons for liquids. They are used, among others, for the packaging of bakery products, biscuits, powders, snacks, fruit juices, milk, and wine. Finally, it is worth mentioning that the oldest commercial transparent flexible film, known under the trade name of cellophane, was produced starting from pure cellulose, originally commercialized by DuPont. The advantages of cellophane include its transparency and gloss, as well as its outstanding barrier properties to gases and, if properly coated (e.g., metallized or coated with PVdC), also to moisture. Owing to its higher cost, starting from the 1970s, it has been replaced in many applications by oriented PP, although its properties, including also stiffness, clarity, and processability, still make cellophane attractive for selected packaging applications (e.g., candies, chocolate, cheese, and snacks).

Biodegradable Packaging Materials

Biodegradation is the chemical process by which organic materials are broken down by enzymes produced by living organisms. Biodegradation of a certain material strongly depends on the conditions in which it is measured (kind of bacteria, temperature, humidity, oxygen concentration, etc.). A polymer could be biodegradable in some conditions (i.e., composting), but not in other conditions (i.e., terrain or marine environment). To reduce the possible ambiguity, some norms that define various characteristics a material must possess in order to be claimed biodegradable have been developed (e.g., EN 13432, ASTM D6400-04, D7081-05, D6868-03, D5511, and D5526).

At the moment, available biodegradable plastics are not able to replace the conventional petroleum-based plastics, both for their costs and limited performance (i.e., low mechanical and barrier properties). However, it is possible to overcome the low performance and process problems by combining several biodegradable materials with different functional characteristics by using lamination in order to make multilayer structures with improved properties. Also by adding to these polymers nanofillers, biodegradable nanocomposites with improved barrier and mechanical properties can be obtained.

The aforementioned cellulosic packaging materials are biodegradable, unless nonbiodegradable coating are used to improve some properties or unless they are laminated with nonbiodegradable materials.

Starch polymers have been in the forefront of the biobased plastics in the plastics market over the last 20 years. Starch is composed of a mixture of two polymers, a linear polysaccharide called amylose and highly branched polysaccharide called amylopectin. Native starch is however too brittle and hydrophilic. To overcome these disadvantages, native starch is chemically, thermally, and/or mechanically processed. Typically, the majority of starch plastics are produced via chemical modification and extrusion/blending of native starch and its derivatives. It is also blended with synthetic aliphatic polyesters to improve the water resistance and processability. The final properties of starch plastics are such that they can be considered potential substitutes for some polyolefins, namely LDPE, HDPE, and PP. European producers have well-established products in the market.

Polylactic acid (PLA) is a thermoplastic, glassy, semicrystalline aliphatic polyester produced via polymerization of a cyclic lactide ester (L,L-lactide). This compound is obtained by the esterification and cyclization of lactic acid, that, in turn, is produced via bacterial fermentation of sugars. The T_G of PLA is approximately 62 °C and the T_M is approximately 175 °C. Many properties of the PLA films are similar to synthetic thermoplastic polymers, i.e., high gloss and transparency, mechanical strength, heat sealability; in addition, PLA is not hygroscopic and has good barrier properties. In fact, PLA can replace PET and PS in several packaging applications in the form of films, sheets, cups, trays, bottles, and containers.

Finally, a class of linear biodegradable rubbery thermoplastic polyesters with good properties for food packaging applications, is that of polyhydroxyalcanoates, obtained via bacterial fermentation of sugars. In particular, polyhydroxybutyrate–valerate copolymer displays properties close to those of PP. The use of this class of polymers in food packaging is still limited due to its performance, processability, and cost as compared to traditional thermoplastics.

Auxiliary Materials

Auxiliary materials are those materials providing additional features to packaging materials or those materials used in the process of manufacturing packaging structures. Examples of the former are lacquers providing improved barrier properties, inks used for printing and labeling, coating used to protect food and package surface in metallic packaging, whereas examples of the latter are adhesives used for laminating polymer films to manufacture multilayer structures.

Regarding the adhesives, after the wetting of the substrates, the adhesive curing takes place by either physical or chemical processes. Examples for the physical curing are the heat-seal coatings and direct labeling adhesives as well as natural latex-based cold seal adhesives. An important example of chemically curing adhesives are solvent-based and solventless polyurethane laminating adhesives. Water-based and UV/electron beam curing systems have also been developed in the last two decades.

Inks for printing on plastic substrates can be divided into four major classes: letterpress and lithographic inks, commonly called paste inks; flexographic and rotogravure inks, which are referred to as solvent inks. Over printing, varnishes

are used in order to cover printing inks with a protective layer and/or to provide functional properties to the packaging such as machinability, gloss or matt appearance, release or sealing properties, scratch resistance, etc. Varnishes called primers are also used to improve the adhesion of inks on some substrates, typically metallized layers.

Several materials are used as coatings for plastic films and containers, with a thickness ranging from few tens of nanometers to a few micrometers, mainly to provide barrier to gases, moisture, and aromas. Examples are micrometric coatings made with polymer nanocomposites and with PVdC (Saran™), nanometric coatings made of SiO_x, AlO_x, and amorphous carbon, nanolayer coatings realized by combustion chemical vapor deposition.

Several types of coatings are used for metal containers to protect the food from direct contact with metal and includes oleoresinous lacquers (enamels), vinyl lacquers (vinyl chloride–vinyl acetate copolymer), phenolic lacquers, epoxy and epoxy-acrylate coatings, and alkyd resins. These materials display different levels of flexibility, adhesion, and retortability. It is worth mentioning that Bisphenol A (BPA), an intermediate in the production of epoxy resins used as an internal coating for a can, has become a major public health issue (see: Bureau of Chemical Safety, Food Directorate, Health Products and Food Branch, Canada. Survey of BPA in Canned Food Products from Canadian Markets (2010)). In fact, BPA can migrate (see Section Migration) from the coating into foods, this phenomenon being particularly relevant for hot-fill or heat-processed canned foods.

Scavenger/absorber materials are frequently used to remove undesired substances from the headspace or to limit the permeation of such substances through the package, by means of physical/chemical mechanisms. Relevant examples are oxygen scavengers, moisture, carbon dioxide, and ethylene absorbers.

Food Packaging Interactions

A packaging material in contact with food can interact with it by releasing undesired substances (migration) to the food and undesired removal of substances from the food (scalping). The amount of migration and scalping should be kept within prescribed limits. Interaction between packaging and food induced on purpose for preservation aiming to prolong the shelf life are discussed in Section Active Packaging.

Migration

Migration can be defined as a food–package interaction in which chemical compounds move from the package into the food. In fact, polymeric packaging materials contain functional additives, residuals from the manufacturing process, and neoforming or decomposition products formed during the processing or aging of plastic materials that can all possibly migrate into the food. The European Union (EU) Regulations EU 1935/2004 and 10/2011 regulate materials and articles intended to come in contact with food and establish the monomers, starting substances, and additives that are authorized in their manufacture as well as the restrictions which they are subjected to, such as overall and specific migration limits (SMLs, see Section International Regulation).

Scalping

Flavor scalping has been reported to be an important factor contributing to alterations of organoleptic quality of packaged food. In particular, it determines the loss of quality related to the absorption of aroma compounds from a food product to the packaging material and may result in a significant alteration of the aromatic profile of the food product. Polymers, in fact, are able to dissolve low m.w. substances present in food and beverages. This phenomenon can be limited to regions at the surface of the materials or may involve mass transport via diffusion through the thickness of the material. Scalping may reduce or alter the flavor of a packed food to such an important and undesirable extent that it should be minimized and possibly avoided.

International Regulation

Important concepts to be defined are those of overall and specific migrations, which are given as follows:

- Overall migration (OM) defines the maximum quantity of substances (nonvolatile) that a packaging structure can release to the foods or food simulants. Substantially this value indicates, in a nonspecific manner, the quantity of substance that migrates into the foods, independently from the kind or nature of the substances.
- Specific migration (SM) defines the maximum quantity of a specific migrable substance that can be released into the foods or food simulants and it must not exceed the fixed specific limitation.

Regulation EU/10/2011 establishes that the OM value is reported in mg dm^{-2} and in particular that "Plastic materials and articles shall not transfer their constituents to food simulants in quantities exceeding 10 mg of total constituents released per dm^2 of food-contact surface (mg/dm^2)." The assumptions are: (1) an intake of 1 kg of food in contact with a particular packaging material per 60-kg person per day and (2) 1 kg of food is exposed to 6 dm^2 surface area of packaging material. As a consequence, the overall level of migration mentioned by the regulation is equivalent to 60 mg kg^{-1} of food mass.

In the USA, the Food and Drug Administration (FDA) regulation assumes that the total daily intake of food and drink is 3 kg per person. An important difference between EU and USA regulation is that in the USA, a consumption factor (CF) and food-type distribution factor (f_T) are used by the FDA to estimate a probable exposure. CF describes the fraction of the daily diet expected to contact specific packaging materials and represents the ratio of the weight of all food contacting a specific packaging material to the weight of all food packaged. CF values for both packaging categories (e.g., metal, glass, polymer, and paper) and specific food-contact polymers

Table 3 Values of consumption factor (CF) for several packaging materials

	Package category	*CF*	*Package category*	*CF*
A. General	Glass	0.1	Adhesives	0.14
	Metal – polymer coated	0.17	Retort pouch	0.0004
	Metal – uncoated	0.03	Microwave susceptor	0.001
	Paper – polymer coated	0.2	All polymers[a]	0.8
	Paper – uncoated and clay-coated	0.1	Polymer	0.4
B. Polymer	Polyolefins	0.35[b]	PVC	0.1
	LDPE	0.12	Rigid/semirigid	0.05
	LLDPE	0.06	Plasticized	0.05

College Park, MD: U.S. Department of Health and Human Services - FDA Center for Food Safety and Applied Nutrition. Available at: www.fda.gov/OHRMS/DOCKETS/98fr/001360gd.pdf (accessed on 29 January 2013).

are summarized in Table 3. These values, however, may be modified as new information is received.

The other factor used by the FDA is f_T. Before migration levels can be combined with CF values to derive estimates of probable exposure, the nature of the food that will likely contact the food-contact article containing the food contact substances (FCSs) must be known. To take into account the nature of food contacting each food-contact article, FDA provides f_T for each packaging material to reflect the fraction of all food contacting each material that is aqueous, acidic, alcoholic, and fatty. f_T values for both packaging categories and polymer types are reported in Table 4.

Another important concept adopted by FDA is the threshold of regulation (TOR) in which the attention is focused on the exposure value, that is the amount related to the daily intake. The idea is that if the dietary concentration of FCS, even if no toxicological data are available, does not exceed 0.5 ppb, it does not require any formal regulation. Substances that are demonstrated to be carcinogens and substances that, based on their chemical structure, are suspected to be carcinogens, are excluded from clearance under the TOR process.

Owing to the complexity of food samples, the legislation allows for the migration tests to be carried out using food simulants instead of real samples with the aim of simplifying the analysis. When the aim is to evaluate the amount of OM, the most classical approach is a gravimetric test. After evaporation of the simulant, the dry residue or sample material after the contact is weighted to determine by difference the amount of solid substances migrated.

Regarding the SML, the Regulation EU/10/2011 establishes the SM value in its Annex I, reported in mg per kg. For substances for which no SML are provided, a generic value of 60 mg kg^{-1} shall apply. The evaluation of the SML is usually performed by means of analytical methods. Generally these substances are present in extremely low amounts, measurable at the ppm level in the best case and very often at the ppt level. Food simulants are liquid or solid substances able to emulate the extraction capacity and solubility of the foodstuff. They are generally volatile substances which can be easily removed after contact with the tested material. In Tables 5 and 6 a schematization of food simulants used in the USA and EU is reported.

A further alternative to assess migration from packaging into food is represented by the use of mathematical and semiempirical models, that allow to circumvent possible analytical difficulties and expensive, time-consuming analyses. This approach provides a mean to determine migration levels using limited or no migration data. In fact, these mass transport models are based on the estimation of diffusion coefficients accounting for nature of the migrant and physical properties of the packaging material. The prevailing legislation allows the use of the results of mathematical modeling if it is proven, on the basis of scientific evidence, that migration levels calculated in this way are equal to or higher than those achieved under real storage conditions, i.e., the tests represent a 'worst case' scenario. In fact, migration estimation is accepted in the USA and EU legislation (EU Commission Directive, 2002/72/EC), and valid models based on scientific evidence can be applied to test for compliance with the existing regulations. These models are considered a useful substitute for, or in addition to, experimental data, under limited circumstances. Nevertheless, when the mathematical predictions indicate noncompliance with the legislation, the migration values must be confirmed by laboratory testing.

Table 4 Values of food type distribution factor (f_T) for several packaging materials and types of food

	Package category	*Food-type distribution (f_T)*			
		Aqueous[a]	*Acidic*[a]	*Alcoholic*	*Fatty*
A. General	Glass	0.08	0.36	0.47	0.09
	Metal – polymer coated	0.16	0.35	0.40	0.09
	Metal – uncoated	0.54	0.25	0.01[b]	0.20
	Paper – polymer coated	0.55	0.04	0.01[b]	0.40
	Paper – Uncoated and clay-coated	0.57	0.01[b]	0.01[b]	0.41
	Polymer	0.49	0.16	0.01[b]	0.34
B. Polymer	Polyolefins	0.67	0.01[b]	0.01[b]	0.31
	Polystyrene	0.67	0.01[b]	0.01[b]	0.31
	Impact polystyrene	0.85	0.01[b]	0.04	0.10
	Nonimpact polystyrene	0.51	0.01	0.01	0.47
	Acrylics, phenolics, etc.	0.17	0.40	0.31	0.12
	PVC	0.01[b]	0.23	0.27	0.49
	Polyacrylonitrile, ionomers, and PVdC	0.01[b]	0.01[b]	0.01[b]	0.97
	Polycarbonates	0.97	0.01[b]	0.01[b]	0.01[b]
	Polyesters	0.01[b]	0.97	0.01[b]	0.01[b]
	Polyamides (nylons)	0.10	0.10	0.05	0.75
	EVA	0.30	0.28	0.28	0.14
	Wax	0.47	0.01[b]	0.01[b]	0.51
	Cellophane	0.05	0.01[b]	0.01[b]	0.93

[a]For 10% ethanol as the food simulant for aqueous and acidic foods, the food-type distribution factors should be summed.
[b]1% or less.

An important concept in relationship with migration issues, is that of functional barrier. Functional barriers are parts of food-contact materials used in multilayer structure to prevent migration of undesirable substances from layers beyond the barrier. For example, as stated in the Regulation 10/2011, in recent years, plastic food-contact materials do not only consist of one plastic but also combine up to 15 different plastic layers to attain optimum functionality and protection of the food, while reducing packaging waste. In such a plastic multilayer material or article, layers may be separated from the food by a functional barrier. Behind a functional barrier, nonauthorized substances may be used, provided they fulfill certain criteria and their migration remains below a given detection limit. Taking into account foods for infants and other particularly susceptible persons, as well as the large analytical tolerance of the migration analysis, a maximum level of 0.01 mg kg^{-1} in food should be established for the migration of a nonauthorized substance through a functional barrier. However, even when a functional barrier is used, mutagenic, carcinogenic, or toxic to reproduction substances

are not allowed for use in food-contact materials or articles without previous authorization. The same caution should be used when dealing with a functional barrier coupled with materials based on nanoscale engineering, as is the case of nanoparticles. Assessment of the risk should be performed on a case-by-case basis.

An example of allowed use of functional barrier is that of recycled plastics. In fact, recycled plastics may be contaminated by various chemicals and a functional barrier is interposed between the recycled plastic and food to prevent such contaminants from reaching the food.

Finally, some relevant food-contact material issues are specifically addressed in the following:

- *Vinyl chloride monomer*: Polymeric materials and articles which are intended to come into contact with foodstuffs can transfer vinyl chloride monomer to these articles in quantities liable to endanger human health. Directive 78/142/EEC specifies that such materials and articles must not contain vinyl chloride monomer in a quantity exceeding 1 mg kg^{-1} of finished product and must not pass on to foodstuffs more than 0.01 mg kg^{-1} of vinyl chloride monomer.
- *Styrene monomer*: Migration of residual styrene monomer to food from polystyrene in contact with it is another important issue. Food-contact applications of polystyrene include containers for diary products and fruit juice, meat trays, biscuit trays, egg cartons, take-away food and drink cups, and boxes. Undesirable flavor and taint to food are caused by styrene migration. Health concerns derive from reported toxic effect of styrene monomer on the liver and by the fact that it can disrupt normal hormone function; moreover, it also acts as a depressant of the central nervous system, causing neurological impairment and is also considered a possible carcinogen. Nevertheless, it is generally found in such low levels in packaged food that risks for consumers are considered low and styrene monomer migration is mainly considered as an organoleptic/quality problem. In fact, there are no SMLs for styrene in foods. Its content is controlled only by the OM limit of 60 mg kg^{-1}. Content of fat and ethanol in food, temperature, and contact time raise the migrated amount.
- *Phthalates*: Plasticizers are routinely added to polymers to make them more pliable and elastic. Among them, phthalates (also known as phthalic acid diesters) are particularly relevant in relation to migration issues. The five phthalates most commonly used in industry are di-(2-ethylhexyl) phthalate, dibutyl phthalate, di-isononyl phthalate, di-isodecyl phthalate, and benzyl butyl phthalate. Since the early 1980s there have been concerns about the effect of phthalates on human health and there has been particular concern over migration from food packaging to foodstuff. In fact, phthalates can be present in some food packaging materials, including printing inks used on flexible packaging, adhesives used for both paper, board and plastics, regenerated cellulose film (cellophane), aluminum foil–paper laminate, and closure seals in bottles. It should be further noted that many PVC 'cling film' food wraps are no longer made with phthalates, but are now manufactured using other plasticizers. The European Community legislation limits the use of phthalates in food plastics, and, where use is permitted, it limits the migration of these chemicals into foods by setting SMLs.
- *BPA, bisphenol A diglycidyl ether (BADGE), bisphenol F diglycidyl ether (BFDGE), and novolac glycidyl ether (NOGE)*: Endocrine-disrupting compounds like BPA, BADGE, BFDGE, and NOGE, are used in coated materials, plastics, and adhesives as is the case of epoxy-based enamels/lacquers for metal cans. Regulation EC 1895/2005 regulates the epoxy resin derivatives BADGE, BFDGE, and NOGE. In this regulation, BADGE and its hydrolysis product's migration is limited to 9 mg kg^{-1} of food and that of BADGE chlorohydrins to 1 mg kg^{-1} of food. BFDGE and NOGE have been completely banned from food-contact materials.
- *Ink contaminants*: Recently, migration of printing ink and varnish ingredients into foodstuffs has become a focus of interest. This was especially caused by the detection of isopropylthioxanthone (ITX) in baby milk, milk products, and cloudy juices packaged in beverage cartons in 2005. Also the latest findings of 4-methylbenzophenone and benzophenone migrating from printed carton packages into cereals highlight that contamination of foodstuffs through printing inks is still a problem. All these packages were printed with UV inks which contain monomers and oligomers, pigments, additives, and photoinitiators such as ITX. UV printing inks and varnishes have a broad range of applications in food packaging and are used in all kinds of materials like paper and carton board, plastics, and multilayered materials.
- *Mineral oil saturated hydrocarbons and mineral oil aromatic hydrocarbons*: Consumers are exposed to a range of mineral oil hydrocarbons (MOHs) via food, with potential health concerns. In particular, mineral oil saturated hydrocarbons (MOSHs) consist of linear and branched alkanes, and alkyl-substituted cycloalkanes, whereas mineral oil aromatic hydrocarbons (MOAHs) include mainly alkyl-substituted polyaromatic hydrocarbons. MOHs are complex mixtures and little is known of their composition in commercial products. In food-grade MOH, the MOAH content is minimized and is in the typical range of 15–35%. MOHs are present in several food-contact materials, including food packaging materials made from recycled paper and board, and printing inks applied to paper and board. Moreover, MOHs are used as additives in the manufacture of plastics and adhesives used in food packaging, wax paper, and board. Extensive migration of MOSH and MOAH can occur from recycled paper and board packaging in the absence of a proper internal barrier. MOSH may accumulate and cause microgranulomas in several tissues and foodborne MOAH may be mutagenic and carcinogenic.
- *3-Monochloropropane-1,2-diol (3-MCPD)*: The manufacturing process of paperboard food packaging can produce small quantities of 3-chloro-1,2-propanediol (3-MCPD) when wet-strength resins containing epichlorohydrin are used. 3-MCPD is from the same family as 1,3-dichloro-2-propanol, which is known to cause cancer in animals.

- *Diisopropylnaphthalenes (DIPNs)*: DIPNs can migrate from recycled paper and paperboard. In fact they are used for ink-jet printers and as solvents in the preparation of specialty papers. As not all DIPNs are removed during the recycling process, some may be present in the finished board and, under certain circumstances, can migrate into food via direct contact or gas phase transport.
- *Tin and Chromium*: Tin is used for coating steel in tinplate. Tin layer is generally covered by a protective organic layer. Tin migration is only an issue where internal protective coatings are not used. Chromium is used at very low levels as a passivation coating for tinplate and at higher levels for electrolytic chromium coated steel. The process ensures that the only species present are Cr0 and CrIII and not CrVI, which is the toxicologically important species. Chromium in food is not generally regulated (there is a World Health Organization (WHO), limit of 0.025 $m l^{-1}$ for drinking water). The level of migration from uncoated tinplate cans (the only metal foodstuff packaging where migration is likely to occur) is negligible and not considered to be of concern. Future change in environmental legislation is encouraging work on alternative passivation systems.

Special Applications and Perspectives

Packaging structures have evolved in the last two decades, introducing innovative concepts and technologies, which has greatly enhanced the shelf life of packaged food. These new applications rely also on the development of new materials.

Intelligent Packaging

Intelligent packaging is a system able to monitor and give indication on the freshness of the food. Definitions stated in Regulation 1935/2004/EC and in Regulation 450/2009/EC consider intelligent materials and articles as: "materials and articles which monitor the condition of packaged food or environment surrounding the food." In particular, intelligent packaging systems provide functions such as detecting, sensing, recording, tracing, and communicating in order to extend the shelf life of packaged food and enhance its safety. Smart package devices are generally labels or tags that are attached onto primary or secondary packaging and are basically of two types: the first type includes data carriers (such as barcode labels and radio frequency identification (RFID) tags) that are used to store and transmit data. The second type includes package indicators (such as time–temperature indicators, gas indicators, and biosensors) that are used to monitor the external environment and, whenever appropriate, issue warnings.

Active Packaging

Active packaging has been defined as a system in which the product, package, and environment interact in a positive way to extend the shelf life or achieve some characteristics that cannot be obtained otherwise. Definitions stated in Regulation 1935/2004/EC and Regulation 450/2009/EC consider active materials and articles as: "materials and articles that are intended to extend the shelf life or to maintain or improve the condition of packaged food." Active systems usually are obtained by embedding active compounds into the packaging materials that are released into or absorb substances from the packaged food or the environment surrounding the food in order to inhibit or delay food degradation. The relevant example of scavengers has been already mentioned (see Section Auxiliary materials). The European Union Regulation 1935/2004 offered for the first time the opportunity for active packaging to be used in Europe providing general provisions on the safety of active and intelligent packaging and setting the framework for the European Food Safety Agency evaluation process.

Modified Atmosphere Packaging (MAP)

Modification of the internal packaging atmosphere is often used to prolong the shelf life of food. It consists in the modification of the absolute pressure (hypobaric and hyperbaric packaging) and/or of the partial pressure of gases present in the package headspace. In particular, in MAP a proper composition of the internal gas mixture, selected on the basis of the preservation requirements of the specific food, is initially substituted to air. Oxygen, carbon dioxide, nitrogen, and argon are the most used gases for this purpose. The headspace mixture composition evolves with time due to outward and inward permeation of gas molecules and of gas production/consumption exerted by the food. In selecting adequate packaging materials for this application, such as plastic packaging, the ratios of permeability of the gases present in the modified atmosphere should be considered to limit excessive modification of the starting composition of the modified atmosphere.

Nanotechnology in Food Packaging Applications

As in many other branches of science and engineering, nanotechnology is also providing an important impulse for the development of new applications in the field of food packaging, with particular reference to barrier packaging, antimicrobial, and antimycotic packaging, improvement of biobased and biodegradable packaging, active and smart packaging. Important examples include (1) polymer nanocomposites obtained by adding a few percent, by weight, of nanofillers (e.g., nanoclays and silica nanoparticles) to polymers to improve barrier and mechanical properties; (2) biopolymer with nanoadditives for controlling and accelerating compostability and biodegradability; (3) polymers including titanium oxide nanoparticles to improve barrier to UV rays; (4) polymers with zinc oxide and silver nanoparticles to control antimicrobial growth in foodstuffs, and (5) active packaging systems based on nanocapsules designed to release chlorine as an antimicrobial agent.

Processing of Packaging and Packaging Lines

Structure and Manufacturing Procedures of Primary Packaging

Primary packaging can be flexible or rigid/semirigid. The choice depends on the type of food, on preservation and

protection requirements, ease of use, and marketing advantages. A brief overview is reported in the Sections Containers and Flexible Packaging that follow for the different types of primary packaging and their manufacturing procedures.

Containers

Glass bottles and containers are manufactured by blow and blow and press and blow processes, followed by thermal or chemical strengthening treatments and surface coating. Plastic bottles and containers are instead produced by extrusion blow molding and by injection blow molding. Also in this case, coatings may be applied, mainly to improve barrier properties. Frequently, containers can be made with a multilayer structure obtained by the coextrusion of different polymeric materials or lamination of different types of material (aluminum foil, plastic films, and cellulosic layers) followed by folding. Each layer in a multilayer structure is intended for a specific aim (e.g., sealing, barrier to light, gases, and moisture, and mechanical strength). Polymeric containers can also be obtained by thermoforming sheets of plastics. Metallic materials can be shaped in the form of cans, trays, aerosol containers, and collapsible tubes. Cans are produced by rolling of metal sheets, by drawing and wall-ironing and drawing and redrawing. The last two methods are also used for trays. Inner surface of trays and cans, to be put in contact with food, are coated with thermoset lacquers to protect the metal surface and food. Collapsible tubes are produced by impact extrusion.

Flexible Packaging

Polymer films are produced by cast extrusion and blown film extrusion. A tenter frame can be used to orient biaxially cast films. Polymer films can have a multilayer structure obtained by the coextrusion of different polymeric materials, by adhesive lamination of several plastic films, or by extrusion lamination. Typical adhesives used in laminating processes are waterborne, solvent based, hot melt, or reactive 100% solids (solventless). Improvement of barrier properties of plastic films can be obtained by lacquering the surface or depositing a very thin layer of aluminum (metallization) or of silicon or aluminum oxide. To convey information to consumers and for marketing purposes, packaging films are subject to printing processes such as offset, flexography, rotogravure, and digital printing. These films are purchased as reels and then used to prepare bags and pouches, at the site of production of the food product. For example, confectionary machines perform the forming, filling, and sealing of the container. Basically, all the confectionery machines can be grouped into two categories: form-fill-seal and separate packaging machines.

Pasteurization and Sterilization in Food Packaging Applications

Heat pasteurization and sterilization are typically used in food packaging applications. Pasteurization is a treatment that reduces the number of pathogenic microorganisms of the food by heating it at a specific temperature (usually less than 100 °C) for a specific time (from seconds to a few minutes). Heat sterilization is a process of heating the food to a temperature over 100 °C for such time until all microorganisms in the food are killed.

High-pressure pasteurization (HPP) and sterilization are steadily gaining as a food preservation method that also preserves natural sensory and nutritional attributes of food with minimal quality loss. Packaged foods, processed by using this technique, maintain most of their original texture and nutritional qualities, additionally exhibiting an extended shelf life. HPP applies high pressure (i.e., 300–800 MPa) to packaged foodstuffs at a temperature significantly lower than the corresponding heat pasteurization and sterilization temperatures.

Selection of the proper packaging system is crucial for the pasteurization and sterilization treatments performed at atmospheric as well as at high pressures. In fact, packaging must be appropriate for the product to be treated and compatible with the specific method of treatment to be used, i.e., steam, ethylene oxide, ozone, irradiation, and extremely high hydrostatic pressure. Maintenance of sterility of the contents until the package is opened, withstanding physical conditions of the specific process without losing mechanical integrity and resistance to tears and punctures are the main requirements.

For these reasons, multilayer packaging structures with high temperature-resistant materials and good sealing properties are used. In addition, reactive systems with high thermal stability after curing are applied as laminating adhesives for thermal treatments.

SAFETY OF FOOD AND BEVERAGES

Safety of Food in Vending Machines

M Saltmarsh, Inglehurst Foods Ltd., Alton, UK

Glossary

Ambient temperature foods Foods that are stable at room temperature.

Food safety management plan Also referred to as the HACCP plan – a plan written to show how a company plans to manage and control food safety hazards within its business.

HACCP A system that identifies, evaluates, and controls hazards that are significant for food safety. The acronym stands for hazard analysis, critical control points.

Vending operator The person who cleans and fills a vending machine.

Work instructions Written instructions for vending operators to ensure they carry out their tasks in a manner designed to protect food safety.

Introduction

Vending machines can dispense a very wide range of foodstuffs and drinks including items that are fresh, frozen, long shelf life, or chilled. These include ice cream, plated meals, sandwiches, fresh fruit, baked goods, confectionery, snacks, and hot and cold drinks. In general, products are vended for immediate consumption but some products require heating before consumption. In these cases the vended product is put through a heating process either in the machine or close by. There are no vending machines currently in use in which products are stored at temperatures above ambient for reasons of food safety.

The Vending Market

In most countries with a significant vending presence, North America, USA, Japan, and Australia, the market is dominated by can, bottle, and snack machines whereas in Europe more than 70% of the vending machines serve hot drinks made from powders.

A small proportion of vending machines are owned by individual institutions and cleaned and restocked by them. Some others are operated by catering companies, but the great majority are cleaned, maintained, and filled by an operating company of which there are 10 000 in Europe alone. While a few of these companies are multinational organizations employing thousands of people, most are small- and medium-size enterprises (SMEs) or family businesses operating between a few hundred and a few thousand machines. Vending machines are sited in workplace, leisure, educational, and public sites; in Europe 80% of all machines are sited in the workplace.

Assessing Food Safety Risks in Vending

Hazard analysis, critical control points (HACCP) is a management tool that gives a structured approach to identification and control of hazards. It requires the journey that any foodstuff follows from farm to fork to be divided into steps, the hazards present at each step to be identified and appropriate measures to be put in place to ensure that the food remains safe at all times.

All vending products follow the same general pathway from supplier to consumer. The vending company purchases foodstuffs that are delivered to a warehouse, distributed to locations where machines are sited and used to stock the machines. Drinks machines are received from manufacturers, connected to a source of potable water and filled with ingredients. Companies would break this pathway down into a series of steps and assess the food safety risks at each step in order to derive their HACCP-based food safety management plan. This same technique will be used in this chapter to provide an overall understanding of the safety of food in vending.

Types of Vended Food

From a food safety point of view, food and drink sold from vending machines falls into three categories; food that can be stored at ambient temperature, drinks made from powders or syrups, and food that must be kept chilled or frozen for food safety reasons.

Most of the food and drink sold from vending machines is stable at ambient temperature and humidity. This includes confectionery (chocolate, cereal, and fruit bars), bagged snacks (nuts, crisps, baked, and extruded snacks), and drinks in cans, bottles, and cartons (long-shelf-life milk drinks, fruit drinks,

carbonated drinks, and water). It also includes the powders for hot drinks and the syrups used for postmix still and carbonated drinks vended by machines.

Some foods, however, need to be stored at lower temperatures in order to inhibit microbiological growth. Foods such as sandwiches and salads must be chilled throughout their shelf life in order to be safe.

Other foods are stored frozen and either vended frozen for eating cold, for example, ice cream, or vended to be heated before eating, like ready meals. A further group of machines heat the frozen products within the machine before vending.

The Steps in the Vending Business

All vending businesses have the same basic process for all foodstuffs, whether ambient, chilled, or frozen, which comprises the following steps:

- Purchase of products from manufacturers or wholesalers.
- Transport of the products to the vending company.
- Storage by the vending company.
- Transport by the vending company to the machine.
- Filling and cleaning of the vending machine.
- Storage within the machine and dispensing of the product.

None of these steps provides a means whereby unsafe food can be treated to make it safe, so the safety of food in vending depends on safe food being purchased by the company and that food being kept safe throughout its shelf life.

Each of the steps in the process will be considered separately.

Purchase of Products from Manufacturers

The first step in the process is the purchase of products. The production of foodstuffs should always be carried out under a food safety management plan that minimizes the risks of contamination by bacteria or physical or chemical hazards. Large food companies have quality assurance departments that can audit suppliers and provide confidence that all necessary actions have been taken to minimize risks. Vending companies, with few exceptions, do not have such teams within their organizations and, in consequence, must rely on other means to assure the safety of the products.

If they are buying from one of the major brands then they can rely on the manufacturer having extensive quality assurance procedures in place to maintain the reputation of the brand. However, if they are buying a product with a less well-known brand then they would have to depend on other indicators, for example, whether the supplier had been audited by a large company. It is not sufficient to rely on the supplier having ISO 9001. This is not a measure of the quality or safety of the foodstuffs, but of the paperwork trail within the company. It would be possible to rely on ISO 22000 or the British Retail Consortium (BRC) global standard but unfortunately it is precisely the smaller manufacturing companies who are less likely to have these standards. Less bureaucratic standards for smaller companies, such as Safe and Local Supplier Approval (SALSA) in the UK, have been developed recently but uptake has been slow.

The situation is exacerbated when purchasing chilled foods such as sandwiches and plated salads. Companies who make these products are often small companies who provide products within the local area. They may be audited by the local authority but rarely by a commercial organization with skills in auditing food manufacturing processes. Unfortunately it is the chilled foods that carry most risk of contamination with pathogens such as *Listeria monocytogenes* and, in general, the purchase of novel or local food items requires considerable diligence by the vending operator to ensure that the manufacturer understands their process well enough to guarantee the safety of the food.

Transport to the Company

Products may either be delivered by the supplier or collected by the vending operator company. Many vending companies collect some smaller batches and have larger volumes delivered by the supplier or wholesaler. The only risks to product safety during this step, for foods that are stable at ambient temperature, are those caused by physical or chemical contamination in the vehicle. These may include broken glass or shards of metal or chemicals such as disinfectant or oil from damaged bottles picked up from the vehicle. This is an unlikely event, but it has occurred, and it would be good practice for those checking in the delivery to give a quick look around the inside of the vehicle before unloading. Companies have greater control over their own vehicles and it is important that vending companies have working practices and training in place to ensure that all vehicles operated by them are clean and tidy and pose no threat to food safety.

Chilled or frozen food must be kept chilled throughout its shelf life. It is important that the delivery vehicle has a refrigeration system that is able to keep the food at the appropriate temperature in all weather conditions. The company's food safety management plan would require the temperature to be monitored and there are several ways in which this can be done depending on the technology on the vehicle. Many modern vehicles have systems that allow continuous monitoring of temperature and technology now allows this information to be continuously transmitted to both the supplier and customer in real time. Older vehicles may only have a thermometer and here, as a minimum, the temperature should be recorded on arrival. Because the vehicle thermometer will measure air temperature, the vending operator should also measure the temperature between two packs of product to ensure that the product is within national standards. Further reassurance would be provided by occasional use of a data logger to show the temperature experience of the product throughout the journey.

Storage

Once the product has been received and passed into the vending company warehouse, care has to be taken that the foodstuffs are not contaminated. Vending companies, being

small companies, tend to have limited space within their premises that are often an industrial unit on a trading estate. Within these premises they will store machines, machine parts and foodstuffs, prepare machines for sale, and repair defective machines. Some companies divide the available space with partitions whereas others operate an open plan system. While it is possible to control the risks of physical and chemical contamination in an open plan arrangement it does need careful management. One of the problems with limited space is effective pest control. It is important that the normal practices of pest control, for example, storage off the floor and away from walls, are followed together with securing the services of a reputable pest control organization. Good pest control consists of more than just putting down bait boxes. It involves good hygiene management of the store and regular monitoring and review by the pest control contractor to ensure that the earliest signs of a possible infestation are recognized and acted on.

It is also important that the practices of good warehouse management are followed including good control of stock rotation. This not only ensures that the consumer has quality product but also assists in managing traceability.

The situation with chilled and frozen food requires yet more care. These foods must be kept at safe temperatures at all stages from manufacturer to consumer. Some vending companies receive chilled food into a temperature-controlled store whereas others contract with the supplier of the chilled food to distribute directly to the vending machines. This removes the need for the vending company to have temperature-controlled storage but takes the process out of their control. However, they still need to check that their contractor's procedures are sufficiently robust to ensure that the temperature of the food is properly controlled throughout its shelf life.

When the vending company stores the food themselves they have to manage the temperature carefully to ensure that it complies with national regulations so that there is no risk to food safety. Temperature control is not yet harmonized across the EU and each Member State has its own national regulations with, in some cases, different temperatures for different types of foodstuffs.

To some extent the situation with frozen food is simpler. The product has to be kept frozen, with the maximum temperature being specified by the manufacturer. Generally specific storage and delivery systems have to be established for frozen product in order to maintain product quality.

Transport to the Machine

Products are transported to machine sites by van. These vans will carry both food products and cleaning materials and it is essential that they are kept clean, tidy, and well organized so that there is no possibility of contamination of food products by cleaning materials. In major cities it is frequently impossible for vans to park close to sites and products have to be loaded onto trolleys for transport to the machine. It is important that staff are properly trained in loading and transporting so that fragile products are not damaged or contaminated during this phase of the journey.

Chilled or frozen product should be transported in insulated bags with cold packs to maintain the temperature at safe levels. The company procedure needs to be tested to ensure that product is still at a safe temperature before it is loaded into the vending machine.

Vending companies provide services to a wide range of clients, from large customers with many machines, to small customers with just one machine. The servicing of these sites depends both on the number of machines on a site and on the proximity of the site to a company depot. Sites with many machines will have operators on site all day, whereas smaller sites will be serviced by operators who have a route that may have a number of sites, each with one or more machines. Some of these operators will be based away from the depot and will receive deliveries of stock to their van. Working practices have to be written to ensure that however the stock is delivered, it is always safe from risk of contamination.

Filling and Cleaning

The frequency of cleaning and filling machines is determined to a large extent by the use of the machine. It is not uncommon for very busy machines to be replenished twice a day, but for infrequently used machines to be visited only weekly. The frequency of visiting chilled food machines will be dictated by the shelf life of the product, which is often 3 days.

The only risk to food safety during filling and cleaning a machine selling ambient temperature foods is that of contamination with the cleaning chemicals. This can be avoided by training and work instructions that ensure that chemicals are never near the foodstuffs.

However, there are two additional concerns with chilled food. The first is that the chilled food vending machines are designed only to maintain chilled food at a safe temperature, not to chill the food down from room temperature. The temperature of food does slowly decrease within a vending machine but too slowly to comply with any national temperature control regulations. So, chilled food must be chilled by the supplier before it is delivered to the machine. This creates a problem for some companies who would like to buy their sandwiches from a local shop. The shop must have chilling facilities that will chill the food sufficiently quickly to comply with national temperature control regulations and must devise a method of safely delivering the food to the vending machine without an unacceptable rise in temperature. It is also important that the machine is open for as short a time as possible so that the food inside does not warm up to an unsafe temperature. It is important that work instructions are developed and that staff are trained to ensure that this is the case.

Frozen food also has to be at the correct temperature before loading into the machine. This requires greater thought and planning to ensure that the temperature does not rise during transport through a warm building or while product is being loaded into the machine.

The great majority of chilled and frozen food vending machines display the temperature inside the machine but do not have facilities to provide records of temperature over time. As a check on the performance of the machine it is good

practice to record the displayed temperature when a machine is filled.

Hot drinks machines will need regular cleaning to control bacterial growth in the mixing bowls and dispense area. There are two common ways of cleaning the drink contact parts of the vending machine. Once the parts have been removed they are either cleaned in a bucket on site or bagged up and replaced by a clean set brought from the main site. It has been demonstrated that disinfectant is not needed for cleaning on site, brushing with detergent and hot water followed by rinsing is quite sufficient to keep bacterial populations below a safe level. Provided that the procedure is carried out carefully there is no difference in the effectiveness of these two methods. It is worth noting that there is only one report in the literature of a food poisoning incident being caused by inadequate cleaning of a hot drinks vending machine.

It is important that the person doing the cleaning does not themselves contaminate the machine and that they wash their hands appropriately. As a minimum this should be on arrival at the premises, after using the toilet and before putting on gloves, if these are worn. It is important to train staff to wash their hands correctly. It is also important to be aware that bacteria can be carried on gloves and transferred from place to place, so it would be good practice to change gloves frequently.

It is sometimes forgotten that the cloths and brushes used in cleaning the machine can be a source of contamination and the work instructions should identify the way of keeping them clean between machines.

Storage and Dispensing

Vending machines are placed in a very wide range of locations. Those in office environments are generally free from risk of pest infestation or chemical contamination but these issues should be considered when placing machines in industrial or public sites. For example, machines have been placed in stables, where they have been infested with flies, in print shops and in bus depots where the surfaces of the cups have become contaminated with solvents and diesel fumes. Sites like these should be avoided and machines should be placed in a clean, well lit area, out of direct sunlight and away from doors to the outside that could provide access for ants. In addition they should not be placed under stairways where dust and contaminants could be dropped from above and they should not be sited where they may attract pests such as cockroaches.

Snack or can vending machines are basically merely boxes in which the products are held. However, there are standards for their design and manufacture, which should be followed. In essence the machines should be designed and manufactured to be easy to clean with no dark areas in which pests could hide. The materials of construction should be robust and smooth and corners should be of sufficient radius to be cleaned easily. Food or water contact parts do not have to be made of stainless steel but should be made of materials such as polycarbonate that comply with national or international Regulations. The tubing in hot drinks vending machines is generally of silicone rubber and all parts of the water pathway should be approved for use with drinking water.

Hot drinks machines must be connected to a source of potable water in order to guarantee the safety of the water. Some growth of bacteria can be expected in water as it passes through the pipework in a building and through a vending machine or water dispenser but there is no evidence that this poses any threat to human health.

Machines must be connected through a check valve to ensure that water cannot, under any circumstances, pass back into the mains water system. In the case of machines dispensing carbonated drinks the valve should be a double check valve since carbonated water can dissolve copper. Machines can remain on site for many years and it would be good practice to change the double check valve after 10 years. Because both soft drinks and carbonated water are acidic, it is very important that the pipework in soft drinks dispensing or vending systems is made of a material that will not corrode with acid. Acute illnesses have occurred in the past from copper leaching from piping and tubing downstream of a check valve should be either plastic or stainless steel.

Chilled and frozen food vending machines are programmed so that they will not vend if the temperature inside rises above a preset limit. This makes it very important that such machines are sited out of direct sunlight which could heat the machine beyond the capacity of the chilling system to maintain a safe temperature. Because chilled food items have a short shelf life in the machine it is important that they are removed before their expiry date. Color-coded labels can be useful for highlighting on which day of the week product should be removed. Product removed from the machine must be taken from the site and disposed of correctly.

Traceability

It is good practice for the vending company to keep records of those from who they purchase foodstuffs and this is generally a legal requirement. In Europe, for example, it is part of Regulation 178/2002. It is not necessary to keep records of batch codes or lot numbers of deliveries as, in the unlikely event of a product recall, all product of the relevant brand can be removed from all machines. Once product is back at the company warehouse then it can be checked for date codes or lot numbers as necessary. This procedure will be much less time consuming and bureaucratic than keeping records of every delivery.

SAFETY OF FOOD AND BEVERAGES

Promotional Material

L Verzegnassi and F Chastellain, Nestec Ltd, Vevey, Switzerland

Glossary

Food contact material Materials and articles intended to come into contact with foodstuffs, including packaging materials, cutlery, dishes, processing machines, containers, etc.

Hazard A microbiological, chemical, or physical property of the promotional item with the potential to cause an adverse health effect.

Nonfood products Articles such as textiles, toys, tableware, electrical devices, etc.

Recall Operation carried out to ensure return of products from consumers to the shop, for example, for quality or safety nonconformities.

Risk evaluation A step in a risk-management process. Risk evaluation is an evaluation of the risk related to a concrete situation and a recognized threat (also called hazard).

Third party Someone other than the principals directly involved in a transaction or agreement.

Withdrawal Removing a product from the warehouses and shelves, for example, quality or safety nonconformities. The operation does not cover goods in the hands of consumers.

Introduction

Promotional items are used to publicize or advertise a product. They are considered as typical marketing tools which, together with public relations and communication activities, are a means to promote awareness and create greater visibility for a brand or a company. They can be printed with a company's name, a logo, or a slogan; they can be distributed at trade shows or conferences, or delivered to consumers packed in/on a food product. Common promotional items are toys, T-shirts, caps, key chains, posters, bumper stickers, pens, booklets, mouse pads, spoons, cups, or mugs.

Promotional items are often used by the food industry. Toys packed inside chocolate eggs or cereal packs, or given away with fast food meals can be cited as concrete examples of promotional items commonly added to the food product. Included into the scope of this article are promotional items foreseen to be in direct contact with food (e.g., cup), packed with food (e.g., toy), or in contact with the mouth or skin of the consumer (e.g., toy, cap, spoon). Cosmetics, as well as tickets for vacations, and samples of food products, are not included into the scope of this article.

Independently from their size or shape, all promotional items must fulfill the following basic requirements: they must be safe, i.e., they must not pose a threat to consumer's health or safety, and they must comply with applicable regulatory requirements.

Although such a statement might seem obvious, the reality appears to be significantly different: based on the number of products recalled by authorities worldwide in 2008–2009, compliance to the above requirements does not seem so straightforward, especially with promotional items targeting children. These can indeed be a source of hazards with serious health consequences varying from death (e.g., suffocation after ingestion of small parts) to potential long-term health effects (e.g., exposure to harmful chemicals as lead paint). Currently, deaths of children due to ingestion of small parts (the small part originated from toy products) are reported in several pediatric and forensic science journals. Given the above, a clear process aimed at ensuring the item's safety needs to be implemented before the product reaches the consumer. This process will guarantee protection of consumer's health and preserve the stability of the manufacturer's business, should the company be (or be perceived as being) incapable of ensuring compliance of its products.

This article will focus on the health and safety risks linked to the promotional items generally used by the food industry, and on the requirements that must be implemented in the product-development phase in order to industrialize a safe product. Examples of the regulatory requirements, international standards, and codes of practice that need to be followed in order to ensure compliance of the promotional material will also be described.

Lessons Learnt

Whenever products bearing a risk are brought to the attention of authorities, the official information is published by most of the governmental bodies on their websites. This publication

 doi:10.1016/B978-0-12-378612-8.00299-7

Table 1 Examples of product recalls carried out worldwide in 2009

Type of promotional item	*Health impact for consumer*	*Reason of recall/withdrawal*
Toy	Choking	Small pieces can break from a toy
Doll clothing	Chemical contamination	Surface paints on the pajama pants contain excessive levels of lead
Magnetic dart board	Death	Magnets found by young children can be swallowed or aspirated. If more than one magnet is swallowed, the magnets can attract each other and cause intestinal perforations or blockages, which can be fatal
Battery powered items	Fire and burn	The electric wires in the item or in the battery compartment can short circuit, posing a fire and burn hazard
Decorative candles	Fire and burn	Noncompliance with the European standard EN 15493
Children clothing	Strangulation	Presence of drawstrings in the hood area of the sweatshirt
Children clothing	Chemical contamination	Presence of azo-based dyes; noncompliance with REACH[a] regulation
Inflatable arm bands	Drowning	Holes for the arms which are too large for children; noncompliance with relevant European standard EN 13138
Inflatable swim-ring	Chemical contamination	Presence of phthalates; noncompliance with REACH[a] requirements for toys that can be placed in the mouth by children

[a]The Registration, Evaluation and Authorisation of Chemicals regulation of the European Union.

is easily available to consumers, other authorities, and the media. The number of product recalls notified has risen steeply during the last few years. Examples of promotional items that have been recently recalled by authorities or voluntarily withdrawn due to the high risk they represented for consumers are listed in Table 1.

In Europe, the rapid alert system for nonfood consumer products (RAPEX) establishes the circulation of information among the Commission and member states' authorities on measures taken in relation to products posing a serious health risk to consumers (with the exception of food, pharmaceutical, and medical devices). Every year, RAPEX issues an annual report entitled Keeping European Consumers Safe, on the operation of the rapid alert system for non-food consumer products, which is available on their internet site. The report lists in a very comprehensive manner, among others, the categories of products recalled or withdrawn during the year, together with, for example, information on their country of origin and the risks associated with them. The most frequently notified categories are toys, which represent a significant part of the promotional items used in food industry. Over half of high-risk items notified during the last years originated from China. The main risks linked with toys taken out of the market were choking, associated with presence of small parts. Toys are also taken off the market due to chemical risk, i.e., because of high levels of undesirable chemical substances. This was the reason in 2007 for a massive recall of products by a well-known toy manufacturer.

Similar alert systems also exist in other countries. In the US, for instance, the Consumer Product Safety Commission (CPSC) has the authority to pursue recalls for products that present a substantial product hazard. Companies becoming aware of hazards linked to their products are required by law to immediately inform the CPSC. CPSC works jointly with the company to recall hazardous item from the shelves. All recall notices are published on the CPSC website, publicly available.

Today, international toy manufacturers have also added to their own websites specific pages with data on their recalls, allowing consumers to get appropriate information directly from the source.

Ensuring Quality, Safety, and Compliance of Promotional Items

Promotional items might cause health or safety threats to consumers due to their design, the quality of the raw materials used, and the accuracy of the manufacturing process. These risks need to be duly assessed and corrective actions implemented before reaching the consumers.

The creation process of the promotional item that you recently received at an exhibition or that your child has just found on his cornflakes box can be summarized in three main phases: idea generation/exploration, product development, and product industrialization (Figure 1).

Phase 1: Idea Generation/Exploration

During the first phase (idea generation/exploration), the marketing department evaluates the need in terms of promotional items, explores new concepts, and defines the business strategy. Will it be stickers? Shall we switch to fancy magnets, or innovate with key holders? Will we develop one item per country of sales or shall one item fit all markets? In this phase, the key features of the selected products will be carefully defined, for example, the type of consumer to whom the promotional item is addressed, its intended use (including the potential misuse), the material composition, product shape, and expected shelf life (how many washing cycles will our tennis cap have to last?). Once the idea generation phase is completed and the product definition is clearly set, the development of the promotional item (phase 2) can start.

Phase 2: The Five Key Steps in Product Development

The product development phase, or phase 2, consists of five steps. The first four are carried out practically simultaneously

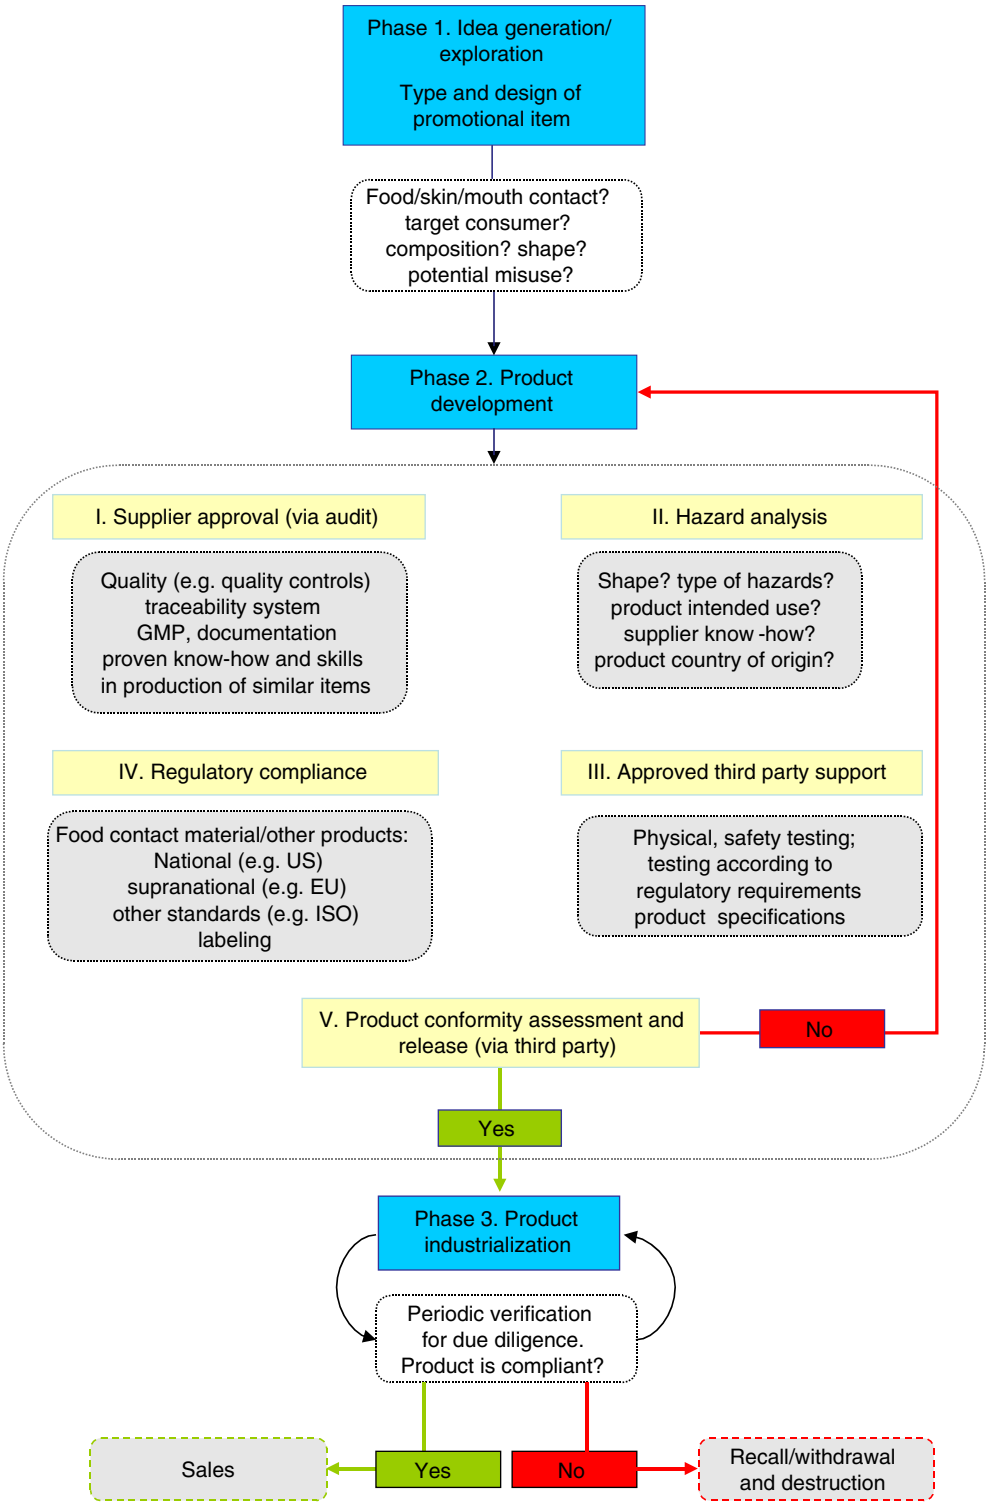

Figure 1 Key phases (in blue) ensuring safety of promotional items, from idea generation to product industrialization. The key phase for ensuring safety of promotional items is clearly the product development (phase 2).

(supplier approval, hazard analysis, third party support, and regulatory compliance). The fifth and last step, consists of the release of the promotional item prototype via a conformity assessment and is generally delegated to an independent third party. It is important to start the product development as early as possible, even before the finalization of the idea-generation phase. By doing so, the threats that can potentially damage the product or the consumer, and the parameters that need to be in place to ensure compliance (e.g., product composition is inappropriate to guarantee consumer safety) can still be

reconsidered and adapted (e.g., change the design or material composition in order to make the product safe).

The five key steps of the product-development phase are as follows:

Supplier Approval

The selection of the supplier is as important as the choice of the promotional item itself. The selected supplier is formally approved by the customer's quality, marketing, and procurement departments based on different criteria. From a quality standpoint, these include the implementation of appropriate quality standards (e.g., a quality control system and a traceability system), a proven know-how in the manufacturing of the product, of typical safety issues potentially linked to it and of applicable regulatory requirements. Customers should make sure that the following aspects are also covered: cleaning of premises and lines, pest control, hazard analysis, product inspection and release, raw material supplier approval, and employee training in quality standards.

Quality control system

A quality control system must be in place at the supplier. The system must be able to identify measures correcting failures in achieving good manufacturing practice (GMP). Quality controls should be documented throughout the production premises, for example, raw material should be controlled at reception to ensure it is in line with agreed requirements. The origins of the raw materials must be known, and their suppliers audited by the product manufacturer. If an audit is not possible (due to logistic or time constraints), appropriate certificates ensuring the quality and regulatory compliance of the raw material must be provided before industrialization (phase 3). A quality control plan should be in place for finished products, possibly in line with the international standard ISO 2859 (sampling procedures for inspection by attributes). The supplier should manage the customer complaints and analyze feedback received from customers in order to improve the parameters of his manufacturing process.

Documentation

Pre-established instructions and working procedures should be made available at the supplier, including product specifications, manufacturing formulae, and processing parameters. Generally, the product specification is a written document containing the detailed description of the product characteristics (size, composition, compliance to regulatory requirements). It is agreed with and signed by the supplier. The specification is also part of the contractual agreement with the client. Certificates of analyses carried out by approved external laboratories (which are relevant to compliance and safety of the promotional material) should also be available on site.

A traceability system

A traceability system, ensuring the supplier can quickly identify in which finished products a given raw material was used, or *vice versa*, should be in place. The system will also be able to localize where a given production of finished items was delivered or is stored. Documents proving traceability implementation need to be available at the production site. A solid traceability system is the best pillar on which recall procedures can be constructed.

Regulatory requirements

The approved suppliers shall be able to demonstrate the required understanding of regulatory compliance matters. This includes knowledge of all components used for manufacturing the promotional item and of the chemicals potentially migrating from it. Suppliers must be aware of the legislation applying to promotional items in their country, as well as to the countries where the product may potentially be sold; they can be asked to share such information with the customer and should be prepared to do so.

The implementation of all the above requirements must be verified through a quality audit, generally carried out by the customer himself or via an accredited third party. Third party groups in charge of such activities will need to be carefully selected and prove to have the appropriate competences. Compliance to regulatory requirements (and to other applicable standards) is also a mandatory point that needs to be carefully evaluated during the audit.

Hazard Analysis

Hazards linked to promotional items

The second key step that has to be carried out to ensure product safety during the development phase is a hazard analysis. A hazard analysis is not only key in ensuring consumer protection, but is also an indispensable tool to protect the manufacturer's business reputation. This could be easily at stake if the media or consumer organizations were to communicate on the injuries or deaths caused by the manufacturer's products.

Clearly, the shape, composition, origin, the intended use of the promotional item, as well as the target consumer, will play a major role in estimating the importance or significance of the hazards associated with the product. It is well known that the shape and structure of the promotional item can be a serious source of safety issues (e.g., choking and wounds), when the product carries strings, or is easily breakable, or bares sharp edges. Lack of GMP at the manufacturer may lead to production parameters out of control, and thus, for example, unexpected presence of toxic components in the final promotional items.

It is the duty of the manufacturer to guarantee safety and compliance of the products delivered. The manufacturer must carry out an assessment that takes into consideration, as a minimum, the health consequences listed in **Table 2**. The hazard analysis of a promotional item follows the same principles of the well-known hazard analysis and critical control point (HACCP) tool, used for ensuring food safety of edible products. In both cases, for food and nonfood products, where a hazard having a significant impact on the consumer's safety is identified, a decision is required as to which control measures to apply in order to reduce the risk to an acceptable level. A modification of the promotional item specification/production process/parameters may also be considered, if needed.

Hazard identification

The following questions can be raised in order to guide the reader in the identification of the hazards that could be linked to promotional materials:

- Composition of the promotional item to define potential contaminants migrating or leaching from the item: Is it

Table 2 Health consequences that need to be considered when developing a promotional item

Type of health consequence	*Origin*
Asthma, cancer, chronic kidney, and liver affection	Specific: Use of noncompliant chemical substances (e.g., lead paints, phthalates in toys) or use of restricted substances above regulatory norms
Intestinal obstruction	Specific: Ingestion of magnets which are easily detachable from the object
Flammability and fire, explosion, electrical shock	Specific: Use of noncompliant raw material/electric devices
Strangulation, entrapment, choking, asphyxiation, septal perforation	Specific: Small parts that can easily fall off/break from the promotional item; presence of strings
Wounds and cuts, laceration, puncture, amputation	Specific: Hazardous shapes of the promotional item
Hot (or cold) burns	Specific: Item not designed for bearing hot or cold temperatures (e.g., nontempered glass cups for hot tea)
Inner ear damage	Specific: Impulsive sound emitted by object (e.g., toy weapons)
Injury by impact of projectiles	Specific: Parts of the premium can act as projectiles

made of plastic (and which one), or of metal? Is the item coated, painted, made with recycled material? Will the item smell due to presence of residual toxic solvents?

- Design of the product to check potential safety threats: Is it made up of several parts? Can these break down easily during manipulation? Small parts that can break off are often responsible for choking issues. Does it contain strings? Strings can cause of accidental strangulation in small children. Are there sharp edges with the potential to cause wounds? Would it pose any other safety risk to the consumer (e.g., burns)?
- Existence of regulatory requirements or other standards for the above mentioned categories of materials or objects.
- Intended use of the promotional item: Is it intended to come in contact with food/mouth (e.g., spoon and glass), or to be packed in direct/indirect contact with food (e.g., toy in a bag-in-box package), or to be placed in contact with the mouth (pacifiers, toys, etc.)? Is it a toy or can it be misused as a toy by children or pets?

Likelihood of occurrence and health consequences

Once the hazards are identified, the risk assessor must consider the likelihood of occurrence of the hazard and the health consequence that this may have on the consumer.

For the evaluation of the likelihood of occurrence of the given hazard, the following elements can be considered:

- Supplier know-how, for example, adequacy of the risk evaluation in place, established know-how in the production of similar promotional items, knowledge of regulatory requirements applying to the product.
- Supplier quality assurance system, for example, existence of on-line quality controls, documentation, application of GMPs.
- Country of origin of the promotional materials, knowing that publications on monitoring and rating a country's political, economical, and financial risk are available, and are updated on a yearly basis.
- Review of the historical evidence of hazards occurring in the categories of products being considered.

The health consequences for consumers will depend essentially on the type of hazard (e.g., small parts breaking off) on the target consumer (i.e., an adult, a child, or a pet), and on the exposure of the consumer to the product (e.g., for direct skin contact or mouth contact). Particular care must be taken when the item is intended for a child, as safety standards will need to be very strict. Indeed children readily put in their mouths a range of different objects; thus, items that are sources of foreign bodies are considered to be high-risk products. Moreover, for pets, the specificity of the animal needs to be considered in the risk evaluation as, for example, the jaws of an adult dog will certainly have a different effect on an object than the jaws of a kitten.

As part of the hazard analysis carried out during the development phase, promotional items packed in/on food products must be considered as an 'ingredient' of the end product, and included in the HACCP study of the food product itself. Clearly, these items should not be in direct contact with food, and should be separated from it by a functional barrier, which prevents the promotional material from contaminating the food product. A functional barrier may be considered to be a barrier consisting of one or more layers. These reduce the migration of authorized monomers and plastics' additives below the specific migration limit (SML), or reduce the potential migration of nonauthorized substances into foods or food simulants to a 'not detectable' level.

Approved Third Party Support

Currently, the manufacturers are held liable for injuries resulting from poor design, from use of inappropriate materials, or from faulty production of articles. Duly selected third parties can help in safeguarding manufacturers (and thus their customers) by providing product safety testing and evaluation. The key element for a third party selection will be the recognition of relevant accreditation bodies, governments, and jurisdictional authorities in most of the countries where the articles manufactured will be launched or marketed.

Best-in-class third parties are able to provide support to product manufacturers on:

- Product design and mock-ups/prototype evaluation.
- Product specification development.
- Various physical testing (mechanical resistance, thermal resistance, life cycle).
- Safety testing.

- Examination and testing according to applicable regulatory requirements.
- Product conformity assessment.

Moreover, they can give very valuable support on a complete range of quality assurance services, including supplier assessments, and laboratory testing.

As a concrete example of support activities supplied by external partners, in the European Union (EU) manufacturers can currently choose between two modules of toy conformity assessment: a self verification or a third party verification. In the case of third party verification, the manufacturer will submit appropriate documentation on the toy to the notified body who will issue an EC type examination certificate. The manufacturer will then need to ensure conformity between his production and the approved model.

Regulatory Compliance

Regulatory requirements applying to promotional items developed for or by the food industry cover items intended;

- to come in contact with food (e.g., spoon and glass);
- to be packed in direct/indirect contact with food (e.g., toy in a bag-in-box package), and;
- to be placed in contact with the mouth (pacifiers, toys, etc.).

Therefore, both product safety regulations and food contact material regulations must be taken into consideration for compliance purposes. These standards are set both at national (e.g., US) and supranational level (e.g., EU). Their main purpose is to protect the consumers and ensure that only safe products are placed on the markets.

Today, regulations do not cover all existing food contact materials, nor all nonfood products. When neither supranational nor national regulations deal with a specific subject/item, the promotional item manufacturer needs to refer to other standards. These include internationally recognized standards, industry-wide standards, community technical specifications, or codes of practice to ensure safety of the material.

Regulatory requirements for promotional items

In terms of product safety, several governments have set a strong legal framework.

In the US, the Code of Federal Regulations (CFR) contains the codification of the general and permanent rules published in the US Federal Register by the executive departments and agencies of the Federal Government. Requirements for nonfood products such as, for example, toys are included in CFR Title 16.

In Europe, the reference document is the General Product Safety Directive (GPSD) 2001/95/EC. One of the objectives of the Directive is to protect consumer safety by setting standards for products that are not covered by sector-specific legislations (e.g., toys, chemicals, cosmetics, and machinery). The Directive provides a generic definition of a safe product: a product which, under normal or reasonably foreseeable conditions of use, does not present any risk or only the minimum risks compatible with the product's use, considered to be consistent with a high level of protection for the safety and health of persons. All products put on the market must comply with this definition.

When there are no specific national rules, the safety of a product is then assessed in accordance with international/supranational standards (see Other standards), and the expectations of consumers.

Regulatory requirements for food contact materials

The legislation on food contact materials has also as an objective the protection of the health of the consumer: the materials in contact with food need to be safe and will not transfer their components into the foodstuff in unacceptable quantities. Food contact materials and articles are regulated in US by the Code of Federal Regulations (CFR), Title 21. In EU they are regulated by the Framework Regulation 1935/2004, by the GMP Regulation (Regulation EC 2023/2006), by specific directives covering groups of materials, and by directives on individual substances used in the manufacture of materials and articles intended for food contact.

Tables 3 and 4 give a list of regulations that need to be applied to ensure product safety. The lists contain references to nonfood products (3) and to food contact materials (4), and are not exhaustive.

Other standards

When this is not dealt by regulatory requirements, several standards, resolutions, or guidelines exist, setting the requirements for manufacturing of safe food contact and nonfood products (e.g., Council of Europe Resolutions (CoE); International Standard Organization (ISO); American Society for Testing and Material Standard (ASTM); European Norms (EN)). Standards help to make sure that products are fit for their purpose, safe, and compatible. Although in principle voluntary and not binding *per se*, some Governments consider them as reference documents which set out criteria of manufactured products to ensure consumer safety, and transpose totally or partially such requirements into their national law.

Tables 5 and 6 list some of the standards that are relevant to promotional items.

Labeling

The labeling of nonfood products is considered by regulatory authorities as another key element to protect consumers.

Generally, the main purpose of a label is to inform consumers on, for example, the origin and composition of the item, the standards according to which it was produced, or its intended use. As an example for Europe, the EU Directive 1935/2004 requires that materials or articles intended to come into contact with foodstuffs, and which are not yet in contact with food when sold, are accompanied by the word 'for food contact' or a specific indication as to their use. This information, however, is not obligatory for articles that, because of their characteristics, are clearly intended to come into contact with food (e.g., a cup or a spoon). If necessary, specific instructions to be observed for safe and appropriate use should accompany the product. The name or trade name and, in either case, the address or registered office of the manufacturer or seller responsible for placing the item on the EU community market, as well as an adequate labeling

Table 3 Examples of regulatory requirements applying to promotional items

Name	*Topic*
EU	
General Product Safety Directive (GPSD) 2001/95/EC	Ensures a high level of product safety throughout the EU for consumer products that are not covered by specific sector legislation (e.g., toys, chemicals, cosmetics, machinery)
Directive on safety of toys 2009/48/EC	Ensures consumers that toys sold in the EU fulfill the highest safety requirements, especially those relating to the use of chemical substances
Decision on phthalates 2005/84/EC	Prohibits the use of certain categories of phthalates in the manufacture of toys and childcare articles intended for children
Decision on magnetic toys 2008/329/EC	Magnetic toys placed on the EU market must carry warning labels. This applies to all toys that contain or consist of loose or detachable magnets, or magnetic components of such size and shape that they can be swallowed by children
Decision on dimethylfumarate (DMF) 2009/251/EC	As of 1 May 2009, all consumer products containing DMF are banned (maximum limit: 0.1 mg DMF per kg of product or part of the product)
Council Directive concerning products which, appearing to be other than they are, endanger the health or safety of consumers 87/357/EEC	Prohibits the marketing, importing, and manufacture of products that look like foodstuffs but that are not in fact edible
REACH, Regulation (EC) 1907/2006	The aim of REACH is to improve the protection of human health and the environment through the better and earlier identification of the intrinsic properties of chemical substances. It concerns the Registration, Evaluation, Authorization, and restriction of Chemicals
Directive 2002/61/EC	Sets restrictions on marketing and use of certain dangerous substances and preparations (azo-dyes)
US	
Code of Federal Regulations, Commercial Practices, Title 16, Chapter II	The regulation covers activities of the Consumer Product Safety Commission (including safety standards and standards for flammability of children's sleepwear and other textiles)
Code of Federal Regulations, Commercial and Foreign Trade, Title 15, Chapter XI – Technology Administration, Department of Commerce, Part 1150 – Marking of Toy, Look-alike and Imitation Firearms	The regulation covers – among others – prohibitions and approved markings relating to toys
US Consumer Product Safety Commission Engineering Test Manual for Rattles	The title is self-explanatory
US Consumer Product Safety Commission Engineering Test Manual for Pacifiers	The title is self-explanatory
US Consumer Product Safety Commission Labeling Requirements for Art Materials Presenting Chronic Hazards (LHAMA)	Labeling hazardous art material is a mandatory rule of the consumer Product Safety Commission
US Child Safety Protection Act, Small Parts Hazard Warning Rule, and Rules for Reporting Choking Incidents	The title is self-explanatory
Age Determination Guidelines: Relating children's ages to toy characteristics and play behavior	The title is self-explanatory
Japan	
The Japan Toy Association Toy Safety Standard	The standard is divided in three parts: Part 1 – Mechanical and physical properties Part 2 – Flammability Part 3 – Chemical properties

or identification to ensure traceability of the material or article, must also be available on the product labeling. In most of the EU countries (and differing from, for example, the US), there is currently no obligation to add the origin of the article on the label of the promotional food-contact material item.

For other promotional items that are not in contact with food (e.g., textiles, pens, toys) several other labeling requirements exist, which cover, for example, the material identification information on the textile sold, age warnings on toys, information that the product meets applicable safety requirements, and sometimes the country of origin. More specifically to the labeling of toys, different legislation exists worldwide (e.g., Japan, Sri Lanka, Taiwan, China, Australia, Fiji, India, south Korea, Malaysia, New Zealand, South American countries, EU, US). The EU toy directive, for example, requires that the 'Conformité Européenne' (CE) marking be affixed visibly, legibly, and indelibly on the toy, to an affixed label or to the packaging before the toy is placed on the market. CE stands for 'European Conformity.' in French. By

Table 4 Nonexhaustive list of food contact material regulations, applying to promotional items in contact with food

Name	*Topic*
EU	
Framework regulation: Regulation on materials and articles intended to come into contact with food, Commission Regulation EC 1935/2004	Sets up general requirements for all food contact materials
Good manufacturing practices : Regulation on good manufacturing practices for materials and articles intended to come into contact with food, Commission Regulation EC 2023/2006	Sets good manufacturing practices that need to be in place at suppliers of materials and articles intended to come into contact with food
Plastics: Regulation on plastic materials and articles intended to come into contact with food, Commission Regulation EU 10/2011	List of authorized substances in plastic materials, multilayer multi-materials; compositional requirements; declaration of compliance; and rules for assessing compliance with migration limits
Active and intelligent materials and articles: Commission Regulation on active and intelligent materials and articles intended to come into contact with food. Commission Regulation EC 450/2009	Ensures safe use of such materials and introduces an authorization scheme for substances used for active and intelligent functions in food contact materials.
Ceramics: Council Directive on the approximation of the laws of the Member States relating to ceramic articles intended to come into contact with foodstuffs. Council Directive 84/500 EC and 2005/31/EC.	Sets migration limits for cadmium and lead which might be released from decoration and glazing. It gives an analytical method for the determination of the migration of these substances
Regenerated cellulose: Commission Directive relating to materials and articles made of regenerated cellulose film intended to come into contact with foodstuffs, Commission Directive 2007/42.	Sets standards for materials made of regenerated cellulose film and intended to come in contact with foodstuffs
Elastomers and rubbers: Commission Directive concerning the release of the *N*-nitrosamines and *N*-nitrosatable substances from rubber teats and soothers Commission Directive 93/11 EEC	Concerns the release of the *N*-nitrosamines and *N*-nitrostable substances from elastomer or rubber teats and soothers
Directives on individual substances or group of substances e.g. Council Directive 78/142 EEC	e.g., Vinyl chloride monomer
USA	
Code of Federal Regulations, Title 21 – Food and Drugs Chapter I – Food and Drug administration Department, Department of health and human services, subchapter B, part 174–178	Detailed requirements for food contact material are listed under the following chapters covering indirect food additives (i.e., additives for food contact materials) 174-General: covers general provisions that apply to indirect food additives (e.g., GMP) 175-Adhesives and components of coatings 176-Paper and paperboard components 177-Polymers 178-Adjuvants, Production aids, and Sanitizers (e.g., colorants for polymers)
Latin America (Mercosur, i.e., Uruguay, Paraguay, Brazil, Argentina)	
GMC RESOLUCION 3/92:	EU regulation is taken as a reference.
GMC RESOLUCION 31/99:	Presently, three general resolutions are in force, covering factory filling equipment in contact with food, a positive list of components allowed to be in contact with food, and analytical methods for verification of food contact materials
GMC RESOLUCION 32/99:	Regarding the plastics food contact materials, there are more than 20 other Mercosur resolutions available
Japan	
Japanese Food Sanitation Law	Chapters IV and V cover, respectively, food contact materials and toys: IV: Apparatus and container packages: general regulatory requirements are set by materials (e.g., metal, glass) V. Toys: test items (e.g., lead), elutions conditions, and regulatory requirements are set

affixing the CE marking to a product, the manufacturer declares that it meets EU safety, health, and environmental requirements, despite its country of origin, and takes sole responsibility for this. Toys that are CE marked can freely circulate in the European Economic Area. Moreover, defined warnings shall specify appropriate user limitations. Where promotional items might be dangerous for children under 36 months of age, for example, they shall bare a warning such as 'Not suitable for children under 36 months' or, 'Not suitable for children under 3 years' or a warning in the form of a graphic (see Annex V, Part B, 1 of the EU Directive 2009/48/EC).

When the labeling cannot be printed, stickered, or engraved on the product itself due to material or size constraints, its content is often added to the leaflet on which are printed the instructions for use.

Table 5 Examples of standards relating to safety of some promotional items

Name	*Topic*
American Society for Testing and Materials (ASTM) Standard Consumer Safety Specification for Toy Safety ASTM F 963	ASTM F963, which includes guidelines and test methods to prevent injuries from choking, sharp edges, and other potential hazards, is part of the Consumer Product Safety Improvement Act of 2008 (CPSIA) The law makes the ASTM F963 standard a mandatory requirement for toys whereas the Consumer Product Safety Commission (CPSC) studies the standard's effectiveness and issues final consumer guidelines for toy safety. ASTM F963 incorporates safety measures already required under federal law
European standard on safety requirements of toys EN 71	Compliance with the standard is legally required for all toys sold in the EU. The standard has been published in 11 parts, containing for example ● Mechanical and physical properties, flammability. ● Specification for migration of certain elements. ● Experimental sets for chemistry and related activities. ● Graphical symbols for age-warning labeling. ● Finger paints. ● Swings, slides, and similar activity toys for indoor and outdoor family domestic use. ● Organic chemical compounds – requirement, sample preparation, and methods of analysis.
International Standard Organization (ISO)	● Safety of toys: safety aspects related to mechanical and physical properties, 8124-1:2009. ● Safety of toys: flammability, 8124-2:2007. ● Safety of toys: migration of certain elements, 8124-3:1997.

Product Conformity Assessment and Release

The last step of the product-development phase, also called conformity assessment, allows checking that the product (at this stage still in the form of a prototype) is compliant to the quality, safety, and regulatory requirements initially set. Ideally, a third party audit needs to be planned for this. It is strongly recommended to list the key points that are verified by the auditors (e.g., compliance with the defined product specification, regulatory compliance, quality controls, hazard analysis, product design, material compliance, and certificates of analysis) on a template, which is signed off by all parties involved. Once signed, the document will prove that key parameters for product safety and compliance are covered. This signed document will be considered as the official 'release' form and the industrialization will finally start (phase 3).

Phase 3: Product Industrialization

As already mentioned, phase 3 – product industrialization – starts only when the conformity assessment of the product is carried out, the prototype is shown to be compliant with the set requirements, and the product is formally released.

During the industrialization phase, usually lasting from a couple of weeks to several months, samples of promotional items must be taken from the production lines and analyzed according to an agreed control plan (established according to, for example, ISO 2859). The plan includes verification of quality defaults as well as of the potential hazards that were found to be relevant for the product.

Once the items are in the marketplace, the manufacturer will carry out periodic verifications of their compliance for due diligence (often via a third party laboratory). This activity will assure that throughout the production period good manufacturing practices were in place, and were aligned with the defined quality and safety criteria.

Moreover, the manufacturer will monitor the possible consumer complaints. Complaints are a very effective means of measuring the quality and safety of the final promotional item, and the satisfactions of the consumer for the product.

The results of the above-mentioned activities will confirm that the work carried out during the development phase was effective, that the product is compliant both from a quality and regulatory perspective, and that the supplier is reliable. Should a problem occur, then a risk evaluation must be carried out to determine whether the promotional items will need to be withdrawn or recalled from the markets and destroyed. Records of the recall and of the destruction will need to be supplied to authorities, based on request.

Crisis Management and Recall procedures

Noncompliance with the established product safety regulations results in commercialization of unsafe products. The notifications described in Table 1 concern products failing to meet the required standards. Wherever this occurs, commercialization of an unsafe product engenders several corrective actions that can be ordered by authorities (such as withdrawal from markets, recall, or sales ban), or be initiated by manufacturers (withdrawal from the market and recalls).

To perform recalls or withdrawals, the manufacturers need to have in place appropriate procedures ensuring that defective products can be identified, located, and removed from all necessary points of the supply chain. Recall procedures are based on the existence of a traceability system at the manufacturer. These procedures are part of the company's crisis management system, together with a contact list for internal and external stakeholders which is periodically updated in the event of a recall. When products are recalled or withdrawn, the safety of other products manufactured under the same conditions (e.g., with the same raw materials or on the same line) needs to be evaluated and the need for public warning must be also taken into consideration.

Recall procedures need to be tested periodically in order to ensure that the system is working correctly, and records of the verifications need to be duly stored.

Conclusions

Promotional items, if not adequately designed or manufactured, can be a source of hazards for the consumers.

To ensure consumer protection and to avoid a very negative impact on the promoted brand, promotional items must imperatively be safe and comply with relevant regulatory requirements, or other applicable standards (e.g., EN, ASTM, or ISO standard). Product safety and compliance must be fully implemented in the product-development phase, via some key steps, for example:

- promotional item suppliers must be duly selected and approved based on their quality standards and on the knowledge they have on applicable regulatory requirements;
- a hazard analysis must be carried out during the development phase in order to define whether the promotional item can be a threat for the consumer and – if yes – the risk will have to be reduced to an acceptable level (see HACCP approach); and
- where support from third parties is deemed necessary, for example, for safety testing or product conformity assessment, the third party will be duly selected. The selection will be based on recognition of relevant accreditation bodies and governments, in the countries where the promotional items will be launched or manufactured.

A positive assessment of the promotional item conformity ends the product-development phase and is considered as the mandatory release step before the industrialization process. A periodic verification of the promotional item's compliance will be carried out by the supplier for due diligence during the production period.

SAFETY OF FOOD AND BEVERAGES

Risks of Food Adulteration

J Spink, Michigan State University, East Lansing, MI, USA

Glossary

Economically motivated adulteration (EMA) As defined by the 2009 Food and Drug Administration Open Meeting on EMA, "EMA includes dilution of products with increased quantities of an already-present substance to the extent that such dilution poses a known or possible health risk to consumers, as well as the addition or substitution of substances in order to mask dilution."

Food adulteration As defined by the Food, Drug and Cosmetic Act (FD&C), including if it causes harm, the consumer does not get the benefit of an ingredient (either the product does not include a valuable ingredient or the ingredient is substituted – if it was not valuable it would be considered misbranded, not adulterated), the product includes alcohol, it is filthy or putrid, or could be a banned product (e.g., a banned food additive).

Food defense The protection of the food supply chain from intentional acts that include the intent to harm in the forms of economic, public health, or terror. It includes acts of terrorism that are often referred as bioterrorism.

Food fraud An intentional act of food misbranding for economic gain.

Food misbranding FD&C defines a product to be misbranded if the label is false or misleading, does not include the name and address of the manufacturer, shows inaccurate weight or measure, required text is not included, the container is misleading in some way, a color additive is specifically mislabeled, and it violates the Poison Prevention Act.

Food protection An overarching concept in food protection: food quality, food safety, food fraud, and food defense. A Food Protection Plan was specifically outlined by the US Food and Drug Administration.

Food security The continuous and nutritious supply of food. This is often confused with food defense, that is, the protection of the food supply chain.

Product counterfeiting (broad) The fraudulent representation of a product, not including digital piracy, currency counterfeiting, document forgery, or artwork forgery.

Product counterfeiting (intellectual property rights) A product that violates international intellectual property protection for trademarks, patents, copyright, or trade secrets.

Introduction

The modern era of food regulations in the US began with the Food, Drug, and Cosmetic Act (FD&C) of 1938 which replaced the Food and Drugs Act of 1906. The concepts, and even much of the text, are present in food laws from around the globe. An article by Tousley in 1941 stated "it is doubtful if any piece of recent legislation has been of greater potential significance to the general public than the Food, Drug, and Cosmetic Act which was enacted June 25, 1938." One of the main triggers was a mass adulteration poisoning of medicine that contained diethylene glycol (DEG) – a component of antifreeze. Unfortunately, DEG has continued to be a threat to public health and was recently a lethal adulterant in branded toothpaste in the US in 2007. Both the 1906 and 1938 acts included a major focus on adulteration and misbranding, and the 1938 law greatly expanded the range of products covered. The FD&C eliminated the 'fraud joker' statement which was in an earlier amendment, so it was no longer necessary to prove fraud (intent to deceive) to apply this law.

In the current FD&C, food adulteration is defined and explained in a section on Adulterated Food which is clearly differentiated from Food Misbranding, which is defined in a separate section. For food adulteration, an ingredient or food product is defined as adulterated for factors including if it causes harm, the consumer does not get the benefit of an ingredient (either the product does not include a valuable ingredient or if the ingredient is substituted – if it was not valuable it would be considered misbranded, not adulterated), the product includes alcohol, the product is filthy or putrid, or the product is banned (e.g., a banned food additive). Food adulteration is the result whereas food fraud is the motivation (an intentional act for economic gain).

Specific types of food and drug adulteration have been defined, such as economically motivated adulteration (EMA). EMA does not include misbranding and was defined by the US Food and Drug Administration (FDA) in a Federal Register

notice as "…the fraudulent, intentional substitution or addition of a substance in a product for the purpose of increasing the apparent value of the product or reducing the cost of its production." Also, "EMA includes dilution of products with increased quantities of an already-present substance to the extent that such dilution poses a known or possible health risk to consumers, as well as the addition or substitution of substances in order to mask dilution." The term is not defined in a law, and considering the FD&C, it is argued that if there is EMA there should also be a focus on economically motivated misbranding.

The US Food Safety Modernization Act (FSMA) was enacted in January 2011 and is considered the next major iteration of the laws pertaining to food safety and food defense, including food adulteration and food misbranding. The act includes 11 mentions of 'intentional adulteration' are not explicitly defined. It is intended to include traditional food adulteration as defined in the FD&C, as well as food fraud, smuggling, tampering, and acts of terrorism. Although there are seven mentions of 'misbranding,' each is included in a standard text of "…provide assurances that such food is not adulterated under section 402 or misbranded under section 403(w)."

FSMA is also important because there is a direct focus on prevention not setting specifications or outlining the response. There are 70 mentions of prevent or prevention in the Act. This is a novel challenge for the organization and agencies as the expertise and systems are traditionally more reactive for inspections and testing of products.

Global initiatives are underway to more precisely address food fraud and food defense – root causes of adulteration. Both the Global Food Safety Initiative and the US Pharmacopeia/Food Chemicals Codex specifically address economically motivated food fraud separate from the food defense acts intended to create terror, economic harm, or a public health threat. Also, in June 2012, under the Codex Alimentarius Commission (the 'food book,' which is a set of voluntary standards), the Food and Agriculture Organization of the United Nations produced their first edition of *Prevention and Reduction of Food and Feed Contamination*.

The concept of food adulteration has been a focus of even the very first food laws dating back to Roman times. More recently the concept is being further refined to differentiate between intentional adulteration to create harm (food defense) and those acts for economical gain (food fraud).

Food Protection

The US has been a leader in food protection and food safety regulations. For protecting the food supply, the overarching concept is food protection: food quality, food safety, food fraud, and food defense. In 2007, the FDA created the Food Protection Plan. An example is the FDA Food Protection Plan which states: "The plan focuses FDA's efforts to prevent problems before they start. It employs risk-based interventions to ensure preventive approaches are effective. This was one of the first major US food agency statements that prioritized prevention. It provides for a rapid response when contaminated food or feed are detected, or when there is harm to humans or animals."

Once a product is considered adulterated, there are two standardized responses for common or uncommon incidents. Common incidents fall in the food safety category where routine responses and methods are used. Uncommon incidents are in the food defense category where the contaminant is often something unexpected in food and potentially very dangerous – such as anthrax or an explosive. Tampering falls into the food defense category. The intervention and response steps are calibrated to the perceived level of risk.

The definitions here are from Spink and Moyer (2011).

- Food quality: "Food Quality focuses on the unintentional spoilage or deterioration of food that only results in economic loss, such as an unsalable or down-graded product. This could be due to specific product characteristics deviating from industry reference standards, including expected physical or chemical attributes. Similarly, food fraud can result in economic losses in the form of unsalable product, lower margins, lost tax revenues, or brand equity damages from recalls or consumer concerns. If a food quality incident leads to a product that is harmful, then, although the *cause* is unintentional, the *effect* makes it a food safety incident."
- Food safety: "Food Safety focuses on the unintentional contamination of food by known ingredients, organisms, mishandling, or processing. Food fraud differs since it is an intentional act perpetrated for economic gain. Food fraud also differs from food safety since the types of adulterants are unconventional and could only become known once encountered. Food fraud and food safety are very similar in that both can lead to public health risks."
- Food fraud: "Food Fraud is a collective term used to encompass the deliberate and intentional substitution, addition, tampering, or misrepresentation of food, food ingredients, or food packaging; or false or misleading statements made about a product, for economic gain. Food fraud is a broader term than either the economically motivated adulteration (EMA) defined by the Food and Drug Administration (FDA) or the more specific general concept of food counterfeiting. Food fraud may not include 'adulteration' or 'misbranding,' as defined in the Food, Drug, and Cosmetic Act (FD&C Act), when it involves acts such as tax-avoidance and smuggling. The economic motivation behind food fraud is distinctly different from those for food safety, food defense, and food quality. The *cause* of an event might be food fraud, but if a public health threat becomes involved, the *effect* is an adulterated product and a food safety incident. All of this is under the umbrella of food protection, which encompasses food fraud, food quality, food safety, and food defense."
- Food defense: "Food Defense is a collective term that encompasses preventing and recovering from an intentional and deliberate contamination or tampering of food, motivated by either economic gain or public health harm. Food fraud differs in that the motivation is *only* for the perpetrator's economic gain." For many regulatory activities in the US, Food Defense is defined by Homeland Security Presidential-7 and -9, which define this as terrorism. The

term 'terrorism' is still not clearly defined where one author stated "no single definition of terrorism that commands full international approval."

These concepts are important to clarify when considering prevention rather than intervention and response. The motivation, or cause, is critical to selecting optimal countermeasure for detection and deterrence. Food Fraud poses unique risks due to the unconventional motivation of the perpetrator.

The Food Fraud Risk

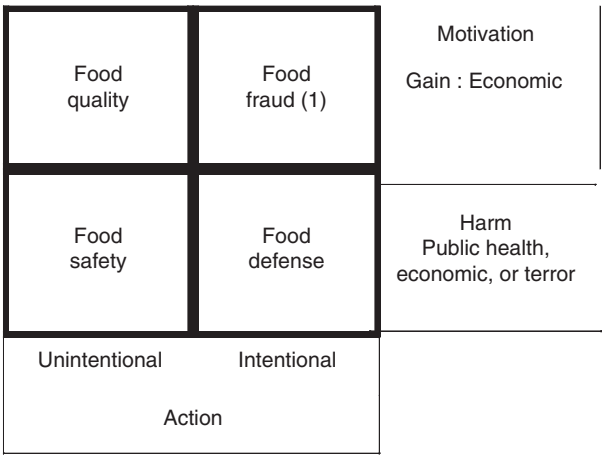
It is important to focus not only on the result of adulteration (contaminated product that is either a food safety or food defense incident) but also on the causes or motivation. To present this, the Food Risk Matrix was developed and published in Spink and Moyer (2011) (Figure 1).

By considering the cause or motivation, countermeasures to detect and deter specific types of risks can be more clearly defined. For example, perpetrator considering food fraud would try to avoid detection where in food defense the intent is to harm the victim – so the food defense attack would be identified quickly due to illnesses.

For food adulteration that is for economic gain, food fraud, there are three types of risks. The food fraud risks are: direct, indirect, and technical. Even though there are public health risks, the motivation is economic gain – the public health risk is an unintended consequence. It is important to consider the worst case scenario where the fraudster is a criminal not concerned with breaking laws, a sociopath not bothered by cheating others, and unaware of the unintended consequences of removing, adding, or modifying food products. The fraudsters who are unaware include operations that are sloppy or filthy. It should be considered that fraudsters do not worry about following standard good manufacturing practices (GMPs), hazard analysis and critical control points, and good hygienic practices which include hand washing and routine sanitation. The following is from Spink and Moyer (2011).

"Direct food fraud risk occurs when the consumer is put at immediate or imminent risk, such as the inclusion of an acutely toxic or lethal contaminant; i.e., one exposure can cause adverse effects in the whole or a smaller at-risk population. *Indirect food fraud risk* occurs when the consumer is put at risk through long-term exposure, such as the build up of a chronically toxic contaminant in the body, through the ingestion of low doses. Indirect risk also includes the omission of beneficial ingredients, such as preservatives or vitamins. *Technical food fraud risk* is non-material in nature. For example, food documentation fraud occurs when product content or country-of-origin information is deliberately misrepresented."

Although these are all risks that apply to all food adulteration, they have been specifically broadened to all fraud. There is a very broad scope of this risk.



(1) Includes the subcategory of economically motivated adulteration and food counterfeiting.

Figure 1 The Food Risk Matrix. Reproduced from Spink J and Moyer DC (2011) Defining the public health threat of food fraud. *Journal of Food Science* 75(9): 57–63.

The Scope of the Food Fraud Risk

As the food supply chains become more global, complex, and consolidated production, new and complex food risks have emerged. Where previous production was on a smaller scale and distributed more locally or regionally, the incidents impacted a smaller number and geographic population. The awareness of food product and safety has increased, including the disruptive acts of terrorism. There is also an emphasis on trusted and engaged supplier network.

It should also be mentioned that the detection methods for fraud are often based on traditional food safety triggers, which include a public health impact. When there is no public health impact – to trigger action – adulterated product may be very prevalent in the marketplace. Another trigger is a quality impact where the product is found not adhering to a production or quality control test. The fraudsters have demonstrated great resilience, intelligence, and ingenuity in circumventing efforts to detect fraud – they adapt to avoid detection including raising the quality of their products.

The technological advancements of the fraudsters, themselves, are amazing. For example, an adulterated product has been found to contain trace amounts of genuine ingredients to deceive authenticity detection tests that only test for the presence of an additive, not the quantity. Some examples of food fraud that could be the root cause of a public health incident include:

- melamine in milk products,
- the carcinogen colorant Sudan Red in foods,
- known *Salmonella*-contaminated peanuts distributed,
- species swapping of fish,
- dilution of fruit juices,
- substandard tomato products up labeled as a higher quality, and
- tax avoidance smuggling of honey.

Although some of these incidents appear to be only technical food fraud risks, the lack of adherence to GMPs lead to constant public health vulnerability. For example, overtreatment of raw fish with too much ice does not seem

like a public health risk, until it is considered that untreated water was probably used.

A review of food ingredient intentional adulteration was conducted by the US Pharmacopeia/Food Chemicals Codex researchers, specifically by Moore *et al.* (2011). From 1980–2010, more than 1000 research reports were identified in scholarly journals and the top 10 targets as broad product groups of olive oil, milk, honey, saffron, orange juice, coffee, apple juice, grape wine, maple syrup, and vanilla extract (Table 1). Broad classes of fraud such as protein adulteration have been researched, as well (Table 1).

The population-wide perspective is important when considering the scope, scale, and threat, but an individual company must take a more macro approach and focus on their own vulnerabilities. Vulnerabilities are only partially defined by the product type or country of origin, and must consider all supply chain and business activities. For example, procuring product from an unscrupulous vendor in a western country may be much more dangerous than buying from a high quality, trusted vendor halfway around the world.

Conclusion

Food adulteration is an evolving concept due to increased detection methods for contaminants ("we're catching more fraud") as well as the growing opportunity for fraudsters to profit from the acts (expanding global markets). The food adulteration risks are being considered from sources across the food protection spectrum including food quality, food safety, food fraud, and food defense. Any food product that is a public health threat is classified as the effect of adulteration though there may be many different types of causes or motivations. Food fraud is a broader term that includes the cause of motivation of the incident. To stay ahead of the growing scope, scale, and threat, new countermeasure approaches are being developed to more efficiently and effectively detect and deter.

SAFETY OF FOOD AND BEVERAGES

Safety of Organic Foods

SU Fabiansson, Castlecrag, NSW, Australia

Glossary

Ecological balance A state of dynamic equilibrium within a community of organisms in which genetic, species, and ecosystem diversity remain relatively stable, subject to gradual changes through natural succession.

Genetically modified organisms The direct manipulation of an organism's hereditary information using biotechnology.

Herbicides Pesticides used to kill unwanted plants (weeds).

Nanotechnology The manipulation of matter with at least one dimension sized from 1 to 100 nm.

Organic certification An approval system run by a third party to convey the practices used in producing the organic food.

Pesticides Substances intended for preventing, destroying, repelling, or mitigating any pest like the damaging influences of weeds, diseases, or insects.

Introduction

Organic food production systems provide clear benefits in relation to the environment and animal health and welfare. The European Commission states as a matter of fact that organic farmers use a range of techniques that help sustain ecosystems and reduce overall pollution. They also explain how organic farming contributes to the protection of natural resources, to biodiversity and animal welfare, and how it helps in the development of rural areas. In simple terms, organic farming is an agricultural system that seeks to provide fresh, tasty, and authentic food while respecting the natural life cycle systems. However, organic foods are often more expensive than their conventionally grown counterparts. This has led to the perception that organic production systems also provide foods that are more nutritious, safer, and have added health benefits, aspects which are very much open for debate.

Looking back at the history of food production, organic farming was the prevailing cultivation method practised for 1000 years as the original type of agriculture. The beginning of the twentieth century saw simultaneous advances in engineering and biochemistry that rapidly and profoundly changed farming. Development of the combustion engine allowed the introduction of tractors and other mechanized farm implements. The chemicals industry developed synthetic fertilizers and a growing range of herbicides and insecticides for weed and insect control. Research in plant breeding led to the commercialization of hybrid seeds requiring more intensive inputs. Fields grew bigger and cropping became more specialized to make more efficient use of machinery. The reduced need for manual labor and work assistance from animals that machinery, herbicides, and fertilizers made possible created an era in which the mechanization of agriculture evolved rapidly.

As a reaction to agriculture's growing reliance on synthetic fertilizers and pesticides, organic farming was revitalized in the 1940s. The term organic farming was coined by Lord Northbourne in a book – Look to the Land – that was published in 1940. From his concept of the farm as an organism, he described a holistic, ecologically balanced approach to farming. He claimed that for this to be attained, the farm itself must have a biological completeness because every branch of work is interlocked with all others. He pointed to vegetables converted through animal digestion into manure that in turn supported the growth of new vegetables in a cycle of great complexity, and highly sensitive to any disturbance of its proper balance (Figure 1).

In the 1970s, global movements concerned with pollution and environmental degradation increased their focus on organic farming. As a result the International Federation of Organic Agriculture Movements (IFOAM) was formed in France in 1972 dedicated to the spread and exchange of information on the principles and practices of organic agriculture across national and linguistic boundaries. In the 1980s, farming and consumer groups around the world began seriously pressuring for government regulation of organic

Figure 1 Organic farming in balance with nature.

 doi:10.1016/B978-0-12-378612-8.00301-2

production. This led to legislation and certification standards being enacted starting in the 1990s. Since this time the retail market for organic farming in developed economies has been growing by approximately 20% annually due to increasing consumer demand. A recent set back seen in some countries due to the economic crisis is considered to be temporary.

Defining Organic Food

The rise of organic farming was initially driven by small, independent producers and by consumers. However, the explosive organic market growth has encouraged the participation of larger agribusiness interests threatening the viability of small-scale dedicated organic farms. The meaning of organic farming as an agricultural method can easily be diluted and confused through an increasing commercial emphasis with a multitude of organic certification systems espousing different definitions.

The basic principle of organic farming is to achieve optimum quantities of produce and food of high nutritional quality without the use of artificial fertilizers or synthetic chemicals like pesticides and herbicides. Organic farming does not support the use of genetically modified foods, growth promoters, or hormones. It has been suggested that the application of nanotechnology to food and agriculture is a further technology that needs to be excluded from organic food production. Organic meat, poultry, eggs, and dairy products should come from animals that are given no antibiotics or growth hormones. Organic farmers attempt to rear animals with care and attention to their welfare by letting them grow and develop in the most natural and humane way possible. Organic farming emphasizes the need to maintain appropriate land management and aims to ecologically achieve the balance between animal life, the natural environment, and food crops. The produce that is produced through organic farming is thus supposed to be in its most natural form.

Here are some key differences between conventional farming and organic farming as outlined by the Mayo Clinic scientists:

Conventional	*Organic*
Apply chemical fertilizers to promote plant growth	Apply natural fertilizers, such as manure or compost, to feed soil and plants
Spray synthetic insecticides to reduce pests and disease	Spray pesticides from natural sources; use beneficial insects and birds, mating disruption or traps to reduce pests and disease
Use synthetic herbicides to manage weeds	Use environmentally generated plant-killing compounds; rotate crops, till, hand weed, or mulch to manage weeds
Give animals antibiotics, growth hormones, and medications to prevent disease and spur growth	Give animals organic feed and allow them access to the outdoors. Use preventive measures – such as rotational grazing, a balanced diet, and clean housing – to help minimize disease

However, it must be made clear that the organic movement represents a spectrum of practices, attitudes, and philosophies. On the one hand are those organic practitioners who would not use chemical fertilizers or pesticides under any circumstances. These producers hold rigidly to their purist philosophy. At the other end of the spectrum, organic farmers advocate a more flexible approach. Although striving to avoid the use of chemical fertilizers and pesticides, these practitioners do not rule them out entirely. Instead, when absolutely necessary, some fertilizers and herbicides are very selectively and sparingly used as a second line of defense. Nevertheless, these farmers too consider themselves to be organic farmers.

To clarify the basic understanding of organic farming and to develop a harmonized approach, a number of minimum objectives and principles were introduced. In 2005, the IFOAM approved a set of four principles to inspire the organic movement and to describe the purpose of organic agriculture to the wider world. The principles are intended to apply to agriculture in the broadest sense, including the way people tend soils, water, plants, and animals in order to produce, prepare, and distribute goods. They are concerned about the way people interact with living landscapes, relate to one another, and shape the legacy of future generations.

The four principles of organic agriculture according to IFOAM are as follows:

1. The health principle – organic agriculture should sustain and enhance the health of soil, plant, animal, and human as one and indivisible.
2. The ecology principle – organic agriculture should be based on the living ecological systems and cycles, work with them, emulate them, and help sustain them.
3. The fairness principle – organic agriculture should build on relationships that ensure fairness with regard to the common environment and life opportunities.
4. The care principle – organic agriculture should be managed in a precautionary and responsible manner to protect the health and well-being of current and future generations and the environment.

Following the above principles typical organic farming practices can be defined as including:

1. Wide crop rotation as a prerequisite for an efficient use of on-site resources.
2. Complete avoidance of or very strict limits on chemical synthetic pesticide and synthetic fertilizer use, livestock antibiotics, food additives and processing aids, and other inputs.
3. Absolute prohibition of the use of genetically modified organisms.
4. Use of on-site resources, such as livestock manure for fertilizer or feed produced on the farm.
5. Choosing plant and animal species that are resistant to disease and adapted to local conditions.
6. Raising livestock in free-range, open-air systems and providing them with organic feed.
7. Using animal husbandry practices appropriate to different livestock species.

Implementation of the overall principles and practices will vary according to individual needs and ethical convictions.

Marketing of produce defined as organic will require not only some objective description of parameters adhered to by the particular agricultural production system used, but also during food processing and further handling.

Food processors need organic certification for both, their ingredients and facilities used. This means that buildings, where ingredients are stored, equipment used, product packaging, and storage areas, for final products must all meet set requirements. Cleaning products and solvents need special approval for use in organic food manufacturing or completely rinsed away before organic production. Pest management in organic operations should be dealt with through preventive practices such as exclusion, sanitation, removal of pest habitat, management of environmental factors, mechanical or physical controls, or lures/repellents. In case of mixed processing systems, commingling of organic and nonorganic food must be avoided. Ingredient storage must be dedicated to organic or any containers that have been in contact with nonorganic products or prohibited substances must be thoroughly cleaned so that they pose no risk of contaminating the organic product. Synthetic fungicides, preservatives, and fumigants may not be used in the facility.

Certification of Organic Production Systems

Initially there was a direct communication link between farmers and consumers of organic foods. Early consumers interested in organic food had to buy it directly from growers or farmers markets – know your farmer, know your food was the motto. By talking to farmers and seeing farming activities and conditions, individual acceptance of what constituted organic production was the norm. As demand for organic food continued to increase, high volume sales through supermarkets rapidly replaced the direct farmer connection. A system to convey the practices used in producing the organic food was needed. An organic certification system was the essential solution aimed at regulating and facilitating the sale of organic products to consumers. It was intended to assure quality and prevent fraud, and to promote commerce (Figure 2).

In some countries, certification is overseen by the government, and commercial use of the term organic is legally restricted. Currently, the European Union, the US, Canada, Japan, and many other countries require producers to obtain special certification in order to market food as organic within their borders. In the context of these regulations, organic food is food produced in a way that complies with organic standards set by national governments and international organizations. Some countries, like Australia, have compulsory export standards to assure overseas customers of the authenticity of the organic food whereas adherence to the standard is voluntary for the domestic market. In countries without specific legislation for organic food, consumers must rely on third party certification alone. In any case, certified organic producers are also subject to the same agricultural, food safety, and other government regulations that apply to noncertified producers.

Figure 2 An example of a logo used for certified organic food.

Nowadays, there are more than 385 organizations worldwide that certify organic food, each according to their specific standards. Requirements vary from country to country and between certification bodies, but all involve a set of production standards for growing, storing, processing, packaging, and shipping of the organic food. At a minimum the standards have to comply with government legislation if available, but some certification bodies set standards that exceed government regulations. In general, any business directly involved in food production can be certified, including seed suppliers, farmers, food processors, retailers, and restaurants. For organic businesses, certification identifies suppliers of products approved for use in their own certified operations.

For a farmer to be certified as an organic producer he must know the relevant organic standards and farm facilities and production methods must comply with the specifics in the standards. Extensive documentation is required, detailing farm history and current set-up, and usually including the results of soil and water tests. A written annual production plan must be submitted, detailing everything from seed sources, field and crop locations, fertilization and pest control activities, harvest methods, and storage locations, for the sales of the organic produce. Annual on-farm inspections are required, with a physical tour, examination of records, and an oral interview. Written day-to-day farming and marketing records covering all activities, must be available for random inspection at any time.

Certification for operations other than farms follows a similar process. The focus is on the quality of ingredients and other inputs, and processing and handling conditions. A transport company would be required to detail the use and maintenance of its vehicles, storage facilities, containers, and so forth. A restaurant would have its premises inspected and its suppliers verified as certified organic.

The word organic is central to the certification process. Where organic laws exist, producers cannot use the term legally without certification. However, the organic labeling made possible by certification itself usually requires explanation. In countries without organic laws, government guidelines may or may not exist, although the actual certification is handled by nonprofit organizations and private companies.

Certification is intended to protect consumers from misuse of the term organic, and make buying organic food easier. Internationally, official equivalency negotiations are underway, with some agreements already in place, to harmonize certification between countries and facilitate international

trade. There are also international certification bodies, including members of the IFOAM, working on harmonization efforts. In 2011, IFOAM introduced a new program that attempts to simplify harmonization. The vision is to establish the use of one single global reference defining compulsory input standards to be applied to organic production systems rather than focusing on bilateral agreements.

Quality of Organic Produce

Although input standards for organic production systems can be established, the output quality of the resulting produce is much more difficult to define. There is a common perception that organic foods are of higher quality and provide added health benefits compared to conventionally grown alternatives. However, the weight of available scientific evidence has not shown a consistent and significant difference between organic and more conventionally grown food in terms of safety, nutritional value, or taste. This is not surprising when taking into account marked seasonal and geographical influences that might mask differences due to production methods.

As an example, an extensive recent cross-sectional review of the available literature on nutrient composition and contaminant analysis studies and human trials found that there were no general differences in nutritional value or risk for bacterial contamination between organic and conventional foods. The studies covered unprocessed foods including fruits, vegetables, grains, milk, eggs, chicken, pork, and meat.

Although organic food consumption reduced exposure to any detectable pesticide residues by approximately 30%, pesticide levels were generally within the allowable limits for safety anyway. However, free-range animal production systems might more easily be influenced by environmental contaminants. There are indications that free-range eggs might have slightly higher levels of dioxins, but with little consequence to the overall dioxin burden expected (Figure 3).

Other findings suggested that the consumption of organic fruits and vegetables had no benefit over conventional foods in terms of improved health. No consistent differences were seen in the vitamin content of organic products, and only phosphorus was significantly higher in organic versus conventionally grown produce, but is of little clinical significance.

Figure 3 Synthetic pesticides are not used in organic farming.

There was also no difference in the protein or fat content between organic and conventional milk, but there was some evidence that organic produce contained significantly higher levels of total phenolic compounds, which have antioxidant properties, and that organic milk and chicken contained higher levels of omega-3 fatty acids.

Other studies have found minor differences in ascorbic acid, protein concentration, and several differences in the micronutrient content have been identified between organic and conventional foods, but it does not appear that these have any impact on human health.

Some focus has been placed on the amount of nitrogen content in certain vegetables, especially green leafy vegetables and tubers, when grown organically as compared to conventionally. Although these vegetables, when grown organically, have been found to have lower nitrogen content, there is no consensus as to whether consumption of lower levels of nitrogen translates to improved health.

Most of the research has looked at differences in nutrient availability whereas other health impact parameters have been only scarcely studied. Some results indicate that carrots grown under strict organic conditions improved the immune status by inducing changes in lymphocyte populations, including an increase in regulatory T cells, when fed to laboratory mice. Such findings will still need to be confirmed.

Similarly, most studies that have compared the taste and organoleptic quality of organic and conventional foods report, no consistent or significant differences between organic and conventional produce. However, a few well-designed studies of fruits and vegetables have found minor differences, the majority in favor of organic produce. This might be due to the fact that some organic fruit seems to be drier than conventionally grown fruit. A slightly drier fruit may have a more intense flavor due to the higher concentration of nutrients, and as a result may be preferred by the consumer.

There is also evidence that some organically grown fruits have a higher resistance to deterioration and better keeping quality, attributed to a lower moisture content. On the contrary, because organic fruits and vegetables are not treated with waxes or preservatives, they may spoil faster. Some organic produce may look less than perfect – odd shapes, varying colors, or smaller sizes. However, organic foods should meet the same quality and safety standards as those of conventional foods.

Safety of Organic Produce

There continues to be widespread public belief in arguments that organic food is significantly safer for consumption than food grown conventionally, based mainly on anecdotal evidence and testimonials rather than scientific evidence. However, reviews of the available body of scientific literature have not found any significant differences between the two production systems in relation to safety. Firm conclusions about the relative safety of organic foods have been hampered by the difficulty in proper study design and relatively small number of studies directly comparing organic food to conventional food.

Figure 4 Animal welfare aspects are important when buying organic food.

Claims of improved safety of organic food have largely focused on pesticide residues. Although studies have shown organically grown fruits and vegetables have significantly lower pesticide residue levels, the significance of this finding on actual health risk reduction is debatable as both conventional foods and organic foods generally have pesticide levels well below government established guidelines for what is considered safe.

Reviews have noted that the risks from microbiological sources or natural toxins are likely to be much more significant than short-term or chronic risks from pesticide residues. There is an anticipated increased risk from microbiological contamination due to increased manure use as fertilizer from organisms like *Escherichia coli* O157:H7 during organic produce production, but little evidence of actual outbreaks that can be positively associated with organic food consumption. Other possible sources of increased safety risk from organic food consumption, like use of biological pesticides or the theoretical risk from mycotoxins from fungi grown on products due to the lack of effective organic compliant fungicides, have likewise not been confirmed by rigorous studies in the scientific literature.

When evaluating environmental toxins such as heavy metals, it was noted that organically raised chicken may have lower arsenic levels, although literature reviews found no significant evidence that the levels of arsenic, cadmium, or other heavy metals differed significantly between organic and conventional food products.

Organic regulations ban or severely restrict the use of food additives, processing aids (substances used during processing, but not added directly to food), and fortifying agents commonly used in nonorganic foods, including preservatives, artificial sweeteners, colorings, flavorings, and monosodium glutamate. The American Cancer Society (ACS) has noted that interest in organic food is partly derived from the perceived risk of cancer caused by additives not found in organic foods. The ACS has stated as their official position that whether organic foods carry a lower risk of cancer because they are less likely to include compounds that might cause cancer is largely unknown.

Conclusion

There seems to be little evidence that organic production systems provide healthier and safer food compared to conventionally grown food. However, looking beyond health effects, there are plenty of other reasons to buy organic food. Such reasons include sustainability of agricultural production systems and concerns about animal welfare and the environment. For a sustained growth of organic food, it is crucial to maintain the trust of consumers that organic production adheres to agreed principles through independent certification (Figure 4).

Safety Consideration in Developing Functional Foods

SU Fabiansson, Castlecrag, NSW, Australia

Glossary

Active phytochemical Compounds that occur naturally in plants that may have biological significance, but are not established as essential nutrients.

Antinutrient Natural or synthetic compounds that interfere with the absorption of nutrients.

Bioactive compound Inherent nonnutrient constituent of food with anticipated health promoting/beneficial and/or toxic effects when ingested.

Biomarkers Indicators of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.

Fortification The addition of an essential micronutrient to a food to improve its nutritional quality and thus provide a public health benefit of nutritionally adequate diets with minimal risk to health.

Nutraceuticals A combination of the words 'nutrition' and 'pharmaceutical' – sometimes used as a synonym for functional foods.

Introduction

The idea of associating certain foods with a beneficial influence on bodily functions emerged in the 1980s in Japan. This was the birth of the modern functional food concept and it has spread from there to become a worldwide dietary and nutritional trend. Functional food development is now a dynamic field in food science due to the increasing popularity of health foods with health conscious consumers and the ability of marketers to promote new and enticing products. It is estimated that the global market of functional foods might reach US$180 billion in 2013 with an annual growth rate of an impressive 7.4%.

In discussing functional foods it is important to first acknowledge that many foods are functional at some physiological level, but some functions might be seen by consumers as more important than others – a fact that the food industry has been keen to explore. With an aging population in many countries, the endeavor to maintain good physical and mental health is a priority topic. What better way then for the industry to capitalize on this need than by being able to provide foods with inbuilt health benefits. And the selling point for functional foods is their link to extra health benefits. Besides the potential problems of bogus health claims, the health concerns regarding functional foods are twofold. One is that they may lead to an unbalanced diet and resulting nutritional deficiencies, but the other is equally important and that is, their safety be assured.

So what constitutes a functional food? Although many definitions exist worldwide, there is unfortunately not yet any official internationally accepted designation of such foods. The difficulty is the fact mentioned above that food products in general are functional as they provide varying amounts of nutrients, energy, or fluids to sustain growth or support vital processes. As a matter of fact a well-balanced and varied diet should be sufficient for normal well-being. However, functional foods are generally considered to offer additional benefits that may reduce the risk of a disease or promote optimal health. Functional foods could thus be seen as foods that have a potentially positive effect on health beyond basic nutrition. But there is still some controversy around applying the concept of functional foods.

The first controversial issue is government prescribed fortification. Common beneficial fortified foods providing particular health benefits include fluoridated water to protect against caries, iodized salt to protect against mental retardation and thyroid dysfunction, and folic acid added to bread, cereals, flour, and other grain products to protect against neural tube birth defects as well as many others. But in an orthodox view of functional foods, government prescribed fortification is not supposed to be part of the concept (Figure 1).

Another difficulty relates to the already existing conventional foods. Some foods now considered to provide positive effects on health are actually natural whole foods where new scientific information about their health qualities can be used to proclaim benefits. Many, if not most, fruits, vegetables, and grains, as well as many fish species contain several natural components that may be argued to deliver health benefits beyond basic nutrition. Examples include lycopene in tomatoes, omega n-3 and n-6 fatty acids in salmon, insoluble fiber in whole grains, and saponins in soy. Many would include such foods in the functional food concept, whereas others think that only fortified, enriched, or enhanced foods with an added component having a health benefit beyond basic nutrition should be considered as functional.

Figure 1 Prevention of tooth decay by fluoridating water is only considered by some as belonging to the functional food concept (photo: Amandabhslater).

Figure 2 Prevention of diseases related to obesity is a claim allowed in Japan (photo: Dennis Sylvester Hurd).

Attempts to Define Functional Foods

There are several attempts to try to better define functional foods from around the world. Although not specifically describing functional foods, the Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO) Codex Alimentarius Commission has a definition of foods for special dietary uses. They are foods which are specially processed or formulated to satisfy specific dietary requirements, which exist because of a particular physical or physiological condition, disease or disorder and which are presented as such. The composition of these foodstuffs must differ significantly from the composition of ordinary foods of comparable nature, if such ordinary foods exist. Although foods of this nature are obviously intended to be 'functional,' the wording of the Codex description also implies that newly discovered beneficial effects of traditional foods are not covered, which is a bit of an anomaly.

Clearer rules exist in Japan and China. In Japan, functional foods are legally approved through a government instituted approval process established in 1991. Under their system, the term 'functional' was actually dropped and they are instead called 'foods for specified health use.' The Japanese Ministry of Health and Welfare highlights three conditions that such foods should satisfy. They should be foods, not capsules, tablets, or powders, and should be derived from naturally occurring ingredients. They should be a dietary component to be consumed as part of the normal diet. Finally, they should have a particular function when ingested, serving to regulate a particular body process, such as enhancement of the biological defense mechanisms, prevention of a specific disease (e.g., heart and arterial disease, cancer, hypertension, and obesity), control of physical and mental conditions, or slowing down the aging process (Figure 2).

China has also constructed a unique system for functional foods. Chinese functional foods are legally approved, with a logo issued by the Ministry of Public Health. They can cover one or more of the 24 functional areas defined in the legislation (see Section Validity of Health Claims, below).

In the rest of the world the situation is less transparent. There is no official legal definition of functional foods in the USA. However, some nongovernmental organizations have developed working definitions for functional foods. The American Dietetic Association includes both whole foods and fortified, enriched, or enhanced foods which have a potentially beneficial effect on health in the functional food concept as long as they are consumed as part of a varied diet on a regular basis, at effective levels. The Institute of Food Technologists simply defines functional foods as foods or food components that provide a health benefit beyond basic nutrition.

In developing health claims legislation, Health Canada had a working definition of functional foods as being similar in appearance to, or being, a conventional food that would be consumed as part of a usual diet, and has been demonstrated to have physiological benefits and/or reduce the risk of chronic disease beyond basic nutritional functions.

Equally, the European Union has no official definition of functional foods. However, the European Commission funded a project named the 'Concerted Action on Functional Food Science in Europe.' Participants in this project proposed that a functional food should be defined as beneficially affecting one or more target functions in the body beyond adequate nutritional effects in a way that is relevant to either an improved state of health and well-being and/or reduction of risk of disease. It should be consumed as part of a normal food pattern. It should not be a pill, a capsule, or any form of dietary supplement.

Although there is no consensus around a clear definition of functional foods, a common view seems to be that they should be natural or processed foods constituting a part of a normal diet and containing a bioactive compound with a discrete beneficial health effect beyond normal nutrition. For the purpose of this article, a functional food is a food that is consumed as part of a usual diet, and that is demonstrated to have physiological benefits and/or reduce the risk of chronic disease beyond basic nutritional functions. This definition does not include the so-called 'nutraceuticals,' which are products isolated or purified from foods that are generally sold in medicinal forms not usually associated with food and which have demonstrated health benefits.

Functional Components

To be considered as a functional food it is most important to have proof of the actual claimed beneficial effect of the functional component. Because any functional food must be based on science, its evaluation should principally be contingent on data from biochemistry, physiology, molecular and cell biology, and other relevant biosciences. A key component in the development of a functional food is the identification and validation of relevant biomarkers that can predict potential benefits relating to a target function in the body. This could be a marker directly involved in the biological process or secondary markers of correlated events.

Among many potential candidates of functional components, research into phytochemical, probiotic, or prebiotic substances has shown a variety of possible beneficial effects for a range of foods. Active phytochemicals, such as indoles, thiocyanates, sulfur-containing compounds, allium compounds, isoflavones, and phenols, have all been shown to have some possible beneficial or protective effects. Probiotics such as lactobacilli and bifidus bacteria, which can modify the bacterial flora in the intestine and enhance certain immune functions, possibly promote absorption of certain essential minerals, and protect against some diseases of the intestine and colon. Prebiotics that are oligosaccharides may moderate risks of intestinal disorders, osteoporosis, cancer, and heart disease.

However, to the frustration of many commercial food manufacturing companies, to convincingly establish the beneficial effects of any of these substances has proved to be difficult. Without conclusive scientific evidence it will not be possible to make associated health claims in the regulated markets of industrialized countries.

Validity of Health Claims

The continued growth of the functional food market is very much contingent on the prospects of convincing consumers of their beneficial effects. Thus functional food products typically include health claims on their label touting their benefits. An example would be: 'Cereal is a significant source of fiber. Studies have shown that an increased amount of fiber in the diet can decrease the risk of certain types of cancer in individuals.' However, this could equally be a claim for a drug. In the past there was no middle ground between foods and drugs, and health-related claims were not permitted on foods. Nevertheless, developments at national and international levels have tended to take into account newer research findings into the possible beneficial or protective effects of foods and their ingredients. This has led to the gradual acceptance of well-founded claims for such effects to be associated with specific foods in some parts of the world.

As functional foods are not defined or set aside as a specific class of product in most countries, they are commonly regulated under the existing laws as foods, novel foods, special dietary foods, medical foods, or as drugs, depending on how they are marketed, and the claims that are made for the products in their labeling, or in advertising.

At the international level, the Codex Alimentarius Commission has completed work at a generic level on basic labeling rules, on nutrition claims and nutrition labeling, and claims for foods for special dietary use. In general, these Codex standards and guidelines state that packaged food should not be described or presented on any label or labeling in a manner that is false, misleading, or deceptive, or is likely to create a wrongful impression regarding its character in any respect.

Japan is more specific in relation to health claims on foods. The Japanese rules require that a manufacturer or marketer of such foods present a dossier to the Japanese government with valid information on the ingredients, processing, labeling, quality, safety, and health effects of each product. If the government authorities are satisfied that the dossier supports quality and safety requirements, and substantiates the health effects to be placed on the label or used in advertising, approval of the functional food can be given.

China is explicit in what type of functional claims that can be made. The functions to be considered must fall into one or more of the following exhaustive areas: immune regulation, postponement of senility, memory improvement, promotion of growth and development, antifatigue, body weight reduction, oxygen deficit tolerance, radiation protection, antimutation, antitumor, blood lipid regulation, improvement of sexual potency, blood glucose regulation, gastrointestinal function improvement, sleep improvement, improvement of nutritional anemia, protection of liver from chemical damage, lactation improvement, improvement for beauty, vision improvement, promotion of lead removal, removal of 'intense heat' from the throat and moistening of the throat, blood pressure regulation, or enhancement of bone calcification.

The Food and Drug Administration (FDA) in the USA regulates claims that manufacturers make about the nutrient content of functional foods and their effects on disease, health, or body function. The FDA regulates these types of foods according to whether a food is considered to be a conventional food, a food additive, a dietary supplement, a medical food, or a food for special dietary use. However, some claims will fall outside of the purview of the FDA and be accompanied by the disclaimer: 'These statements have not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease.'

The European Commission is responsible for authorizing health claims on foods in the European Union according to legislation on nutrition and health claims applied from mid-2007. Foods covered include natural foods, fortified foods, food supplements, and dietetic foods in the absence of any specific legislation for functional foods. The legislation harmonized the rules governing nutrition and health claims across all Member States of the European Union while providing assurance to consumers that only standardized nutritional claims or specifically authorized health claims may be carried on food. The European Food Safety Authority (EFSA) is responsible for assessing the scientific validity of health claims and advising the European Commission of the results of its evaluations. EFSA's scientific evaluation helps to ensure that claims made on food labeling and advertising regarding nutrition and health are meaningful and accurate, and will thereby help consumers in making healthy dietary choices.

Originally, industry submitted 44 000 claims on functional foods through EU Member States for evaluation by EFSA.

Figure 3 Reduction of blood cholesterol levels is an allowed claim associated with a decrease in the development of coronary heart disease (photo: Gabriella Camerotti).

These claims were consolidated into a list of 4637 differentiated claims. They are differentiated into three areas:

1. general functional claims that relate to the growth, development, and functions of the body, or refer to psychological and behavioral functions or are concerned with slimming or weight control;
2. risk reduction claims that refer to a reduction of a risk factor in the development of a disease, for example, reduction of blood cholesterol levels which is a risk factor in the development of coronary heart disease (Figure 3); and
3. health claims that are linked to children's development.

EFSA completed its evaluations of all general function claims, other than those related to botanicals, in June 2011, having published a total of 341 opinions covering 2758 claims. Using EFSA's scientific advice, the Commission has adopted a list of 222 approved general function claims for use in the European Union. This is less than a 10% approval rate with many functional ingredients considered to be not sufficiently characterized, or with insufficient evidence to establish a cause and effect relationship between the consumption of the food and the claimed effect.

Summarizing the activities needed, it is clear that manufacturers of foods which fit the profile of functional foods must develop or access adequate scientific data to substantiate any claims that they wish to make on products. This will typically involve at least three steps:

1. fundamental research to identify and understand the mechanisms of interaction between the food or ingredient and cellular biochemical functions to be able to demonstrate a potential theoretical effect;
2. elaboration of models and methodologies including possible biomarkers to demonstrate through studies on human nutrition possible functional effects and their impact to justify specific functional or physiological claims; and
3. performance of relevant human nutrition studies to establish the functional effects and benefits to health, including reduction of disease where appropriate, to substantiate the health claim.

Safety Assessment of Functional Foods

Given the differences in regulation of food, special dietary foods, novel foods, foods for special dietary use, and medical foods in different countries and regions, potential manufacturers of these foods must be prepared to fully understand the regulatory requirements which apply in each marketing area to be able to establish their safety.

There are two potential food safety issues related to functional foods. The first one is misdirected or misinterpreted advertising messages in relation to health claims. It is easy to misconstrue a health claim to mean 'the more the better of the food'. If 3 g of plant sterols are good for heart health, what about doubling or tripling the intake of the enhanced food? This could skew the diet away from being balanced and thus be counterproductive. To counter such a response, some countries specify the exact text for any authorized health claim to make sure that it is not overstating the beneficial effect. The second issue is the more traditional food safety evaluation of toxicity, allergenicity, or antinutrient properties.

Many substances in food are considered safe based wholly or in part on the empirical evidence from long periods of consumption, i.e., prior history of safe use. In the absence of a prior history of safe use, potential new functional ingredients must be evaluated for safety before introduction into the market. The safety evaluation of new functional ingredients should adhere to the same safety testing principles used for other substances and should replicate the intended use levels. The safety evaluation should cover both the functional ingredient and the functional food itself. For novel foods that cannot be considered to be equivalent to a traditional food, a more elaborate process will be necessary (see other articles in this encyclopedia).

An objective, science-based evaluation process must establish that the functional components are safe at their estimated use levels. The scope of potential new functional foods is very broad so the safety assessment framework must be effective for many types of functional ingredients over a wide range of consumer intake levels. The nature of the ingredient and the sensitivity of subgroups of the population should be considered. An example is the advice provided by a medical practitioner in Sydney to a pregnant woman to increase her intake of omega n-3 fatty acids by increasing her fish consumption. In response to the advice she exclusively consumed swordfish several times a day for several months resulting in mercury levels well above safe levels.

Typically, a safety assessment of a functional food will include the following steps:

1. documentation of the history of food use;
2. realistic estimates of current and proposed intakes of the functional component for the general population and for high consumers; and
3. a toxicological assessment at predicted intake levels.

Substances without a prior history of safe use will require a comprehensive and critical review of the scientific literature covering their expected biological effects. Based on an initial review, specific studies will generally be required to define:

1. bioavailability and likely modes of action;
2. estimated half-life in the body;
3. estimated dose–response for pertinent potential effects;
4. recognized pharmacologic or toxic effects;
5. evidence of allergenicity; and
6. toxicity testing and safety conclusion.

Any new protein in a functional food should be evaluated for potential allergic effects. Although no single test can absolutely predict the potential allergenicity of a novel protein, the application of a series of tests can provide reasonable assurance that the novel protein is not likely to become an allergen.

Epidemiological studies can confirm relationships between dietary patterns and biomarkers of disease or disease occurrence. Such studies have been widely used to relate diet intakes to the occurrence of heart disease or cancer. However, people can only record food consumed, not isolated ingredients, so food intake studies cannot directly assess the intake of a specific bioactive component. Consequently, epidemiological studies have to combine the food intake data with other compositional data to estimate the actual intake of the substances of interest. However, many bioactive components have not been well characterized and quantitative data for such components may be very limited or nonexistent. In addition, isolating the effect of a specific food or nutrient can be difficult because the substances are consumed as a mixture that may have synergistic effects.

Postmarket Surveillance

To assist in the evaluation of functional foods, postmarket surveillance can be very useful. The term 'postmarket surveillance' refers to the process of acquiring information on the effects of the functional ingredient after it has been introduced into the marketplace. Such evidence can confirm the conclusions reached during premarket evaluations regarding safety and efficacy of the functional component. It will monitor actual consumption patterns and consequential health impact. It can also determine if there are any adverse health effects that were not identified in premarket testing.

A postmarket surveillance program may be active or passive. In an active program, an appropriate professional group is employed to methodically poll consumers regarding intake patterns. It may include additional research to further evaluate tolerability or efficacy or to address scientific questions that arose after marketing. A passive program involves the collection, documentation, and evaluation of complaints about the product and may include reports of adverse health events, often through the inclusion of a free telephone number to the food manufacturer on the label of the product. The information obtained from a passive program cannot establish a causal relationship between the ingredient and the alleged adverse health effect, but remain useful in documenting trends over time and identifying unanticipated effects that may require further evaluation.

Probiotics and Prebiotics

FX Malcata, University of Porto, Porto, Portugal
TS Granja Tavares, New University of Lisbon, Oeiras, Portugal
A Hernández-Mendoza, Center for Food Research and Development, A.C. (CIAD), Hermosillo, Sonora, México

Glossary

Bioavailability Refers to extent and rate at which the active moiety (drug or metabolite) enters systemic circulation, thereby accessing its site of action.
Crohn's disease A chronic inflammatory disease of the intestine that occurs when the immune system mistakenly attacks and destroys healthy body tissue (autoimmune disorder).
Homeostasis The maintenance of metabolic equilibrium within an biological system by a tendency to compensate for disrupting changes.
Xenobiotics Chemical compounds that are foreign to a biological system. They may include naturally occurring compounds, as well as drugs, environmental agents, carcinogens, insecticides, etc.

Current Trends of Functional Foods

In recent years, health has become one of the major reasons of consumers' choice of food. However, the difficulty in having consumers to change their eating habits drastically has prompted the emergence of functional foods that resemble conventional ones in appearance, but contain specific nutraceutical ingredients, i.e., be able to bring health benefits, in addition to responding to nutritional issues. Reduction of incidence of chronic diseases using such dietary supplements will obviously promote one's health, and thus helps reduce the overall costs of public health care.

Several definitions of functional foods exist, which makes it difficult to provide industry with solid information on market trends and potential, or to appropriately protect consumers via legislation. Generally speaking a food maybe considered as 'functional' if, beyond its nutritional effect, it provides benefits on one or more functions of the body, thus improving health or welfare, or reducing the risk of illness; obviously such type of food must be part of a standard diet, consumed on a regular basis and in reasonable amounts. In this definition proposed by Functional Food Science in Europe, one should highlight that: (1) the functional effect is different from the nutritional one; (2) the benefit provided shall be rationalized; and (3) an improvement is to exist in physiological functions, or a reduction in the risk of developing pathological conditions. Because of the growing consumer awareness of the relationship between nutrition and health, the market of functional foods is booming.

To treat or prevent disease, wide ranges of chemotherapeutics are nowadays prescribed to patients; however, exposure to excessive use of antibiotics leads to an imbalance between beneficial and harmful microorganisms, thus turning our body more susceptible to infections brought about by resistant strains. The importance of the digestive tract in this endeavor often owns second relative to heart and brain diseases and conditions, yet it plays an extremely important role in absorbing nutrients and maintaining a state of overall good health. Probiotics are living microorganisms added to food, which remain essentially intact throughout the digestive process so they can reach the colon in viable form where they stimulate metabolic activities. Prebiotics are dietary supplements that selectively stimulate growth of said probiotics during its passage through the gut; and which suppress growth and activity of otherwise deleterious bacteria. Combination of probiotics and prebiotics affect the host beneficially by improving a healthy microbial balance – and adding them together in a single product may bring about synergistic effects.

Among functional food ingredients, prebiotics have been attracting more and more attention, as they offer the potential to change the gut microbial balance toward health benefits in a nonexpensive fashion. Although there are many different types of prebiotics available in the market today (e.g., in bread, cereal bars, spreads, sauces, infant milk formulae, beverages, and drinks), it is important to stress that some are just not so good as advertised; for instance, despite most evidence on prebiotic role against infections being positive, few studies indicate that they may increase the susceptibility to specific gastrointestinal (GI) infections. Hence, the aim of this entry is to describe the probiotics/prebiotics concept, their dietary sources and range of products, and their positive and negative involvement in safety issues.

Concept and Selection Criteria

Probiotics

The word 'probiotics' is derived from the Greek 'pro bios,' which means 'for life'; its origin can be traced back to 1953, when Kollath used it to describe restoration of health of malnourished patients using organic and inorganic supplements. Later, Lilly and Stillwell in 1965 used it to describe compounds secreted by one microorganism that stimulate the growth of another, thus contrasting with the term 'antibiotic.' But it was not until 1974 that the term probiotic acquired its current meaning with Parker – yet an important evolution of this concept has been witnessed; however, there is no consensus about an appropriate definition.

Following recommendations of the Food and Agricultural Organization/World Health Organization working group on evaluation of probiotics in food (2006), the suggested definition describes probiotics as live microorganisms that, when administered in adequate amounts, confer a health benefit on the host. Based on this definition, a significant number of microorganisms have been isolated and labeled as probiotics.

There is a number of minimal criteria to assess the potential of a microorganism to function as probiotic, including: safety criteria (be nonpathogenic, nontoxic, and free of significant adverse side effects); technological criteria (be compatible with the food matrix, as well as the processing and storage conditions associated therewith); functional criteria (be able to survive through the GI tract, and colonize the intestinal mucosa both *in vitro* and *in vivo*); and physiological criteria (be able to demonstrate beneficial effects on the host).

The microorganisms most commonly used as probiotics belong to the (wide) group of lactic acid bacteria (LAB) (e.g., *Lactobacillus* and *Enterococcus*) and the genus *Bifidobacterium* – but *Streptococcus, Escherichia coli, Bacillus*, and *Saccharomyces* strains have also been claimed as probiotics. These bacteria are beneficial to human health by decreasing the presence of intestinal pathogens and/or promoting production of health-related bacterial substances, such us bacteriocins, metabolic products, and short-chain fatty acids (SCFAs), which are generally believed as favorable for colonic health. For instance, SCFAs decrease gut pH to low levels, and enhance mucin production, besides affecting epithelial and immune cells by binding to specific cellular receptors and thus improving the mucosal integrity and defense systems based thereon.

Prebiotics

The definition of prebiotic has been refined over time; in 1995, Gibson and Roberfroid introduced that word by changing 'pro' to 'pre' in the word 'probiotics,' which means 'before' (or 'for') – and defining prebiotics as nondigestible food ingredients that, when consumed, provide beneficial physiological effects on the host by selectively stimulating growth and/or activity of one or a limited number of indigenous bacteria in the colon (Gibson and Roberfroid, 1995). Prebiotics encompass dietary fiber, except for its selectivity toward certain species; and Cummings *et al.* (2001) defended that prebiotics are carbohydrates with relatively short chain length – with oligosaccharide as particularly promising. In 2007, Roberfroid updated the aforementioned definition by stating that prebiotics (inulin-type prebiotics and galactooligosaccharides (GOS)) are ingredients susceptible to colonic enzymatic activity and fermentation, and able to selectively promote specific changes, both in composition and activity, in the desirable types of gut bacteria (e.g., *Lactobacillus* and *Bifidobacterium*) (Roberfroid, 2007). The action of prebiotics is consequently indirect; they indeed alter the GI microbiota composition, by increasing the number of bifidobacteria and lactobacilli (**Figure 1**). However, health benefits of prebiotics go beyond microbiota modulation, and include the impact on immune-associated diseases (e.g., allergies, inflammatory bowel diseases, and cardiovascular diseases), as well as improvement of bowel function, mineral absorption, satiety/obesity control, and certain types of diabetes.

Many prebiotics identified to date are members of the carbohydrate family, but are grouped by their ability to promote growth of specific beneficial (probiotic) gut bacteria rather by structural similarities. According to the International Union of Pure and Applied Chemistry (IUPAC), carbohydrates can be classified based on their molecular size or degree of polymerization (number of monosaccharide units) as monosaccharides, oligosaccharides, and polysaccharides; oligosaccharides are defined as low molecular weight carbohydrates. Based on their biochemical and physiological features, carbohydrates can be classified as digestible or nondigestible (prebiotics as in the case of), and the configuration of the anomeric C atom of the monosaccharide units causes this major difference; nondigestible oligosaccharides (NDOs) have glycosidic bonds resistant to hydrolytic activity, so they are not be broken down into smaller pieces or absorbed in the gut because humans and higher animals do not possess the necessary digestive enzymes. The monosaccharide units usually present in NDOs are fructose, galactose, glucose, or xylose. Dietary fibers encompass both polysaccharides and lignin that are not digested by the endogenous digestive enzymes of the human GI tract; they are classified as water-soluble (e.g., inulin and oligofructose), insoluble (e.g., cellulose), and mixed (e.g., bran).

In his definition, Roberfroid considered only inulin type and GOS as prebiotics, but many other dietary fibers (especially soluble ones) are also to be considered; this is the case of gentiooligosaccharides, glucooligosaccharides, fructooligosaccharides (FOS), isomaltooligosaccharides, mannan oligosaccharides, *N*-acetylchitooligosaccharides, oligosaccharides from melibiose, pectic oligosaccharides, xylooligosaccharides, gums (like arabic gum), hemicellulose-rich substrates, resistant starches (maltodextrin), lactosucrose, oligodextrans, and polydextrose. Furthermore, nonfiber compounds are not precluded from being classified as prebiotics, as long as they abide to such functional criteria; this is the case of germinated barley, gluconic acid, glutamine, lactose, and tagatose. Nevertheless, inulin, GOS, FOS, and its derivatives are the best established and most studied prebiotics; beside inhibiting exogenous pathogens and modulating human gut microbiota, their manufacture is relatively nonexpensive.

Regular dietary sources of prebiotics entail certain fruits and vegetables; for instance, fructans are frequently eaten in

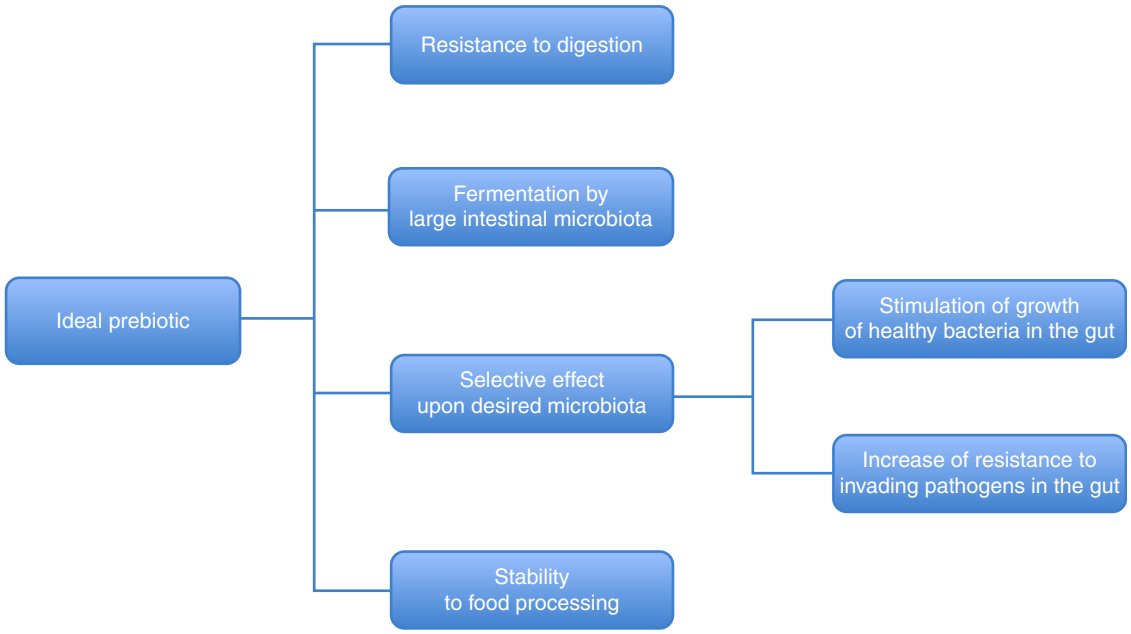

Figure 1 Characteristic features of ideal prebiotics.

classical diets as vegetables – asparagus, wheat, garlic, tomato, leek, artichoke, and onion, its commercial product, inulin, is produced and used as food and feed ingredient. β-Glucans are present in grains and cereals, whereas GOS appear in human breast milk. To bring about a substantial effect, daily intake of prebiotics should be more than 2–3 g; if 5–8 servings of fruits and vegetables were eaten per day, the dietary fiber needs would be fully met. Because the vast majority of the population does not attain that threshold, prebiotics are now added to many common food choices, such as cereals, biscuits, breads, table spreads, drinks, and yogurts.

Health Benefits and Mechanisms of Action

Probiotics

The role of the gut microbiota on host health is increasingly appreciated; the human body, especially the GI tract, is home to a variety of bacteria, which are normally referred as commensal bacteria (meaning that they live in peaceful coexistence with the host); when both, host and bacteria, benefit from each other's presence, then one has symbiotic bacteria. The host provides food and shelter for the bacteria, which digest unused energy sources, thus leading to release of beneficial metabolites. Although in relatively small number in healthy individuals, the human gut also contains (potentially) harmful bacteria. Although the exact mechanisms behind host–microbial interactions are unknown, and also which species of bacteria are involved in maintenance of a healthy gut environment, it is generally accepted that *Bifidobacterium* and *Lactobacillus* genera play a significant role; they indeed play an important role in the maintenance of colonization resistance. These bacteria are consequently pointed as largely responsible to mediate a variety of health effects, such as regulation of intestinal homeostasis; modulation of local and systemic immune responses; repression of procarcinogenic enzymatic activities; promotion of bioconversion of dietary compounds into bioactive healthy molecules; carbohydrate transporters; and interference with the ability of pathogenic bacteria to infect intestinal mucosa, through numerous proposed mechanisms (**Table 1**). Turpin *et al.* (2010) proposed a most comprehensive leistering of benefits, viz.: synthesizing and enhancing bioavailability of nutrients; reduction of symptoms of lactose intolerance; positive influence on urogenital flora following antibiotic and radiation therapies, yeast infections, and vaginitis; prevention and reduction of intestinal tract infections induced by bacteria, virus, *Candida enteritis*, and *Helicobacter pylori*; improved regulation of gut motility (by reducing constipation and irritable bowel syndrome); lower incidence of diarrheal diseases (antibiotic-associated, and caused by *Clostridium difficile* and rotaviruses); promoting maintenance of mucosal integrity; enhancing immune system; reducing risk to certain cancers (e.g., colon cancer); prevention of osteoporosis; regulation of inflammatory conditions, such as inflammatory bowel disease (Crohn's disease and ulcerative colitis); reduction (and even elimination) of small bowel bacterial overgrowth; relieving urinary tract infections; inactivating enterotoxins; preventing dental caries; controlling cardiovascular diseases (by reduction of cholesterol levels and blood pressure); and modulation of insulin resistance and sensitivity.

The mechanisms followed by probiotics when exerting their effects are still largely unknown, but may involve modifying gut pH, antagonizing pathogens via production of antimicrobial compounds, competing for pathogen binding and receptor sites, as well as for available nutrients and growth factors, stimulating immunomodulatory cells, producing lactase, and improving the intestinal barrier.

Table 1 Potential and established health effects of probiotic bacteria

Target health benefit	*Probiotic genus/species*		*Postulated mechanism*
Aid in lactose malabsorption	*Bifidobacterium*	*breve* *infantis* *longum*	Bacterial lactase-mediated hydrolysis of lactose
	Lactobacillus	*acidophilus* *casei* *rhamnosus*	
Prevention of diarrheal diseases (antibiotic-associated, acute, and traveler's diarrhea)	*Lactobacillus*	*rhamnosus* *reuteri* *acidophilus*	Compete with pathogens for nutrients and receptors, induce hydrolysis of toxins and receptors, and regulate intestinal permeability by modulating the epithelial tight junctions
	Saccharomyces	*boulardii*	
	Bifidobacterium	*bifidum*	
Antimicrobial activity	*Lactobacillus*	*rhamnosus acidophilus paracasei* *casei* *plantarum* *reuteri*	Decrease luminal pH, secrete antimicrobial compounds (peptides, organic acids), and block bacterial adhesion to epithelial cells
	Lactococcus	*lactis* L1A	
Anticancer effect	*Bifidobacterium*	*bifidum* *longum* *animalis*	Mutagen binding, carcinogen deactivation, inhibition of carcinogen-producing enzymes (nitroreductase, azoreductase, and β-glucuronidase), enhancement of immune response, influence on secondary bile salt concentration, increase in levels of glutathione S transferase, inhibition of proliferation of damaged cells by increasing apoptosis, and reduction of reactive oxygen species
	Lactobacillus	*rhamnosus* *acidophilus* *casei* *reuteri* *fermentum*	
Immune system modulation	*Lactobacillus*	*acidophilus* LA1 *johnsonii* *rhamnosus* *casei* Shirota	Effect on epithelial, dendritic, monocyte/macrophage, and lymphocyte cells; enhancement of secretory IgA production; and production of modulatory hormones (cytokines)
	Bifidobacterium	*bifidum* Bb12 *lactis*	
Reduction of cardiovascular conditions	*Bifidobacterium*	*animalis* *longum* BL1	Assimilation/binding of cholesterol, deconjugation of bile salts, release of peptides with antioxidative and angiotensin-converting enzyme inhibition activities, and modulation of key genes and proteins involved in hepatic cholesterol metabolism
	Lactobacillus	*rhamnosus* *casei* *acidophilus paracasei plantarum* *helveticus*	
	Enterococcus	*faecium*	
Protection against urogenital infection	*Lactobacillus*	*acidophilus* *fermentum* *casei*	Adhesion to urinary and vaginal tract cells, colonization resistance, and inhibitor production (H_2O_2, biosurfactants)
Reduction of chronic liver damage (cirrhosis, hepatic encephalopathy)	*Bifidobacterium*	*bifidum* *breve* *infantis*	Stimulation of tight junction proteins, increase mucin production, decrease of intestinal bacterium overgrowth, decrease in production of lipopolysaccharides by intestinal microbiota, inhibition of urease-producing gut flora, and balance of production between pro- and anti-inflammatory cytokines
	Lactobacillus	*rhamnosus* GG *plantarum* *casei* *acidophilus*	
	Enterococcus	*faecium*	

(*Continued*)

Table 1 Continued

Target health benefit	*Probiotic genus/species*		*Postulated mechanism*
Prevention of dental caries	*Lactobacillus*	*rhamnosus* GG *reuteri*	Production of antimicrobial substances, binding in oral cavity, stimulation of nonspecific immunity and cellular immune response, and modulation of pH and modification of oxidation reduction potential
Prevention of allergies (rhinitis and asthma) and topic diseases (eczema, atopic dermatitis)	*Bifidobacterium* *Lactobacillus*	*animalis* *lactis* *rhamnosus* GG, *sakei* *acidophilus* *casei* Shirota *paracasei* *johnsonii*	Improvement of gut-associated lymphoid tissue, attenuation of proinflammatory response, induction of release of IFN-γ and TNF-α by monocyte-derived DCs, and modulation of Th1/Th2 balance and mucosal IgA levels as well as allergen-specific B- and T-cell responses
Reduction of urinary stones	*Lactobacillus*	*animalis*	Degradation of oxalate by oxalyl-CoA decarboxylase and formyl-CoA transferase
Prevention of Crohn's disease, ulcerative colitis, and irritable bowel syndrome	*Lactobacillus*	*rhamnosus* GG *casei* Shirota	Enhancement of barrier function (increase in mucus production, enhancement of barrier integrity) and downregulation of proinflammatory agents
Reduction of pain perception	*Lactobacillus*	*paracasei* *reuteri* *acidophilus* *plantarum*	Activation of submucosal immune cell sensitizing sensory terminals, and/or regulation of tight junctions, interaction with ion channel in enteric sensory nerves, and modulation of transcription of genes implicated in pain transmission
Prevention of osteoporosis	*Lactobacillus* *Bifidobacterium*	*helveticus* *salivarius* *brevis* *infantis* *longum* *breve*	Degradation of mineral-complexing phytic acid and stimulation of calcium uptake by enterocytes

Abbreviations: DCs, dendritic cells; IFN-γ, interferon-gamma; IgA, immunoglobulin A, and TNF-α, tumor necrosis factor-alpha.

Regarding regulation of health claims focused on probiotics, the European Union (EU) decided that such claims should be approved (or vetoed) centrally through the European Food Safety Authority (EFSA) (Parma, Italy) to ensure that consumers are not misled by false, ambiguous, or misleading claims of any sort. EFSA, in turn, delivers a scientific opinion based on the dossier submitted with the claim and on the relevant Nutrition and Health Claims Regulation (1924/2006) after resorting to specialized panels. Despite the vast scientific evidence (e.g., peer-reviewed publications, human trials, metaanalyses) describing beneficial effects associated with probiotic consumption in well-designed studies, more than 300 applications pertaining to probiotics submitted under the EU Nutrition and Health Claims Regulation have received negative assessment by EFSA, and consequently no approval by European Commission. Among the most problematic rejections, one may outline refusal of the health claim dossier related to *Lactobacillus casei* Shirota (Yakult strain), *L. casei* DN-114-001 (Danone strain), and *Lactobacillus rhamnosus* GG (LGG) (Valio-licensed bacteria). Other strains rejected by the health panel, on submission to EFSA under digestive and vaginal health claims, were *L. casei* DG CNCM I-1572, *Lactobacillus crispatus* BCCM/ Gent Laboratory of Microbiology (LMG) P-17631 (ID1030, 2950), *Lactobacillus gasseri* BCCM/LMG P-17632 (ID 2956), *L. gasseri* BCCM/ LMG P-18137 (ID 2957, 2958), *Lactobacillus paracasei* CNCM I-1687 (ID 2960, 2961), *L. paracasei* CNCM I-1688 (ID 2962, 2963), *Lactobacillus plantarum* BCCM/ LMG P-17630 (ID 2966, 2967), *Lactobacillus salivarius* CNCM I-1794 (ID 2970, 2971), a blend of *Bifidobacterium animalis* ssp. *lactis* Bf-6, and *Lactobacillus johnsonii* La-1 (ACD-1) (CLbA22) (ID 4231). In addition, EFSA's Panel on Dietetic Products, Nutrition and Allergies rejected *L. casei* DG CNCM I-1572, *Saccharomyces cerevisiae* var. *boulardii*, *Propionibacterium freudenreichii* SI 41, and *P. freudenreichii* SI 26.

Most probiotic health claims have so far been rejected by EFSA on the basis that the strains involved were not adequately characterized, the cause-and-effect links have been poorly substantiated, and ambiguous experimental designs were followed (e.g., inappropriate sample size and daily dose

intake in human trials). EFSA has also criticized the scientific validity of some biomarkers used, e.g., cytokines, chemokines, and antibody titers. The fact that such dossiers were rejected should not be interpreted as lack of substantiated probiotics, nor that products containing rejected strains have not been shown to provide health benefits to humans – nor even that probiotics have failed to satisfy specific safety standards. Moreover, many studies on probiotics proceeded from academic sources with no intention of product testing, and were conducted before EU regulation. Consequently, EFSA has published in 2011 a guidance document on the scientific requirements for health claims related to gut and immune function so as to facilitate submission of applications for authorization of health claims; this guide addresses the beneficial effects and outcome measures that are acceptable for substantiation of claims in these areas. However, such guidance also leaves several important issues unaddressed, such as recognition of biomarkers for probiotic validation, requirements for study protocols and clarification of the definition of 'healthy subjects' – which still leaves a number of hurdles in preparing a dossier that meets EFSA standards. In this regard, an expert panel formed by academic scientists with a documented record in probiotic research recommended that future studies should be designed, executed, and evaluated by multidisciplinary teams consisting of microbiologists, nutritionists, statisticians, etc.; should always formulate a precise and concrete hypothesis, and appropriate goals and parameters before starting a trial; should ensure that trials have a sufficient sample size, so that they are adequately powered to reach statistically significant conclusions, either supporting or rejecting any *a priori* hypothesis – and taking into account adjustment for multiple testing (this might necessitate more than one recruitment site), appropriate duration, focus on single, primary objective, and evaluation of multiple parameters only when they are hypothesis driven.

Probiotics as Intestinal Barrier against Ingested Toxic Compounds

It is well established that diet is an important etiological factor in human carcinogenesis, as mutagenic/carcinogenic substances have been found in food – e.g., heterocyclic amines, acrylamide, and mycotoxins. However, the ability of probiotic bacteria to adhere to mucus and/or intestinal epithelial cells is one of the mechanisms aimed at protection of the host organism from pathogen invasion and noxious molecules. In this respect, it has been reported that intestinal bacteria can bind mutagenic compounds *in vitro*, and the ability of such bacteria to bind those toxic compounds correlates well with *in vivo* assays – as noted by reduced rates of intestinal toxin absorption after exposure to the bacterial strains. Some LAB may indeed act as biological barrier under normal intestinal conditions, thereby reducing the bioavailability and toxic effects of these dietary xenobiotics.

Biological Control of Intestinal Absorption of Aflatoxin (AF)

AFs are a group of toxic secondary metabolites produced in nature during growth of some fungi (*Aspergillus flavus, Aspergillus parasiticus*, and *Aspergillus nomius*) on a variety of substrates, such as grains, cereals, and dried fruits in their pre- and/or postharvest period, storage, and/or transport. As many as 20 forms of AFs and their metabolites exist; of these, AFB_1 is considered one of the most potent mycotoxins in nature. In humans, its ingestion through contaminated food has been associated with liver and kidney necrosis, and mutagenic, carcinogenic, teratogenic, immunosuppressive, and cytotoxic effects, as well as Reye's syndrome. Moreover, presence of AFB_1 goes along with the very high incidence of primary liver cancer in some countries. Various pre- and postharvest methods have been implemented to detoxify and/or inactivate AFs, which include removal of AFs when they are present in identifiable portions, or degradation by physical and/or chemical methods. However, these strategies are far from being effective in detoxifying food because they generate adverse effects on nutritional and sensory quality, exhibit poor performance and/or its implementation is expensive.

Therefore, biological methods have attracted considerable interest as alternative to reduce or minimize the toxic effects of food contaminated with AFs. Such biological methods include biodegradation of mycotoxins in food, or diet modification through improved nutritional content – either by addition of phytochemicals or by addition of agents able to taken up a degrade AFs. In this respect, recent studies have shown that select strains from *Lactobacillus, Bifidobacterium*, and *Lactoccocus* genera can remove AFs in the *in vitro*, *ex vivo*, and even *in vivo*; it appears that their antiaflatoxigenic mechanisms entail binding of AFs by some of its cell wall components, but the binding mechanisms are not well-understood yet. Lahtinen *et al.* (2004) have suggested that AF binds predominantly to polysaccharides and peptidoglycans of the bacterial cell wall (BCW), including a relevant role of teichoic acid.

AFs and probiotic bacteria

Although direct experimental evidence on the suppression of cancer in humans mediated by probiotic bacteria is still scarce, many indirect evidence is available: for instance, the *in vitro* assay conducted at University of Perugia, Perugia, Italy, demonstrated the ability of LAB obtained from various commercial dairy products to inhibit the genotoxic effect of a potent carcinogen (4-quinoline-1-oxide), but such protective effect is strain and genus dependent. Additionally, studies involving animal models have established beyond reasonable doubt an indirect relationship between probiotic microorganism consumption and cancer development. Among the underlying mechanisms, the following appears likely: (1) modulation of immune system (improved resistance to chemicals, inflammation, and other factors); (2) alteration of metabolic activities of the intestinal microflora (production of antitumorigenic and antimutagenic compounds); (3) alteration of physicochemical conditions in the colon (improved intestinal permeability, delayed or denied absorption of toxins, and improved renewal of colonocytes); (4) improvement (quantitatively and qualitatively) of the intestinal microflora, reducing the putative producers of carcinogens and cancer promoters (by improvement of the intestinal microecology as more bile acid-degrading bacteria, and fewer bacteria-producing azoreductase, nitroreductase, β-glucuronidase, and β-glucosidase); and (5) binding and/or degradation of carcinogens themselves.

The latter hypothesis is of particular relevance with regard to probiotic bacteria: the cell wall of Gram-positive bacteria

chiefly comprises a single homogeneous layer of peptidoglycan or murein (20–80 nm), composed of identical subunits of sugars and amino acids that form a mesh-like layer. Its sugar component consists of alternating residues of β-(1,4) linked, *N*-acetylglucosamine (NAG), and *N*-acetylmuramic (NAM) residues (Figure 2(a)); attached to the NAM acid is a tetrapeptide chain, which can be cross-linked to the peptide chain of another strand forming the 3D mesh-like layer (Figure 2(b)). Teichoic acids are associated with peptidoglycan through a covalent bond with the NAM acid, to the cell membrane lipids (lipoteichoic acids), or to a terminal D-alanine in the tetrapeptide cross-links between molecules of NAM (Figure 3); the said acids extend to the surface of the peptidoglycan – and contribute to provide a negative charge to the cell wall. Recall that the basic structure of teichoic acid is a linear chain of repeated units of glycerol or ribitol linked via phosphodiester bonds (Figure 3); this basic structure allows for minor changes, for example, inclusion of sugar residues or replacement of the side chain, as well as frequency of substitution in linear chain or polymer backbone. However, several bacteria produce exopolysaccharides (EPS) that play an important protective role against conditions of desiccation, toxic agents, bacteriophages, and osmotic stress, while also allowing adherence to surfaces and formation of biofilms. These EPS are present in two different forms, depending on their location: as surface polymers closely related to the cell surface,

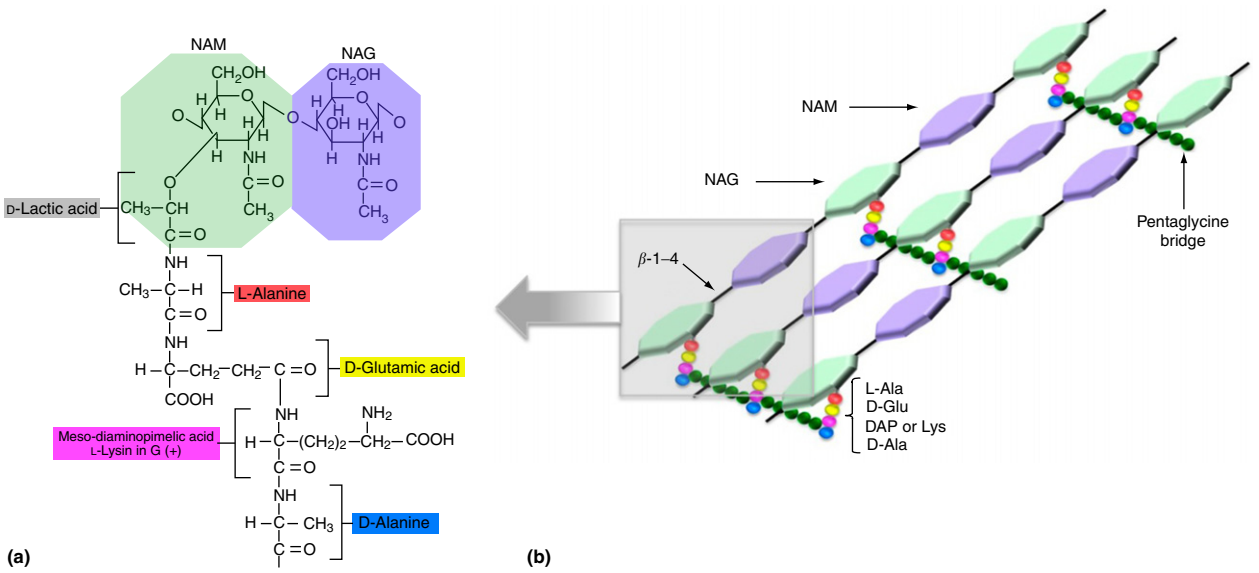

Figure 2 Peptidoglycan subunit (a) and structure (b).

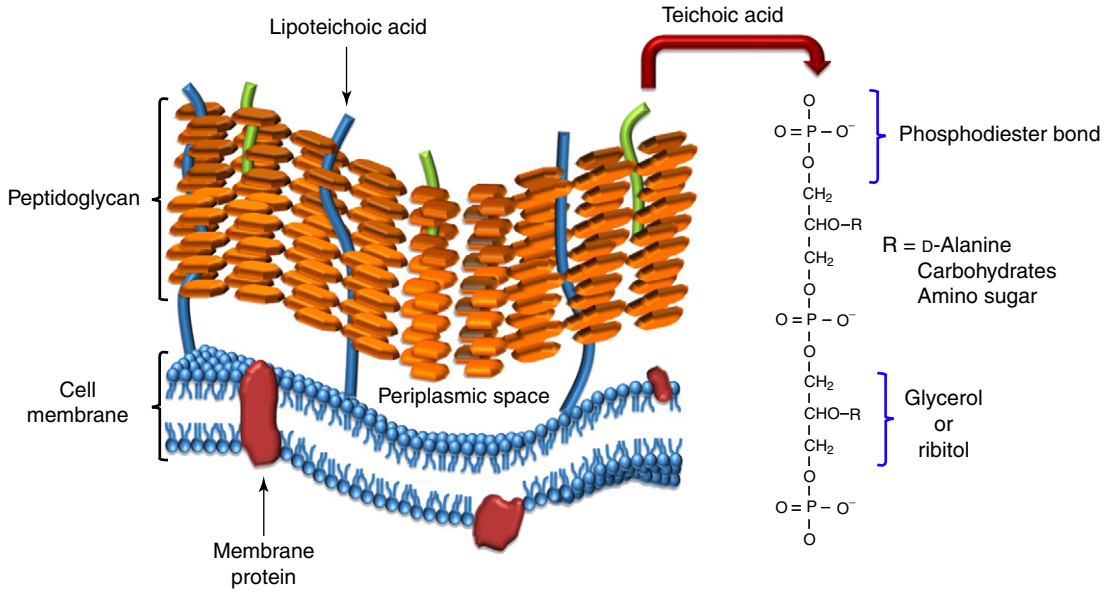

Figure 3 Typical cell wall of Gram-positive bacteria and basic structure of teichoic acids.

or viscous polymers loosely associated therewith. Information concerning the presence of polysaccharides, teichoic and lipoteichoic acids, as well as surface proteins apparently relate to the binding capacity of AFB_1 by probiotic bacteria.

Zhang and Ohta (1991) have accordingly reported that some intestinal bacteria are capable of inactivating pyrolyzed mutagens by absorption; both intact cell and cell wall fragments bound the mutagen at different extents, thus suggesting that the main components involved in binding are polysaccharides and peptidoglycan. It was also reported that purified cell walls of *Bifidobacterium longum* (SBT 2928) and four different strains of *Lactobacillus acidophilus* have a higher binding capacity of 3-amino-1,4 dimethyl-5H-pyrido [4,3-b] indole compared with the crude extracts, peptidoglycans, or cell extracts. Additionally, the mutagen-binding capacity was reduced when the cell walls were treated with compounds that degrade carbohydrates or release polymers therefrom (metaperiodate or trichloroacetic acid, respectively); conversely there was no effect when they were treated with proteolytic enzymes (trypsin or proteinase K). Two viable strains of LAB were also tested for their ability to bind such carcinogenic compounds in human diet as heterocyclic amines, benzo(a)-pirene, and AFB_1, which was influenced by pH. The results of recent studies on the ability of viable and nonviable probiotic bacteria (*Lactobacillus* and *Bifidobacterium*) to remove AFs in aqueous media, probably via the BCW or some of its components such as peptidoglycans and polysaccharides, support the hypothesis that some probiotic bacteria are able to bind specific dietary contaminants, in a process dependent on the strain used, the nature of the bacterial population and its viability, its physiological state, and pH of the medium.

The efficiency of nonviable bacteria (inactivated by heat treatment or acid) to bind AFs, indicate that toxin removal is not dependent on active metabolism; the inhibitory effects of periodate and pronase E (compound and nonspecific enzyme able to degrade carbohydrates and proteins, respectively) support that carbohydrates and proteins in the cell wall are crucial in the process of AFB_1 binding, with a major role of cell surface hydrophobicity in the case of *Bifidobacterium bifidum* BGN4. Additionally, Lahtinen *et al.* (2004) carried out experiments to establish which components of the cell envelope maybe involved in the AFB_1 binding process by LGG and evidence was found for AFB_1 binding to cell wall peptidoglycan or compounds tightly associated with it (e.g., proteins not covalently bound). Although cell wall peptidoglycans and polysaccharides appear as the two most important compounds in binding of AFB_1 by probiotic bacteria, recent evidence has shown that teichoic acids might be highly related in this phenomenon (Figure 4). The actual extent of binding of AFB_1 by LGG in the presence of divalent ions (Ca^{2+}) is low, so it suggests that the strongly cationic character of the polycation (Polymyxin B) may reduce AFB_1 binding by blocking possible interactions of AFB_1 and teichoic acids on the surface of BCWs.

However, there are variations of structure among wall teichoic acids (such as inclusion of sugar residues in the polymer backbone, or side chain substitution of the polyol residues) – and it is likely that all these structural variations convey different AFB_1 binding properties: they (partially) explain the differences in AFB_1 binding ability among bacteria. Additionally, changes

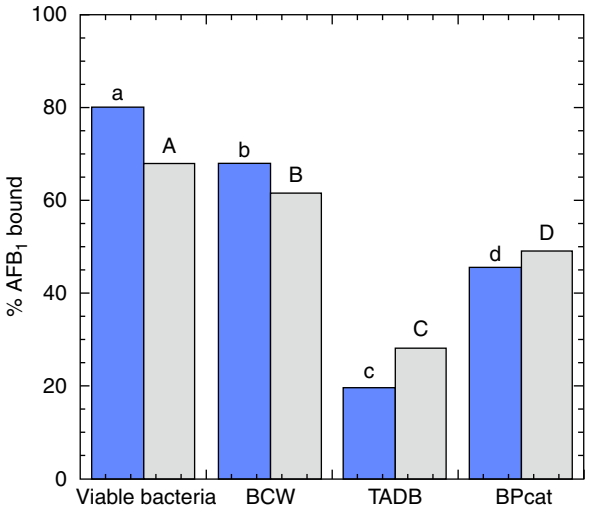

Figure 4 Percentage of AFB_1 bound by viable bacteria (*Lactobacillus reuteri* (*n*), *L. casei* Shirota (*n*)), BCW, teichoic acid-deficient bacteria (TADB), and bacteria treated with polycation (BPcat). Reaction conditions: pH 7.2, initial level of 6 μg AFB_1, exposure time of 4 h, inoculum of 1–3 × 10^{10} CFU per ml, and temperature of 37 °C. Treatments with different letters for each column are statistically different from one another for each strain ($p \leq .05$); capital letters represent statistically significant differences for *L. casei* Shirota, and small letters represent statistically significant differences for *L. reuteri*.

in surface morphology of the bacteria induced by the AFB_1 binding were determined using atom force microscopy (Figure 5). The interaction of AFB_1 with the cell wall causes conformational changes that alter the bacterial cell surface, probably via attachment to the primary polymer layer.

Prebiotics

Probiotic bacteria are highly specialized in metabolizing complex carbohydrates, being primarily carbohydrate-fermenting bacteria; the products of carbohydrate fermentation are beneficial to host health, in opposition to products released by proteolytic activity and amino acid fermentation. However, prebiotic carbohydrate may directly interact with pathogens, thus also protecting the host. The first step in pathogenesis is the interaction between pathogens and epithelial cell surface receptors – which is likely affected by the presence of prebiotics that mimic host cell receptors; some prebiotics have indeed been shown to structurally resemble the saccharide-containing glycoproteins of intestinal cells. Inhibition of bacterial adherence is strain dependent, so the effects shown by prebiotics may be due to modulation of virulence genes of the pathogen; expression of virulence genes could in turn be related to prebiotics acting as signaling molecules, or to a more global control as catabolite repression.

Prebiotics and Immune Function

Several pieces of evidence suggest that prebiotics do influence some aspects of host immunity. Supplements containing

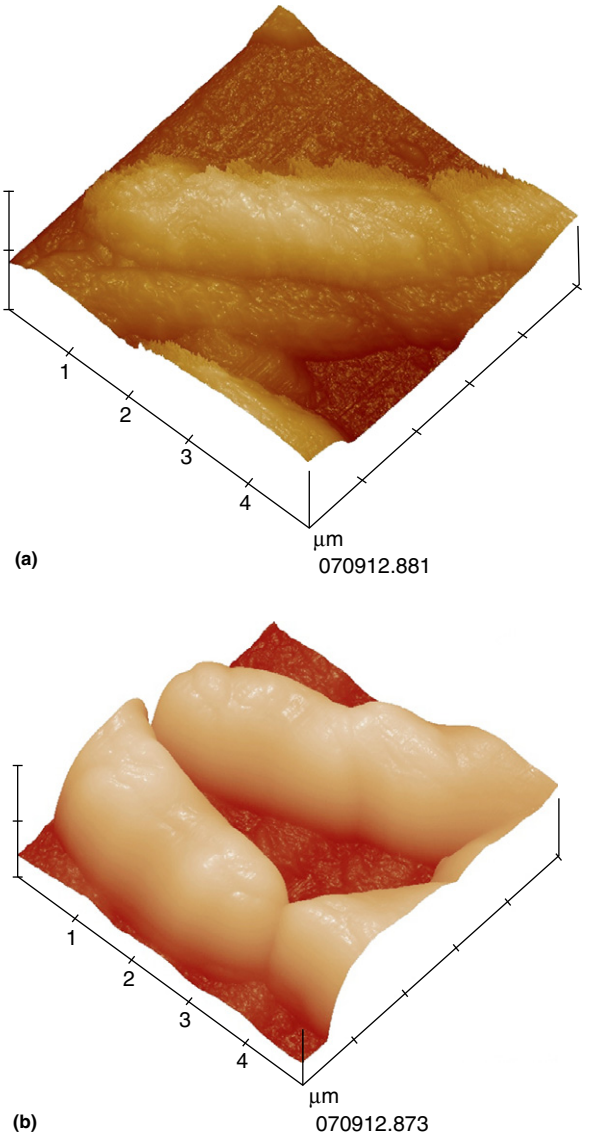

Figure 5 Atomic force micrographs, taken in taping mode (scan size 5.0 µm, scan rate 0.15 Hz), of *Lactobacillus casei* Shirota: (a) with, and (b) without, AFB_1 bound to their cell surface.

prebiotics, especially β-fructans, either alone or in combination with other components (e.g., other prebiotics, antioxidants, vitamins, minerals, and fats, as well as probiotics) were studied via ingestion by animals and humans – and resolved the effects on gut-associated lymphoid tissues (GALT), made up of the mucosa-associated lymphoid tissues of the gut and located underneath an epithelial layer and mucus layer, and the systemic immune system itself – via measurement of blood immune markers and immune cell responses. Recall that specific epithelial layer cells are responsible for antigen transport from the gut into the GALT, where antigen is processed and exposed to lymphocytes (that play an important role in the antitumor immunity and destruction of virus-infected cells, which are in turn responsible for activation and transportation to mesenteric lymph nodes (MLNs) and blood (where they are relocalized in the intestine).

Innate immune system

Studies related to GALT in innate immune system showed enhancement of cecal macrophage and granulocyte numbers and respiratory burst, as well as increase of peritoneal macrophage phagocytic activity in response to antibiotic treatment following ingestion of prebiotics. Major histocompatability complex (MHC) II molecule expression was also shown to increase in antigen-presenting cells in the MLN of rats. It appears that intake of prebiotics can improve the innate immune system of the gut, thus leading to a beneficial effect on the host's primary response to infection; however, lymphocyte natural killer cell activity was not affected by said prebiotics.

The systemic immune system has been more widely studied regarding prebiotic supplementation than GALT; however, all animal studies pointed at minimal (or none) effect of various prebiotics and prebiotic mixtures. No effect on monocyte, eosinophil, and neutrophil numbers in the blood, nor on phagocytic activity in the blood or spleen were found; as observed in GALT, MHCII expression was increased in antigen-presenting cells in the spleen and thymus of rats; and likewise prebiotic supplementation did not affect natural killer cell activity in peripheral blood, though increased natural killer activity of splenocytes, and natural killer cell-like cytotoxic function was unfolded in the spleen. Conversely, a decrease in monocyte and granulocyte phagocytosis was observed in human studies.

Adaptive immune system

As immunoglobulin A (IgA) antibodies prevent adherence of pathogens to the gut mucosa surface, IgA is used as a marker, to measure the potential effect of supplementation with prebiotics. In GALT animal studies, the animal used and its age seems determinant to enhance the prebiotic-mediated immune function: the effect is higher in younger animals, perhaps due to their gut immune system being under development, and thus more susceptible to modulation. Other studies using T cells as markers show that the effects of prebiotic supplementation on cell-mediated immunity in GALT are dependent on site of origin of cells and animal model used. In what concerns the systemic immune system, prebiotic supplementation tends to be associated with a decrease in serum antibody concentrations, a decrease in proportion of B cells in the peripheral blood, and a decrease in serum IgG_1 – yet no effect on total serum Ig exists. Once again, prebiotic supplementation causes little effect on systemic immunity, and – if present, it is a suppressive effect. As with GALT, prebiotics may alter T-cell subpopulations, but appear not to have any effect on lymphocyte proliferation in the spleen.

Unlike results reported in human studies regarding the innate immune system, experimental results regarding the adaptive immune system suggest modification by prebiotics: An increase in blood B cell numbers was indeed recorded, but no effect on serum Ig concentrations (IgA, IgG, and IgM) was achieved; an increase in fecal secretory IgA levels (correlating with enhancement of antibody response in GALT by prebiotics) was observed, but no effect on salivary secretory IgA levels. Prebiotics may also increase the response to some vaccines (or vaccine components), but different results on blood lymphocyte subsets are found depending on the site of origin of the cells.

Table 2 Selected effects of prebiotics on infections and inflammation in animal models and in humans

Type	*Effects on infections*	*Effects on inflammation*
Inulin	*Animal studies*	
	In *Salmonella typhimurium*-infected host, decrease in severity of enterocyte sloughing and epithelial damage, via decrease in ileal Na^+	Decrease in mucosal damage in several parts of the gut and decrease in myeloperoxidase activity in induced colitis
	Decrease in mortality by *S. typhimurium*	Plus probiotics, decrease in colonic inflammation after induced colitis
	Decrease in *S. typhimurium* translocation to liver and levels of serum aminotransferase	
	With calcium deficiency, increase in *Salmonella enteritidis* colonization and translocation and increase in myeloperoxidase activity in cecum and colon	
	Decrease in densities of *Candida albicans* in small intestine	
	Vanishment of mortality from *Listeria monocytogenes*	
	Decrease in *Oesophagostomum dentatum* fecal egg count, as well as total colonic intestinal worm recovery	
	Plus fiber, decrease in *O. dentatum* fecal egg count and numbers in large intestine, as well as female worm fecundity	
	Decrease in fecal egg count, number of worms recovered in large intestine, and fecundity of female *Trichuris suis*	
	Plus fiber, decrease in fecal egg count and worms of *T. suis*	
	Human studies	
	Plus probiotic *Saccharomyces boulardii*, eradication of *Helicobacter pylori* in children	Reduction in total histological and endoscopic scores, mucous exudates, and total pouchitis disease activity index in patients with ileal pouch–anal anastomosis
	Plus fiber and probiotics, decrease in duration of antibiotic therapy, and incidence of postoperative upper and lower urinary tract infections in adult patients undergoing liver transplantation	Reduction in disease activity scores and increased expression of toll-like receptor 4 on dendritic cells in lamina propria in patients with ileocolonic Crohn's disease
	Plus fibers and probiotics; decrease in duration of antibiotic therapy; and the bacterial infections in wounds, peritonitis, and pneumonia in adult patients undergoing duodenal surgery	Plus probiotics, amino acids, and vitamins, decrease in abdominal pain, distension, and constipation in irritable bowel syndrome in adults
	Plus fibers and probiotics, decrease in systemic infection rate, septic complications and inflammatory response syndrome, severe sepsis, and duration of stay in intensive care unit and under mechanical ventilation	
	Increase in calcium and magnesium absorption	
Fructooligosaccharides (FOS)	*Animal studies*	
	In *S. typhimurium*-infected host, decrease in severity of enterocyte sloughing and decrease in epithelial damage	Decrease in gut mucosa inflammation, myeloperoxidase activity, and macroscopic damage in induced colitis
	In *S. typhimurium*-infected host, increase in ileal glutamine transporters and prevention of diarrhea	Decreased disease activity index and damage to distal colon in colitis-induced animal, faster recovery from damage
	Decreased shedding of *S. typhimurium* in feces and decreased mortality thereby	Decrease in occurrence and severity of intestinal lesions, dependent on clostridial species used to induce colitis
	Decreased cecal counts of *S. enteritidis*	
	Decreased mortality by *Candida difficile*	
	Decreased densities of *C. albicans* in small intestine	
	Decreased mortality by *L. monocytogenes*	

	Decreased mortality by *Escherichia coli,* and of symptoms of diarrhea, anorexia, pyrexia, and dehydration Plus probiotics, decrease in duration of diarrhea induced by *Rhesus rotavirus*	
	Human studies Increase in lactic acid bacteria concentration, fecal content of bifidobacteria, and mucin excretion Decrease in duration of diarrhea in children aged 1–14 years with acute diarrhea Plus vitamins and minerals, decrease in median days of upper respiratory tract infections in adults aged >65 years Decrease in relapse of diarrhea, in consecutive patients suffering from *Clostridium difficile*-associated diarrhea Increase in feeling of well-being, in healthy adults traveling to countries with a high risk of travelers, diarrhea Reduction in incidence of diarrhea-associated symptoms (fever, uncomfortable bowel movements, antibiotic use, and daycare absenteeism) in nonbreastfed infants Decrease in pathogenic Clostridia and lower incidence of diarrhea, vomiting, and fever during supplementation, and decrease in number of infectious diseases requiring antibiotic treatment in healthy infants Plus probiotics, reduction in incidence of pathogenic bacteria and multiple organisms in nasogastric aspirates	Reduction in disease activity scores and increased expression of toll-like receptor 4 on dendritic cells in lamina propria
Galactooligosaccharides (GOS)	*Animal studies* Reduction in numbers of *S. typhimurium* in organs (chiefly spleen), prevention of colonization and associated pathology of *S. typhimurium* in ileal loops Decrease in prevalence of *L. monocytogenes* in intestinal samples and in liver, spleen, and mesenteric lymph nodes (MLNs)	
	Human studies Decrease in incidence and duration of travelers' diarrhea, less abdominal pain, and better assessment of overall life quality in healthy adults traveling to countries with high risk of travelers' diarrhea Plus probiotics, decrease in respiratory infection frequency in infants	
Xylooligosaccharides	*Animal studies* Increase in prevalence of *S. typhimurium* in liver, spleen, and MLNs, and higher levels of serum haptoglobin Decrease in prevalence of *L. monocytogenes* in intestinal samples, and in liver, spleen, and MLNs	
Soyaoligosaccharides (SOS)	*Animal studies* In *S. typhimurium*-infected host, increase in ileal glutamine transports and prevention of diarrhea	
Transglucosylated oligosaccharides	*Animal studies* Plus probiotics, prevention of *S. typhimurium* growth in intestine, and subsequent translocation of some bifidobacteria	

(*Continued*)

Table 2 Continued

Type	*Effects on infections*	*Effects on inflammation*
Lactulose	*Animal studies* Reduced excretion in feces of *S. enteritidis*, and calcium-decrease translocation to the systemic circulation	
FOS/inulin	*Animal studies* Increased IgG in blood and fecal IgA against *S. typhimurium* (virulent strain) and macrophage phagocytic activity	Decrease in development of colitis (in terms of gross cecal scores, inflammatory histological scores in cecum and colon, and inflammation of gut mucosa) in induced colitis Plus probiotics, decrease in bacterial translocation to MLN, colonic myeloperoxidase activity as indicator of inflammatory granulocyte infiltration, and disease activity index in induced colitis
	Human studies Plus protein, fat, carbohydrate, vitamins and *Lactobacillus paracasei*, reduction in infections of respiratory, skin, gastrointestinal, and genitourinary nature in elderly free-living adults immunized with influenza and pneumococcal vaccines Increase in intestinal permeability to infants	Decrease in fecal calprotectin as marker of intestinal inflammation and perception of abdominal pain Plus probiotic, decreases in TNF-α and interleukin 1 alpha messenger ribonucleic acid (mRNA) levels in mucosal tissue and C-reactive protein levels in blood, and in mucosal tissue mRNA levels of β-defensins upregulated in ulcerative colitis
GOS/inulin	*Human studies* Increase in intestinal permeability to infants	
SOS/inulin	*Human studies* Plus *Lactobacillus rhamnosus*, zinc, and iron, decrease in duration of diarrhea in infants with acute diarrhea, and moderate dehydration	
FOS/GOS	*Human studies* Reduction in number of infectious episodes and incidence of recurring infections in infants with parental history of atopy Reduction in episodes of diagnosed infections, respiratory tract infections, and antibiotic prescriptions Reduction in intestinal infections and respiratory infections during the first year of life in healthy infants Decrease in incidence of acute diarrhea and number of children with more than three episodes of upper respiratory tract infections per year, as well as number of children receiving more than two antibiotic courses per year	Reduction in development of atopic dermatitis

Prebiotics in Infection and Inflammation

To improve host immune defenses, prebiotics would be expected to decrease susceptibility to and/or severity of infection. Available studies provide a consistent picture of prebiotics improving host resistance, thus preventing or reducing microbial gut infections (Table 2). It should be emphasized that a prebiotic effect does not necessarily imply that unwanted microorganisms are unable to ferment the prebiotic, as they may be stimulated thereby in the presence of surrounding microbiota.

A portfolio of distinct results of prebiotics have been reported in human studies (Table 2), including effects on frequency and duration of diarrhea; incidence of upper respiratory tract infections; intestinal permeability; and skin, GI, and genitourinary infections. Mostly studies show absence of or a beneficial effect, and, in general, suggest a reduction in incidence or duration of infections; nevertheless, with regard to advantages studies of prebiotics in adults are less convincing than studies in infants and children. Synbiotics (i.e., foods containing probiotics and prebiotics) appear to exert some beneficial effects on infections of intensive care patients, who are particularly susceptible to modifications of their immune system; the prebiotic effects in what concern the bacterial gut infections depend chiefly on the prebiotic site of action and the infective site of the pathogen.

In animal models of inflammation, prebiotics (e.g., β-fructans) convey a fairly strong protective effect in models of colitis and necrotizing entercolitis, unlike allergic airway eosinophilia. Findings appear be related to the proximity of the prebiotics site of action, as it happens with infection. Inflammatory bowel conditions in human adults are also improved following prebiotic supplementation, and a synbiotic supplement increases the protection against acute pancreatitis. Maybe due to the nature of the irritable bowel syndrome regarding relapse and remission pattern, most trials have failed to report beneficial effects of prebiotics administration.

Risks and Safety Assessment

Functional foods have been increasingly supplemented with probiotics and prebiotics despite uncertainties regarding their efficacy and safety. To be accepted as probiotic- and prebiotic-supplemented food, such ingredients should undergo preliminary comprehensive studies in order to determine their potential short- and long-term benefits, and their nutritional adequacy and toxicity – so as to eventually lead to a safe product.

The minimum effective prebiotic dose of a functional food ingredient to justify a health claims is 5–10 g day^{-1}, leading to a consumer exposure of 10–20 g day^{-1} (or even more) – thus becoming a nonnegligible fraction ($>$2–4%) of the daily diet. In this context, it is interesting to analyze the approach adopted to evaluate the safety of these products, since safety of most foods relies only on assessment of its macrocomponents – instead of undergoing evaluation as done with a food additives or drugs.

A food ingredient of natural biological origin, which has been widely consumed for its nutrient properties, without known detrimental effects, which is subject only to conventional processing, and for which unknown safety hazards exist, should be regarded as generally recognized as safe (GRAS). Hence, prebiotics (e.g., inulin-type fructans and GOS) have been recognized with their GRAS status, as their history of safe use is sufficient to guarantee safety to public authorities, users, and consumers. In the case of most prebiotics, however, the data of toxicological trials are insufficient (or not fully appropriate) for a complete safety assessment; although a great number of beneficial effects (e.g., prevention of lifestyle-related diseases) and toxic studies suggest that the administration of probiotics and/or prebiotics does not raise safety concerns of any kind some evidence points at adverse effects (or less beneficial side effects) of prebiotics regarding pathogen infections – e.g., increased susceptibility to pathogen translocation; and safety and clinical effects of a given product cannot be extrapolated to others. Furthermore, published evidence show that prebiotics increase the total number of beneficial bacteria, yet their clinical benefits may be subject to debate.

A wide range of probiotics and prebiotics (alone or incorporated in food) has been made available in recent years and this calls for caution in overinterpretation of some results; there is indeed too much uncertainty to draw reliable (and general) conclusions at present. Accreditation organizations and related food committees are very careful when they recommend routine ingestion of prebiotics, owing to the lack of data on long-term effects. In general, no dangerous risks to consumer health by prebiotics have been unfolded. The GI symptoms reported by some consumers are similar to those that follow an excessive consumption of fibers – and such reactions are largely individual in nature, so each consumer may experience a personal set of tolerance limits to these products, so they can adjust consumption to their own sensitivity.

Safety of Probiotics and Prebiotics

UK Svensson, UKS Life Science Consulting AB, Lund, Sweden; Lund University, Lund, Sweden
J Håkansson, ASIC, Arla Foods, Stockholm, Sweden

Glossary

Denaturing gradient gel electrophoresis A method for separating deoxyribonucleic acid (DNA) fragments according to their mobility under increasingly denaturing conditions.
Necrotizing enterocolitis Bacterial infection in the intestine, primarily of sick or premature newborn infants.
Pancreatitis Inflammation of the pancreas.
Prebiotics A selectively fermented ingredient that results in specific changes in the composition and/or activity of the gastrointestinal microbiota, thus conferring benefit(s) upon the host health.
Probiotics Live microorganisms, which when administered in adequate amounts, confer a health benefit on the host.
Pulsed field gel electrophoresis An electrophoretic technique in which the gel is subjected to electrical fields alternating between different angles, allowing very large DNA fragments to snake through the gel, and hence permitting efficient separation of mixtures of such large fragments.
Sepsis A systemic inflammatory response to a infection.

Introduction

Probiotics are defined by Food and Agricultural Organization of the United Nations (FAO)/World Health Organization (WHO) as "live microorganisms, which when administered in adequate amounts, confer a health benefit on the host." One of the most recent definitions of prebiotics is by Gibson *et al.* (2010) saying that prebiotics are "a selectively fermented ingredient that results in specific changes in the composition and/or activity of the gastrointestinal microbiota, thus conferring benefit(s) upon the host health." This definition is still limited to the gastrointestinal tract; however, a possibility to widen it to also include the oral cavity, skin, and urogenital tract is discussed.

Fermentation by lactic acid bacteria (LAB), molds, and yeasts is one of the oldest methods for a natural safe preservation of foods. The genus *Lactobacillus* has played a major role in food preservation. Today most of the probiotic bacterial strains that are used belong to the genus *Bifidobacterium* and the LAB group, e.g. lactobacilli. These are bacteria that have been safely used in foods by humans for a long time and have acquired a status as 'generally recognized as safe' (GRAS). Many prebiotic carbohydrates have their origin in plants and vegetables and occur naturally in chicory root, asparagus, onions, different vegetable roots, wheat, and oats that have been consumed as part of our daily food for thousands of years without any adverse effects.

During the past three decades, the number of food products with added pro- and prebiotics has increased considerably. Also new genera, species, and strains are introduced as probiotics. A few cases of adverse effects have been documented in severely ill patients or immune compromised individuals. This puts the focus on the necessity to handle the safety aspects of pro- and prebiotics in an appropriate way, and especially when probiotics are given to potentially vulnerable persons, the safety issues should be considered with great care.

This overview article deals with two kinds of safety issues for probiotics, namely, the potential risk of adverse effects from probiotics and the possibility to improve safety in a product by the use of food-grade bacteria or probiotic bacteria. The article also addresses the risk of adverse effects of prebiotics.

Safety Concerns Linked to the Probiotic Microorganisms

General Safety of Probiotics

Today both different bacteria and yeasts are used as probiotics (Table 1). Because the most commonly used probiotic bacteria belong to the *Lactobacillus* and *Bifidobacterium* genera, most of our knowledge on the general safety of probiotics is based on the experience gained from their use. Despite the common use of probiotics, reported correlations between consumption of probiotics and adverse effects are very rare. Adverse effects have only been reported in seriously ill patients or immune compromised persons, with a very few exceptions. Bifidobacteria and lactobacilli have been isolated from persons with bacteremia; however, no case is known where commercially used probiotic strains have been identified to cause an infection in healthy humans. Furthermore, in Finland, a country where the consumption of probiotics has increased significantly during the

Table 1 Examples of microorganisms used as probiotics in food, food supplements, and feed

Microorganism used as probiotics
Genera *Lactobacillus*
Species
● *Lactobacillus acidophilus*
● *Lactobacillus bulgaricus*

Species
● *Bifidobacterium bifidum*
● *Bifidobacterium infantis*
● *Bifidobacterium lactis*
● *Bifidobacterium longum*
Streptococcus
Genera *Enterococcus*
● *Enterococcus faecalis*
● *Enterococcus faecium*
Saccharomyces cerevisiae *biovar.* boulardii
Propionibacterium
Genera *Bacillus*
● *Bacillus subtilis*
● *Bacillus licheniformis*
Escherichia coli

past decades, no correlation between the increased consumption of probiotics and increase in bacteremia caused by lactobacilli has been identified. The risk of *Lactobacillus* infection in healthy persons has been calculated by Bernardeau *et al.* (2006), based on the ingestion and infection frequency of lactobacilli in France, to be approximately one in 10 million individuals during a century of probiotic consumption. This means that lactobacilli are a nearly negligible risk. In a large study supported by National Institutes of Health, 12 databases were searched for studies and reviews on safety of probiotics. It resulted in 622 studies being included in the analyses. The conclusion from this study is that 'the available evidence in randomized controlled trials does not indicate an increased risk; however, rare adverse events are difficult to assess.'

Safety of Probiotics When Used in Vulnerable Human Populations

The cases identified when probiotics have caused illness have been nearly exclusively when they have been given to seriously ill persons, for example, severely immune compromised individuals, people in hospital care, and neonates. Probiotics have been shown to have a potential to significantly lower the risks of infections and the need for antibiotics and thus positively influence the chance to become healthy. However, when used for those purposes in severely ill or hospitalized individuals, a few cases where the probiotic organisms have given an infection have been identified. When probiotics are used under those circumstances, they cannot be considered as food but are used as drugs and therefore a risk–benefit calculation needs to be done. However today, no probiotics are documented or sold as drugs, but as foods or food supplements, meaning that the risk–benefit calculations are missing. If probiotics are going to be used in the future for these groups at risk, careful assessments of risks must be done.

Areas Where Safety Issues Linked to Probiotics Are Especially Important

Transmissible Antibiotic Resistance

Humans or animals exposed to probiotic strains carrying antibiotic resistance genes that might be transferred to the commensal microbiota *in vivo* are at a risk. This issue has been addressed in the European Union (EU) founded project 'Biosafety Evaluation of Probiotic Lactic Acid Bacteria for Human Consumption' and in the 'Assessment and Critical Evaluation of Antibiotic Resistance Transferability in the Food Chain' project where the antibiotic resistance character of a large number of strains was analyzed and recommendations on the determination of safety was given. The cut-off values for different antibiotics in different bacterial species were set. Antibiotic susceptibility of other strains belonging to the same species can be compared with those cut-off values to judge the possible acquired antibiotic susceptibility in a specific strain. Special focus on the transfer of antibiotic resistance genes and the presence of virulence genes has been given to the genus *Enterococcus*. The antibiotic resistance questions have also been in focus in the International Organization for Standardization (ISO) and International Dairy Federation joint Action Team on Probiotics.

Probiotics to Severely Ill Individuals

In severely ill patients, the gut function is critical and the risk of a breakdown of the gut barrier is increased. This increases the risk of sepsis, systematic inflammation, and multiorgan failure. The potential for probiotics to act beneficially in this group is large; however, the risk of adverse effect is also increased compared with healthy individuals.

A number of studies on the incidence of infection and the need for antibiotics in patients undergoing abdominal surgery have shown significantly fewer infections in patients who were given probiotics. In one study, the probiotic prophylaxis in predicted severe acute pancreatitis (PROPATRIA) study, a combination of six strains, belonging to the *Lactobacillus* and *Bifidobacterium* genera were given to patients severely ill with pancreatitis. The incidence of infection was similar in the placebo and the probiotic groups; however, the mortality rate was significantly higher in the probiotic group, 16% compared with 6% in the placebo group. The discussions on demands for better risk assessment methods when probiotics are given to the seriously ill patients raised by this study were summarized by Morrow *et al.* (2012).

A large review study by **Whelan** and **Myers (2010)** was done, according to Cochrane and Preferred Reporting Item for Systematic Reviews and Meta-Analyses (PRISMA) recommendations, to investigate the possible adverse effects of probiotics given to patients receiving nutritional support. The participants were hospitalized patients – undergoing surgery or transplantation or pancreatitis patients. A total of 53 trials

were included where 4131 patients received probiotics and 3643 placebo. According to the outcome of mortality or infection, most trials showed less mortality and less infections or no effect in the probiotic group compared with placebo. There were case reports of adverse effects for 32 patients due to infections with *Lactobacillus rhamnosus* or *Saccharomyces boulardii*. The main risk factor was the use of a central venous catheter and increased translocation.

Immune Compromised Persons

The gut microbiota is essential for the development and maintenance of the immune function, which also involves maintenance of the gut barrier function. Probiotics might give a great benefit to immune compromised persons; however, this is also a group of individuals where the risk of adverse effects, such as sepsis is large. The mechanisms behind probiotic effects on the immune system are not very well known. Some strains have been seen to stimulate the immune system and enhance the response to pathogens, whereas some other strains can decrease inflammation and allergy. Thus to achieve the desired effects on the immune system, the choice of strains is very important.

Infants

The sterile gut of a newborn baby is quickly colonized with different microorganisms, including bifidobacteria, lactobacilli, enterococci, and *Escherichia coli*, and at 1 year of age the gut microbiota is similar to the adult one. The colonization of the gut is crucial for its maturation and for the development and maintenance of the immune system. Many studies have been conducted on probiotics in healthy full-term infants with positive effects on health and no adverse effects. Still, long-term effects are not well studied and methodologies to identify infants at possible risk for adverse effects are missing. Thus there is a need for more studies on long-term effects of probiotics in term infants.

Preterm infants are often separated from their mothers and raised during their first period of life under strict hygienic conditions, with impaired enteral feeding and exposure to antibiotics. This means that the colonization of the gut is very different from that of term infants, for example, fewer species are colonizing the gut and the colonization with bifidobacteria is delayed. A risk in preterm infants is the development of necrotizing enterocolitis (NEC), which is a rare but severe consequence of an immature gut and impaired mucosal barrier. Intervention studies with probiotic strains of lactobacilli, bifidobacteria, or streptococci have been seen to reduce the incidence and severity of NEC. Neither in this study by Dani *et al.* (2002) nor in a study by Lin *et al.* (2008), altogether including 729 infants, was sepsis identified. Thus in preterm infants, the use of probiotics to diminish the risk of NEC is very promising but risk–benefit estimation needs to be done. As in term infants the long-term effects of probiotics is not known and need to be investigated.

Humans produce L(−)-lactate only and all the D(+)-lactate present in humans is produced by microorganisms or through microbial conversion of L(−)-lactate to D(+)-lactate. If large amounts of D-lactate is built up in children, it may create acidosis. This has been detected in children with short bowel syndrome and with a gut microbiota dominated by lactobacilli. Acidosis has not been detected in healthy children, but it cannot be ruled out that giving large doses of LAB producing the D(+)- isomer might be a risk. To avoid this, probiotics given to children shall produce only L(−)-lactate.

Weight Gain and Probiotics

The gut microbiota has been shown to be important for carbohydrate and fat metabolism. The microbiota differs between obese and lean persons and the major difference identified so far is that the diversity is less in obese subjects. These results together with the fact that probiotics have long been used to avoid the need for antibiotics to keep animals raised for meat production healthy, and for quick gain of weight initiated a question on whether the use of probiotics induces obesity. However, it is important to keep in mind that when young animals get probiotics they get fewer infections and grow faster because they are healthy. From this no conclusion on cause of obesity can be drawn. There are studies that have shown that probiotics might influence fat metabolism in a favorable way and reduce fat deposition. Thus today there are no data supporting the view that probiotics contributes to obesity in humans.

Safety Regulations and Probiotics

In Europe, the European Food Safety Authority (EFSA) has introduced an approach for safety assessment of bacterial strains including probiotics called 'qualified presumption of safety' (QPS). The approach was introduced in 2007 and is updated every year for new microorganisms. The safety assessment of specific taxonomic groups of microorganisms is done according to taxonomic identity of the strain, body of knowledge, possible safety concern (pathogenicity), and intended end use. If the taxonomic identity does not raise safety concerns, the taxonomic unit can be put on the QPS list and the only further safety studies needed are on antibiotic resistance. If a microorganism does not belong on the QPS list, considerable assessments of food safety are needed before it can be used in foods. The genera *Lactobacillus* and *Bifidobacterium* are all on the QPS list.

FAO/WHO introduced guidelines for the use of probiotics in foods. This includes establishing the safe use in traditional products, absence of transmissible antibiotic resistance, absence of risks with virulence properties, no production of D-lactate, no toxin production, no hemolytic properties, no side effects in human interventions, and epidemiologically known to be safe (the latter is done postlaunching). No proper instructions on how the documentation shall be done are available. Lactobacilli, bifidobacteria, and *Saccharomyces cerevisiae* belong to the organisms stated as GRAS.

Canada has recently developed guidelines for the industry called 'recommendations for the evidence requirements for efficacy, safety, and quality of natural health products containing probiotics.' In Norway, the Norwegian Scientific Committee for Food Safety has evaluated the safety of a few probiotic strains. Guidelines for the regulation of probiotics in food are to be introduced.

In China, guidelines are available since 2005 and all foods with a health claim require an application to and approval by

the State Food and Drug Administration concerning efficacy, safety, and quality.

Basic Safety Documentation for Probiotics

Based on the regulations in different countries and from the available literature, the following issues are important for a proper safety assessment of a probiotic organism:

- Proper taxonomic identification at strain level.
- The nature of the microbe (linked to taxonomy).
- Absence of transmissible antibiotic resistance genes.
- Genetic stability.
- Absence of infectivity and translocation properties.
- Absence of toxin production.
- The population for which the product is intended for must be considered and if it is intended for any vulnerable population, extended risk assessments need to be done.
- Method of administration.
- For production of the probiotic products, good manufacturing procedures need to be used to ensure the hygiene and safety standards needed.

Sequencing of the genome of a probiotic organism is a useful tool to analyze the presence of possible genes that are linked to unwanted characteristics, such as antibiotic resistance and toxin production.

Modern molecular biological methods should be used for proper taxonomic identification at species and strain levels. These include the analysis of the ribosomal ribonucleic acid subunit 16S, the use of strain-specific primers, and deoxyribonucleic acid finger printing techniques, such as ribotyping, pulsed field gel electrophoresis, and denaturing gradient gel electrophoresis.

Safety Issues Linked to Prebiotics

The target microbiota of prebiotics is dominated by the genera *Lactobacillus* and *Bifidobacterium*. It is the bifidobacteria that have been in the main focus and the possibility of these influencing the gut microbiota and increasing the number of bifidobacteria has gained much attention. The requirement for a prebiotic was more precisely described by Gibson *et al*. as a substance resistant to gastric acidity and hydrolyzes by mammalian enzymes and adsorption. It can be fermented by intestinal microflora and it selectively stimulates the growth and/or activity of intestinal bacteria associated with health and wellbeing.

Many prebiotic carbohydrates such as inulin and fructooligosaccharides (FOS) are natural constituents of foods. In the US, inulin and FOS have a status as GRAS since 1999. No severe side effects have been seen with prebiotics and the major side effect attributed to prebiotics is cause of osmotic diarrhea, rumbling, and abdominal pain due to bloating, cramping, and/or flatulence. This is because the polysaccharides and oligosaccharides are not broken down by intestinal enzymes but transported to the colon where they are fermented. Daily high doses, 40–50 g, have been seen to cause osmotic effect, whereas low doses 2.5–10 g may cause fermentation and possible flatulence. It appears that the chain length of inulin-type prebiotics influence the severity of side effect, that is, shorter chain length increases the side effect. The theory behind this is that shorter inulin molecules are metabolized primarily in the proximal colon and thus are more rapidly fermented, whereas longer chains are fermented in the distal colon.

The daily dose required to achieve a positive effect on the gut microbiota or on other health effects from prebiotics is in most studies 2.5–10 g and most products on the market today have doses of 1.5–5 g per portion. This means that the dose for a positive effect touches the dose for a mild side effect. Most probably the large majority of humans can eat this amount without side effects but if more and more products are being fortified with prebiotics, this needs additional attention (Table 2).

Table 2 Examples of carbohydrate used as prebiotics in food and feed supplements

Carbohydrates with documented prebiotic effect
Fructans
● Short chain fructooligosaccharides
● Fructooligosaccharides
● Inulin
Galactooligosaccharides
● Transgalactooligosaccharides
● Lactulose
Carbohydrates suggested to be prebiotics
Polydextrose
Glucans
Resistant starch
Pectins

Discrimination between the EFSA Health Claim Regulation and Safety Issues

When EU launched the Regulation (EC) No 1924/2006 in 2007 for health claims, the basis for the regulation was a concept of consumer protection, that is, the labeling of foods should be appropriate according to nutrients and health claims. So far no health claim for pro- or prebiotics has been approved. Van Loveren *et al.* (2012) have summarized the reason for health claim rejection and link to safety. The reason for health claim rejection is not a matter of safety of probiotic or prebiotics. The reason is instead linked to that in some cases the probiotic bacteria has not been taxonomically identified to the appropriate detailed level and before the regulations, studies on pro- and prebiotics were done more in an explorative way and not according to the current claim regulations. In 2011 and 2012 EFSA published guidelines for human intervention studies in different areas, and the application of those guidelines will facilitate studies and dossiers for approval of health claims. If a probiotic bacterium is included on the EFSA QPS list, which also most probiotics are, safety is not an issue for getting health claims. Thus the common demands for health claims and for safety judgment is that the probiotic or prebiotic used is appropriately

identified. However, if the probiotic strain is not on the QPS list, safety considerations are recommended according to the novel food regulations.

Use of Probiotic Bacteria/LAB to Increase the Safety of a Product

Use of Microorganisms for Natural Biopreservation of Foods

LAB, fungi, and molds have been used for the preservation of foods for thousands of years. The most common method of biopreservation is fermentation. The preservation effect is due to the production of organic acid, diacetyl, and hydrogen peroxide but also to specific antimicrobial compounds such as bacteriocins and antifungal peptides. Mathematical models and predictive microbiology have been used to address the importance of process factors together with acid and bacteriocin production. When the food industry now is looking for natural preservation methods, the use of LAB with its GRAS status is attractive. Bacteriocin-producing LAB have been applied to improve food quality and safety in sourdough and sausages production and in cheese production for competition, antilisteria, and anticlostridia purposes. The most studied bacteriocin is nisin for its preservative effects in foods, especially cheese. Also the potential of application within the malting and brewing process to diminish the growth of naturally occurring unwanted microorganisms has been suggested. The possibility to use bacteriocin-producing bacteria as probiotics for human and animal health to lower the risk of infection and for therapeutic purposes is an interesting possibility with a potential to lower the wide use of antibiotics. Bacteriocin production might also strengthen the competiveness of a probiotic bacteria in complex microbial communities such as those in the gut.

Binding of Toxic Compounds (Mycotoxins, Heterocyclic Aromatic Amines, and Heavy Metals)

Production of mycotoxins in foods and feeds create severe spoilage and is a threat to human health. The mycotoxins might be carcinogenic, immunotoxic, neurotoxic, nephrotoxic, or hepatotoxic. The use of LAB as natural preservatives to produce organic acids and bacteriocins to diminish the growth of the unwanted microflora as well as the capacity of LAB to bind mycotoxins is an interesting natural preservation method. One of the most common mycotoxin is aflatoxin, which is produced by *Aspergillus* strains of fungi. The ability to bind aflatoxin is strain dependent, and binding of toxic substances has been seen both in *in vitro* and *in vivo* situations. Different examples on the potential for probiotics to bind and detoxify mycotoxins have been described by Amalaradjou and Buhnia (2012) and Salminen *et al.* (2010), for example, different probiotic strains have been seen to bind and reduce the bioavailability of different forms of aflatoxin, including the most potent one aflatoxin B1, ochratoxin A, fusarium toxins, and patulin. Studies have shown that the mechanism behind removing of mycotoxins most probably is binding of the toxins and not a metabolic process since, for example, both dead and live probiotics have the ability to remove the toxins. Similarly, strains of *L. rhamnosus, Propionibacterium*, and *S. cerevisiae* have been shown to bind aflatoxin B1 also in the chicken or ruminant gastrointestinal tract and thus have the potential to be used as a feed additive to reduce the bioavailability of aflatoxin. Only a few studies have been performed in humans and a study in China showed that feeding a dietary supplement with specific strains of probiotics reduces the urinary excretion of aflatoxin B1. It should be noted that the binding capacity seems to be strain specific.

The production of toxins by cyanobacteria in aquatic and marine environments and specifically in drinking water is a risk of poisoning. The possibility to remove microcystin toxins produced by cyanobacteria in drinking water has been investigated using various lactobacilli and bifidobacteria separately or in combination with promising results.

When meat is cooked at 150–300 °C heterocyclic aromatic amines (HAA) are formed. These compounds have a high mutagenic potential and might contribute to gastrointestinal cancer. The possibility to utilize probiotic bacteria to eliminate theses mutagenic substances is interesting and investigations by Nowak and Libudzisz have shown *in vitro* that the probiotic bacteria *Lactobacillus casei* DN-114001 reduces the amount of three different HAA compounds by 27–99%, indicating that the toxins are metabolized.

The use of different microorganisms to bind metal cations has been studied for waste management. This could be expanded to foods by the use of food-grade microorganisms. The potential to use probiotic bacteria in this area for the decontamination of foods and the intestine from heavy metals have been investigated and the ability to bind, for example, lead and cadmium, has been shown to be dependent on the strain and pH.

SAFETY OF FOOD AND BEVERAGES

Safety of Irradiated Foods

DAE Ehlermann, formerly Federal Research Centre for Nutrition, Karlsruhe, Germany

Glossary

Codex Alimentarius International Standards for food (codes, practices, guidelines, etc.) as adopted by the Codex Alimentarius Commission in which more than 160 states are represented; this Commission works under the Joint FAO/WHO Food Standards Program.

Dose (radiation absorbed dose) The amount of energy at a point of interest in a volume of matter containing a given amount of mass, expressed as the quotient of energy imparted divided by the mass contained; SI units are Joule per kilogram (J/kg^{-1}) or Gray (Gy). Note: dose is usually expressed in kGy (kilogray).

Free radical An atom or molecule with an unpaired electron; usually highly reactive and lasting – in particular in humid media as food – only for extremely short periods of time.

***G*-value** The yield of chemical changes in an irradiated substance, expressed as the number of specified chemical changes per amount of energy imparted; traditionally given as 1/100 eV, in SI units as ne per Joule (1/Jo).

Polyploidy Occurrence of cells containing more than the normal number of chromosomes; for humans the normal is 46. Occasionally, double, triple, or multiple sets are found.

Radiolysis Chemical change caused by ionizing radiation, typically the cleavage of molecules.

Radiolytic product A substance produced in the process of radiolysis, i.e., any substance submitted to ionizing irradiation, including food.

Wholesomeness The safety of food for consumption. This has to be considered for food processed by ionizing radiation, and covers aspects such as radiological safety, toxicological safety, microbiological safety, as well as nutritional adequacy.

Introduction

Food irradiation is the best studied food technology ever. More than 60 years of research is well documented, and during this period the sensitivity of analytical methods has increased tremendously. Meanwhile, new and more sensitive analytical methods have evolved, which have added new insight. Experiences gained while researching into food irradiation have added to the fundamental knowledge about food, food processing, nutrition, food chemistry, and engineering.

A number of national expert panels have confirmed this conclusion. On top of all, a Joint FAO/IAEA/WHO Expert Committee on Food Irradiation (JECFI) and a Joint FAO/IAEA/WHO Study Group on High-Dose Irradiation (JSGHDI) have validated this technology and confirmed that it is wholesome. Furthermore, the World Health Organization (WHO) has recommended its use and complained that unfounded resistance to introduce this technology negatively affects those countries and regions where the benefits are most needed. The arguments against food irradiation and their scientific background have been evaluated and refuted by many expert groups; however, opponents and activists against food irradiation still rely on these long refuted considerations. Of course, it is well documented that in political disputes about new technologies the negative has more success.

It is fair to say that nearly all the arguments against food irradiation voiced by advocacy groups have a sound scientific background. However, all these considerations and arguments have been carefully checked and finally refuted based on sound science.

It should be understood that this short article on the safety of irradiated food cannot substitute a full scientific review of this issue; the entries below may be taken as headlines or query terms for further interest in this topic.

Definition of Wholesomeness

The terminology of 'wholesomeness' was first introduced as a legal conception by the US FDA in 1957:

> "The term wholesome means sound, healthful, clean, and otherwise fit for human food."

Another terminology which is also easier to translate into foreign languages is 'safety for consumption.' With regard to food processed by ionizing radiation, the JECFI in 1980 listed a number of further aspects to be specifically discussed: radiological safety, toxicological safety, microbiological safety, and nutritional adequacy.

Role of Overall Average Dose

The terminology of 'overall average dose' was introduced by JECFI in 1980 to provide a tool to estimate the total chemical turnover induced by a given radiation absorbed dose (short dose) in order to allow a more generalized estimate of chemical changes even in situations where a full and detailed analytical verification would not be possible. As the main chemical changes are well-known and characterized by the respective *G*-values (number of molecules changed per amount of energy imparted, usually measured in eV) of the individual chemical compounds making up the food item under study and as the full spectrum of the chemical composition of such food is also known, a calculation of the final changes can be made and the results can be confirmed by chemical analysis. There are a number of hypothetical chemical changes induced by ionizing radiation, but as the main transformations are well known, this amount can be subtracted and the remaining unknown amount can be estimated. Thus, using overall average dose can help to estimate which risk might originate from this small amount of compounds assuming the highest possible specific toxicological effect of these compounds. And, conversely, assuming the maximum tolerable concentration of these hypothetical compounds, the standard approach of toxicology can also be used to extrapolate the tolerable intake by a consumer for any substance under scrutiny. Having arrived at such value, the maximum tolerable overall average dose can be derived with the help of the summarized *G*-values for the food under consideration. This concept also allows for the estimation of expected chemical changes when large quantities of food are irradiated, not all receiving the identical dose or being irradiated under varying situations or at different times. It is very important to understand this approach by JECFI in order to make a reasonable use of their findings and conclusions.

The above considerations are valid for the reason that chemical transition in the dose range applicable for the food treatment is linearly proportional to the dose. Consequently, summing-up overall components is allowable, and a summary *G*-value can be derived and multiplied by the grand average of the dose in order to estimate the total turnover. More detailed considerations are not needed here, and the interested reader can find such information in the respective text books.

General Aspects of Chemical Changes

Processing food by ionizing radiation is a physical process imparting energy; but the final purpose is to induce chemical changes by many other processing methods like cooking, salting, pickling, etc. The advantage of ionizing radiation is that it does not heat the food and, therefore, does nost change the identity of the food; a dose of 10 kGy will heat water only by 2.5 °C! In other words, a raw meat will remain raw, a fresh fish will remain fresh, a fresh fruit will remain fresh, and a deep-frozen product will remain deep-frozen. In most – nearly all – applications of radiation processing of food, the target chemical is a rupture of the DNA molecules thus disabling the biological activities in a living plant, microorganism, or animal cell. This is achieved by direct hits cleaving the molecule or by indirect action of free radicals mainly formed in water. Of course, the components of the DNA molecules remain and their overall composition is not affected. However, any molecule hit by ionizing radiation will undergo changes characterized by their respective *G*-value; and there are molecules, for example, unsaturated fatty acids with their double bonds, which are particularly sensitive, possibly resulting in rancidity. For such reasons it is essential in several applications to design the irradiation process and treatment in a way as to minimize such undesirable changes, for example, by irradiation in the deep-frozen state.

Particular Chemical Changes

In judging the toxicological implications of the chemical changes to be expected, great interest has been paid to the possible existence of unique radiolytic products (URPs). The idea had been that there must be cleavage molecules which cannot be produced by other techniques of food processing. Their detection would also help to screen for irradiated foods in the marketplace that are not labeled appropriately. With one single exception, such URPs have not been found; the exception is the class of 2-alkylcyclobutanones (2-ACBs), a group of compounds derived from the fatty acids making up the fat moiety. Because of their particular chemical structure, some toxic properties had to be expected and a number of studies in model systems have been conducted. Finally, the conclusion was that these compounds have some toxicological potential but no consequence for the human consumption of irradiated food containing fat. However, with an enormous increase in the sensitivity of analytical methods, the existence of these URPs meanwhile has become a standard method for the detection and verification of irradiated food in the marketplace.

Biological Changes

As most applications of food irradiation aim at some biological effect, it was quite natural to question whether such changes would have any effect on the consumer. The changes in the DNA are not relevant to the consumer as the DNA does not contribute to nutrition. Another effect is the change of cell permeability, which might be used to increase the yield in juice production; but again, this has no nutritional consequence. Microorganisms are killed, but the remaining chemical compounds have no implication on nutrition. Ripening of fruits can be delayed or accelerated but this again has no nutritional consequence; however, the treated fruits might become less palatable, for example, by softening of the tissue. There are a number of microorganisms less sensitive to ionizing radiation, and it might be quite difficult to eliminate their spores. This latter effect is not different from other processes; for example, some microorganisms are quite tolerant to heat treatment, and the process must be designed appropriately to achieve the desired effect and the microbiological safety of the final product. Furthermore, it is virtually impossible to eliminate viruses by irradiation; the necessary dose will be much higher than needed for sterilization. Parasites

and insects that occur in food are quite sensitive to irradiation; they however, are not contributing to nutrition. There is a vast literature available on the biological effects of ionizing radiation, and reviews and textbooks give a lot of information for the practical exploitation of the irradiation process.

Radiological Safety

The question whether irradiated food may become radioactive is a very sensitive concern of the general public and laypersons. First of all, it must be understood that any object, including food, is already radioactive: it is the primordial radioactivity that originates from the creation of our world. For example, if we consider potassium, there is always the isotope K-40, which is naturally radioactive. If we consider carbon – a main chemical constituent of our food – it always contains some C-14, which is created by cosmic radiation in the world's atmosphere. Hence, the question of radioactivity induced by the radiation processing of food must be considered in this context. To avoid any measurable induced radioactivity, the number of permitted radiation sources has been limited to gamma-rays from cobalt-60 or cesium-137, to electrons up to 10 MeV particle energy, and X-rays generated from converting electrons with up to 5 MeV (USA up to 7.5 MeV) from machine sources. In other words, any kind of radiation known to induce radioactivity – for example, neutrons – are not permissible. However, there are also several isotopes of the elements contained in food that may be activated theoretically, even by the energies of the permitted radiation types. However, such isotopes as indium-119 are very rare in food and are not activated to any measurable extent, and, therefore, will not contribute to any measurable increase in the natural radioactivity of our food. In the early days, national authorities were required to measure the radioactivity of all irradiated food, but this requirement is no longer maintained according to the scientific evidence that no radioactivity is induced.

Toxicological Safety

No doubt, there are radiolytic changes in any irradiated food, which are partially responsible for the beneficial effects in food irradiation. Most of the radiolytic effects only change the relative composition of the chemical spectrum contained in food. This was confirmed by a number of experiments including microbial test systems, feeding tests on a wide variety of animals, and even studies with human volunteers. None of these studies revealed any negative effect. This is also true for the 2-ACBs (see Particular Chemical Changes). These particular compounds have a toxicological potential. However, because of the extremely low concentration of those components in irradiated fat-containing food, it has not been found to be relevant. From the wealth of experimental results and the conclusions reached by national and international expert bodies, it must be accepted that irradiated food is safe to consume. This is valid without any restriction on the maximum tolerable dose, without any discussion of overall average dose, as long as the irradiated food remains palatable and maintains its technological properties. This conclusion has already been incorporated by Codex Alimentarius in its International Standard on Irradiated Food, but has not yet been implemented worldwide for national regulations.

Microbiological Safety

From the beginning of the research into food irradiation, there have been concerns that irradiation of food could cause genetic changes in microorganisms and by repeated irradiation microorganisms might become resistant to ionizing radiation as already proven for chemical treatments. However, none of the many experimental studies rendered any evidence for such suspicion. It is also true that all species of microorganisms have a different sensitivity to irradiation; the same is true for heating and other treatments. Consequently, radiation processing will inevitably change the relative spectrum of microorganisms present, except in the case of total sterilization, which can also be achieved by irradiation. The relevant question, consequently, is whether such relative change can favor the outgrowth of hazardous microorganisms, thus creating a risk for the consumer. No experiment hitherto has confirmed such suspicion. Furthermore, it has been confirmed that any irradiated food when undergoing spoilage will still have sensory warning signals for the consumer, particularly smell and appearance. There is a rule that irradiated food needs the same care for handling in the kitchen as food processed by any other technology. Another question that has been asked this whether some mutation of irradiated microorganisms would not only create microorganisms more resistant to ionizing radiation but also create more hazardous microorganisms producing more toxic substances. There have been scientific publications on such effects; however, the irradiated microorganisms needed to be cultivated in a protected laboratory environment and shielded from the competition of the normal microbial populations in our food. In such laboratory studies, it has been shown that the mutated microorganisms did produce more toxins per surviving microorganism; however, such mutated microorganisms would never survive under conditions of the real food environment.

Nutritional Adequacy

In the initial JECFI conclusions of 1980 it was already, pointed out for consideration that certain groups or populations living on a diet restricted in variation and composition would encounter nutritional problems if all their food would be irradiated without exception. However, it is quite unlikely that, for example, the boat people in Thailand would receive all their food irradiated. It is also quite unlikely that any other special group would encounter nutritional deficiencies if some of their typical food has been processed by ionizing radiation. It has further been shown that any permission of radiation processing would not have any consequence on the supply of nutritionally appropriate food to the consumers. It is true that some nutrients are affected by ionizing radiation and may be even totally depleted at extremely high doses; in such cases other food consumed will compensate for such deficiencies.

In extreme situations, as for astronauts, their radiation-sterilized food will be carefully controlled for the sufficient supply of all indispensable nutrients, and occasionally even supplements are added to compensate for possible deficiencies.

Expert Evaluations of Wholesomeness

All these concerns and suspicions about the wholesomeness of irradiated food have been considered by national and international expert committees. Without validating the personal expertise of the members of the various committees, it must be convincing that all the committees came to the conclusion that irradiated food is safe to consume. Of course, there have been studies reporting negative effects; however, where put in context, it has been proven that these results could not be substantiated in subsequent experiments by independent expert and research groups. Other reported negative effects have been shown to have no relevance in the real situation of human nutrition. In any field of science, there will always be some dissent by researchers in minority. However, for judging the situation and arriving at legal consequences for regulations or bans, it is indispensable to hear the results from the mainstream of science. This vote is clear: there is no argument based on sound science against the general accepting of radiation processing for irradiated food. Based on this argument, in 2003, Codex Alimentarius has accepted food irradiation without any limitation to the kind of food or any restriction to maximum permissible dose.

Concerns about Food Irradiation

Opponents to food irradiation and advocacy groups have voiced a range of arguments, which are not related to the wholesomeness of irradiated food: the nuclear industry wants to get rid of their waste; interest the process is mainly from the military; the necessity of huge transportation vehicles carrying radioactive materials and the risk of a spill on the roads; workers in irradiation facilities are not sufficiently protected; and radioactive emissions from irradiation facilities are much higher than those of nuclear power plants. This variety of arguments illustrates the emotional and ideological basis of this reasoning. In fact, such technically based arguments can best be refuted by the truth: food irradiation is not related to nuclear waste, the interest is not mainly from the military (and what would be the argument?), there are no huge transports of radioactive materials for the large number of irradiation facilities world wide (irradiating huge volumes of nonfood items), workers in such facilities are sufficiently protected, and there are no radioactive emissions from irradiation plants. Having looked into such concerns and the arguments to resolve them it becomes evident how difficult it would be to pass arguments against the wide-spread skepticism into the wholesomeness of irradiated food.

There are a number of concerns that have, at least, some scientific foundation and justification: foods may become devitalized, denatured, and dead; spoiled food may be cosmetically converted to make it marketable, thus convincing the consumer; natural goodness of food is destroyed; food may be over-irradiated and become harmful; a dose high enough to kill microorganisms, insects, plants and animals, and even humans cannot be healthy when applied to food intended for human consumption; irradiated food can become re-contaminated undermining the purpose of the treatment; bacterial toxins already formed will not be eliminated; and consumers might place too much trust too the effect of the treatment to limit spoilage. The arguments needed to answer the concerns need some basic understanding of human nutrition. There is no evidence that certain vital forces may be ingested with our food; nutrition relies exclusively on the components of which food is made up, i.e., vitamins, minerals, amino acids, proteins, starch, and so on. Consumption of food such as a raw potato is not nutritious as the raw starch is indigestible and only after cooking and consequent denaturation does it becomes digestible. There is no chance to revert spoilage with the help of radiation processing: a spoiled fish will remain stinky, a rotten potato will remain rotten, and so on; the consumer will be warned by the symptoms of spoilage not to consume such items the same way as with the unirradiated food. Natural goodness of food is assumed, particularly for products of organic farming, and most regulations do not permit radiation processing for such products; however, there is no argument based on sound science for such conclusion. On the contrary, processing by ionizing radiation would be the best method to be combined with organic and sustainable agricultural production. It does not change the identity, quality, and nature of the product, and it could be used to avoid the application of any chemical treatment.

It must also be considered that a large number of experimental studies have been published that report a detrimental or even noxious effect of radiation processing of food. All these publications have been considered and validated by national and international expert panels. All these experiments have been repeated by other groups of scientists in order to verify the published findings. In many of these follow-up studies, the experimental parameters also have been varied in order to render a better insight into the underlying principles. All this wealth of accumulated scientific knowledge has led to the final conclusion that irradiated food is safe to consume. However, for the layperson it would remain very difficult to verify these conclusions without knowing and understanding the wealth of the available publications.

The hypothesis of the existence of radiotoxins has been postulated, in order to explain the specific chemical effects induced by ionizing radiation. However, all experiments to verify such theory failed. The other common argument is that free radicals are introduced, which is true. However, in a system containing water in abundance, i.e., in food, such free radicals have a very short lifespan and disappear immediately by recombination or by reaction with other compounds of the food. These latter effects have been extensively analyzed in the studies reported above. The evidence is, even from feeding studies with rather dry substances as irradiated milk powder, that no harmful effects could be found. As expected, the free radicals contained (and proven by electron spin resonance (ESR) analysis) immediately decay on contact with the saliva

of the test animals; and if not, they are quenched away by the aqueous chemistry of the digestive system.

An Example: The Polyploidy Issue

A frequently cited study to prove that irradiated food may be unsafe to consume is an Indian experiment on malnourished children in a hospital; the diet to foster recovery contained freshly irradiated wheat. First of all, it is not known what the increased-rate of polyploidy could mean; in other words, the biological significance of polyploidy is not known; what is known for sure is that a certain spontaneous rate of polyploidy is a part of life. Polyploidy means the occurrence of cells that do not have the normal number of chromosomes (for humans 46), but the duplicate or even multiple sets (i.e., 92, 136, 184, or even more). To do a valid evaluation on polyploidy, a sufficiently large number of cells must be examined and counted under the microscope. There are a number of technical deficiencies in the Indian study even thought it is published and peer-reviewed. It is not only the low number of slides counted, but also the lack of the full information about material and methods applied. For example: how was the freshly irradiated wheat integrated in the diet? Whole wheat, baked, or cooked? It is evident that the children did not consume raw grains. There are sufficient reports that other parameters may influence the occurrence of polyploidy cells as even the circadian rhythm of food intake may have an effect. National and international experts have evaluated the technical details of this study and concluded that the experimental design was essentially unsuitable to draw any conclusion and that there were even founded doubts on the statistical validity of the results. A basic observation, easy to understand even by a layperson: a group of 15 malnourished children in custody of the hospital had been chosen; three subgroups with five children each were formed, (1) normal hospital diet for recovery, (2) this diet with inclusion of unirradiated wheat, and (3) a diet containing the irradiated wheat (0.75 kGy). An experimental plan with such small treatment groups can never be sufficient to draw any statistical conclusion. And even more puzzling, the authors appear to be unable to produce in their reference group of children the expected standard incidence of polyploidy of approximately 0.8% (normal) or 1.8% (slightly above normal), but instead report an absolute zero. What was the underlying fundamental error in these experiments? Furthermore, the number of cells counted for each child was rather low (500), and data for all the five children of a group were pooled in the report. Pooling of data is only acceptable after a check of the statistical quality, i.e., answering the question whether the observations belong to the same group of data. Consequently it was found that a single child within one group having an increased polyploidy would contaminate the data and no statistical verification is possible. There was no health evaluation reported and one child might have been affected by inflammation of an inner organ which is also known to increase polyploidy.

With the poor information given by the authors, nobody would be able to repeat and confirm their experiments and results. Furthermore, there would be ethical limitations to execute such experiments on children (volunteers?) in a critical state of malnutrition. For such reasons, model systems, in particular test animals under malnutrition conditions, have been used in a number of experiments. None of these studies could reveal an incidence of polyploidy caused by the irradiated feed.

Reference to this issue of polyploidy is made here, as the respective publications have been used aggressively at many instances by opponents to food irradiation and advocacy groups. Never an answer was given to the scientific doubts into these studies. Several follow-up publications on the initial Indian study have been published by opponents, still insisting on the enhancement of polyploidy, but none giving any answers to the basic doubts in these studies.

In summary, the scientist/expert must pay respect to the concerns voiced by laypersons; however, there is still a need to translate the results from the mainstream of science into information understandable by ordinary people. This is also important with regard to food irradiation as the regulators essentially are laypersons.

Regulations and Wholesomeness

By common consent it is agreed that governments are obliged to protect their people. Particularly in relation to food, it is generally assumed that consumers are unable to judge the quality of their food. This is also a consequence of the industrial production of food, where the applied treatments and the used ingredients and additives are not obvious from the appearance of the product. For such reasons, also, the food sector is governed by a wide range of regulations. At the beginning of the twentieth century, no regulations of food irradiation existed, which for some countries implied "what is not regulated is not permitted," and for other countries "not regulated means not forbidden". During the first five decades of scientific work, some concerns were raised that food processed by ionizing radiation might impose some hazards with its consumptions; scientific research commenced into the wholesomeness of irradiated food. In 1957, the world's first commercial irradiation facility for food (spices) was put in operation in Germany (the situation: not regulated means not forbidden); however, already in 1958 a general ban of food irradiation was introduced in Germany as a precautionary measure with the reasoning that not enough was known about this new technology. However, the USA, for example, took the other approach, and beginning in the early 1960s permitted certain commodities for certain treatments at specified doses. But even here, the uncertainty about the wholesomeness of irradiated food led to the cancellation of a number of the early clearances. This situation only changed with the emergence of JECFI, which initially recommended even conditional and which in 1980 declared any kind of food to be wholesome up to a treatment of 10 kGy overall average dose. This finding was adopted in 1983 by Codex Alimentarius in its General Standard on Irradiated Food.

Despite the fact that after this decision irradiated food had to be considered safe for consumption and, consequently, no further protection of the consumer needed to be implemented, very few governments implemented the full Standard

into national regulation. Instead, a number of countries began to permit radiation processing of clearly defined food categories or even subgroups from a category and introduced dose limits far below the set value of 10 kGy. Of course, such restrictions were never based on considerations of wholesomeness. However, the US approach to issue clearances on the basis of received petitions allowed the industry to introduce food irradiation on a commercial scale and to bring such products on the market. This approach allowed the US regulators to re-evaluate the wholesomeness aspect any time a new petition was submitted. Petitioned by the industry, most dose values were set below the 10 kGy as no higher dose was needed for the respective application. And again in the USA, the 30 kGy maximum dose for spices was derived from wholesomeness considerations: as spice is a minute component of food ingested and considering the original definition of overall average dose. The conclusion was that in this particular case the ingestion of an extremely low concentration of hypothetically harmful radiolytic products would not pose any health risk. The exact value of 30 kGy was derived the following way: the minimum dose needed to eliminate harmful microorganisms from this dry product was assumed at 8 kGy; as common irradiation facilities would be able to provide a dose range between maximum and minimum of less than 3, the maximum dose for the intended treatment would be calculated to be 24 kGy; and rounding this value ended at a regulated 30 kGy.

The European Union (EU) in 1999 regulated food irradiation compulsory for all the member states using the terminology of overall average dose; only a single commodity was listed at a dose value of 10 kGy. The member states were permitted to maintain any clearance that was in place before this general regulation. In other words, the EU-regulation is not governed by consideration of wholesomeness, otherwise there would be no justification for any differentiation by country.

The 10 kGy overall average dose of JECFI and Codex Alimentarius did not provide for radiation sterilization of food, which requires doses up to or above 50 kGy. Such applications were used in South Africa for rations of out door enthusiasts and in USA for their astronauts. This created the desire to arrive at a verdict on the general wholesomeness of radiation sterilized food, and both countries – through their membership to, the International Consultative Group on Food Irradiation (ICGFI), were among the sponsors of the JSGHI, in 1997. Both governments now have the confirmation that their decisions are based on the assured wholesomeness of the radiation-sterilized products.

Conclusion

Irradiated food is wholesome, this means safe to consume regardless of kind of food and dose applied. This is even valid for the highest doses as long as the food remains palatable i.e., of high quality to enjoy its consumption, and as long as the technological properties, for example, the thickening effect of starch ingredients is maintained. There is a wealth of scientific publications on this topic, and mainstream science confirms again and again these conclusions. Any adverse or negative finding has been refuted by substantiated arguments and scientific evidence.

SAFETY OF FOOD AND BEVERAGES

Safety of Genetically Modified Foods

ECD Todd, Ewen Todd Consulting LLC, Okemos, MI, USA

Glossary

Arthropods Any invertebrate of the phylum Arthropoda, having a segmented body, jointed limbs, and usually a chitinous shell that undergoes moltings, including the insects, spiders and other arachnids, crustaceans, and myriapods.
Biofuel Fuel derived from organic matter (obtained directly from plants, or indirectly from agricultural, commercial, domestic, and/or industrial wastes) instead of from fossil products.
Bioremediation Degradation of organic contaminants (such as chemicals, heavy metals, and oil) in the soil or water, by the action of cultured microorganisms selected for their ability to metabolize the specific contaminants.
Endotoxin A toxin, usually heat resistant, present in the intact bacterial cell but not in cell-free filtrates of cultures of intact bacteria.
Eutrophication The process by which a body of water becomes enriched in dissolved nutrients (as phosphates) that stimulate the growth of aquatic plant life usually resulting in the depletion of dissolved oxygen.
Lignocelluloses A combination of lignin and cellulose that strengthens woody plant cells (biomass).
Monoculture The cultivation of a single crop on a farm or in a region or country; monoculture crops do not provide a rich habitat for other flora and fauna and inhibit diversity.
Nucleator An ice nucleus is a particle, which acts as the nucleus for the formation of an ice crystal.
Prion Protein particle similar to a virus but lacking nucleic acid, thought to be the infectious agent responsible for scrapie, variant Creutzfeldt-Jakob disease (vCJD), and certain other degenerative diseases of the nervous system.
Sporulation Formation of spores, usually very resistant to heat and dessication.
Supercooling Supercooling is the process of chilling a liquid below its freezing point, without it becoming solid.
Superweeds A wild plant that has been accidentally pollinated by a genetically modified plant and contains that plant's abilities to resist herbicides and insects.
Transgenic Organism containing genes altered by insertion of DNA from an unrelated organism, and to have that trait expressed in the offspring.
vCJD A variant of Creutzfeldt–Jakob disease caused by the prion associated with bovine spongiform encephalopathy and contracted by consuming infected beef or beef products, which are invariably fatal.

Introduction

Genetic modification of plant and animals can occur spontaneously as part of the evolutionary process. However, selective breeding of plants and animals in agriculture allowed small human nomadic group to settle down and eventual form larger urban societies with more opportunities for diversification of employment activities and the improvement of life. In other words, human control of plant and animal genes gave rise to civilization as we know it in the present day. In the past few centuries, agriculture has benefitted from improvements in crop and animal varieties, which was able to keep up with the food demands of an ever-increasing human population. These benefits were most apparent when climate was suitable, infestation was minimal, and crop spoilage lose was controlled; however, the cycle of feast and famine continued to occur well into the nineteenth and twentieth centuries, particularly in developing regions. As the world faced limitations of arable land and fresh water and other challenges, there was a motivation for research to improve productivity by modifying plants by introducing changes in the DNA. This became feasible once the genome was better understood and tools to manipulate the DNA structure were developed in the latter half of the twentieth century.

The commercial use of genetically modified crops in agriculture began in1990s by a few multinational corporations based in the United States (US) that possessed this new technology. Genetically modified plants (GM plants) were generated in a laboratory by altering their genetic makeup to introduce desired qualities. This was usually done by either inserting or deleting genes from a plant's genome by genetic engineering. These new organisms with recombinant DNA are generally referred to as genetically modified organisms (GMOs). In 1994, the first commercial GM product was introduced in the US. The *Flavr Savr* tomato had a deleted gene, which caused postharvest fruit softening, and thus the genetically modified (GM) tomato had a longer shelf life. However, it was taken off the market shortly afterwards because it could not compete with conventionally bred tomatoes with long shelf lives and better flavor. In 1996, GM maize

(corn) and GM soybeans were approved and planted in the US, and thereafter processed foods containing GMOs started to appear in retail stores in the US and Canada. The genetically derived advantage of most GM crops, such as soybean, corn, rapeseed, and cotton, is the ability to be resistant to specific herbicides or certain plant pests and pathogens.

The Use of GM Technology in Agriculture and Foods

Canola (Canadian oil, low acid) for human consumption was developed in the early 1970s in Manitoba through conventional plant breeding from rapeseed to distinguish it from natural rapeseed oil, which has much higher erucic acid content. By 1998, a more disease- and drought-resistant variety was developed through genetic engineering. In the present day, Canola is produced widely in Canada, the US, and other countries, and it is generally recognized as safe by the United States Food and Drug Administration (USFDA), and in 2013 was permitted in infant formulas with Canola oil at levels up to 31% of the total fat blend.

Other widely consumed GM products are corn and soybeans from GM crops. The herbicide glyphosate inhibits the enzyme 5-enolpyruvylshikimate-3-phosphate synthase, which is present in plants, fungi, and bacteria but not in animals. This enzyme is a key step in the formation of hormones through production of aromatic amino acids. The use of the broad-spectrum herbicide became much more widespread with the development of Roundup® ready (GM) soybeans and maize, which contained the glyphosate-*N*-acetyltransferase gene. With the application of the herbicide, these GM crops would not be affected, but certain weeds would be killed. In the present day, different commercial glyphosate products are able to control more than 100 broadleaf and grass varieties of weeds. Toxicological studies showed that even though new metabolites are formed in the edible parts of the GM crops that were not observed in conventional crops, the Joint FAO/WHO Meeting on Pesticide Residues concluded there was no human health concerns for the short- or long-term consumption of these commodities or their products. The number of approved GM crops worldwide is expected to increase from 30 in 2009 to 110 by 2015. Even in Europe where concern by the population to GM foods is greatest, approximately 30 million tons of GM crops are imported each year and many varieties of herbicide-resistant maize are now allowed to be grown in the European Union (EU). However, glyphosate is only slowly degraded by soil microorganisms and may pose a risk of water contamination. In addition, resistance of some species of weeds to the herbicide is a growing concern.

Another successful application of GM technology is the insertion of a gene for the biological pesticide produced by *Bacillus thuringiensis* (Bt), a close relative of the very common soil and dust bacterium *Bacillus cereus.* In 1901, Bt was first observed in a colony of sick or dying silkworms in Japan. The main difference between Bt and *B. cereus* is that Bt produces an endotoxin that kills lepidoptera. This is accomplished by the protein toxin, which occurs as a parasporal body ('crystal') in the bacterium during sporulation. The insect gut proteases activates the toxin proteins, allowing them to bind to receptors, and affect the midgut cells by forming pores in the larval digestive tract (hemocoel). These pores allow naturally occurring enteric bacteria to enter the hemocoel, where they multiply and cause sepsis The Bt toxin in the form of spray-dried wettable powder of the Bt culture became commercially available in the 1950s and was used extensively in Canada in a spray over wide areas of forests infested by spruce budworm and gypsy moth. In forestry, however, by the mid-1980s, Bt strains had virtually replaced the major chemical pesticides for spruce budworm and gypsy moth control in Ontario, Quebec, and the Atlantic provinces. Since then, various modifications have been made to target certain insects, mainly destructive caterpillars. However, for food and forage crops, its use has been more limited, mainly targeted against cabbage worms, tomato hornworm, European corn borer, alfalfa caterpillar, and alfalfa webworm. Bt can be applied through overhead irrigation systems or as granules. Available data suggest that spores may remain in soil from months to years under field conditions, but little is known about the longevity of the toxin in soil or water.

Two isolates of this genus are highly active against insects of great economic importance; Bt subsp. *kurstaki* attacks lepidopterous insects and Bt subsp. *israelensis* kills mosquitoes and black flies. The Bt *kurstaki* strain is the one used most frequently as a spray to control caterpillars on vegetables. Bt insecticides are the only bacterial insecticides in widespread use, and one advantage they have is that they neither target pollinators, like bees, nor predators or parasites of the pests of concern. In 2012, the European Food Safety Authority conducted a risk assessment on the Bt *kurstaki* strain and concluded that the health risk to mammals, reptiles, amphibians, birds, algae, and nonlepidoptera terrestrial arthropods, and probably soil microorganisms is low. From a GMO perspective, Bt maize is a variant of maize, genetically altered by inserting the gene for Bt toxin into the maize genome to kill European maize borer and more recently the maize ear worm and root worm. Unlike Bt, transgenic plants like corn do not release the Bt toxin. Instead, the cell must be digested by the insect in order to release the active ingredient in the gut. This is an improvement on the sprayed Bt because it is not susceptible to degradation by sunlight or washed away by rain. Most sprayed formulations are less effective over time, perhaps a few days or weeks after application, unlike the GM version, which is effective for the life of the plant. One risk however, is that continual exposure of insects to the GM derived Bt may confer resistance to insect predation.

Although insects are capable of developing high levels of resistance under laboratory experiments, this has not been observed to any great extent where crops have been sprayed. Now it is generally agreed that 'high dose/refuge strategy' is the most promising and practical approach to prolong the effectiveness of Bt toxins. This requires toxin free host plants as refuges near insecticidal crops, and toxin doses intended to be sufficiently high to kill insects. After more than a decade because of initial commercialization of Bt crops, most target pest populations remain susceptible, but field-evolved resistance has been documented in some populations of three noctuid moth species feeding on Bt maize in Puerto Rico and South Africa and in Bt cotton in the southeastern US. Field outcomes are consistent with predictions from theory, suggesting that

factors delaying resistance include recessive inheritance of resistance, abundant refuges of nonBt host plants, and two-toxin Bt crops deployed separately from one-toxin Bt crops. The use of Bt crops is popular worldwide with more than 32 million hectares in cultivation, including Bt cotton and Bt potatoes. Even some countries with concerns about GM foods in general, such as in the EU, permit the use of Bt transgenic crops, and it is likely their use will expand in the future. Other GMOs permitted in the US and some other countries include cotton resistant to the herbicide bromoxynil; delayed ripening tomatoes; squash, zucchini, and papaya modified to resist viruses (80% of Hawaiian papaya is genetically engineered because there is still no conventional or organic method to control ringspot virus). Sugar beets that are glyphosate resistant have been approved in Australia, Canada, Colombia, EU, Japan, Korea, Mexico, New Zealand, Philippines, Russian Federation, Singapore, and the US.

The potential of this technology can also be used to enhance nutrition such as vitamin production; a good example of this is 'golden rice', a GM variety of *Oryza sativa* rice, which produces beta-carotene, a precursor of vitamin A, in the edible parts of rice, produced in 2000. Golden rice was created by transforming rice with two beta-carotene biosynthesis genes: Phytoene synthase from a daffodil and *crtI* from an *Erwinia* species, and actually is golden in color, quite distinct from nonGM rice. The reason for the research was to plant this variety in regions, such as in Africa and India, where thousands of children die each year from a lack of vitamin A. In 2005, a newer variety producing much more beta-carotene was developed, but unfortunately neither the original nor the newer version is yet grown for human consumption. The GM crop approach for vitamin A fortification is seen by many as a less expensive and more practical alternative to vitamin supplements or a change in diet to greater consumption of vegetables and animal products.

The usual concerns expressed about GM crops have also been raised in regard to golden rice: spread of GM genes into the environment; loss of local varieties and biodiversity; opening the door to more controversial GMOs; obscene profits made by multinational companies from those who can least afford the cost of the seed; and vitamin A could be derived from other food sources. Other opponents have argued that adults and children would have to eat inordinate amounts of golden rice to see any benefit. However, recent trials showed that golden rice delivered dietary vitamin A as good as supplements and better than the natural beta-carotene in spinach. To permit widespread use, GM companies have now agreed that farmers could obtain the seed and replant it free of charge, unless they made more than USD$10 000 a year from the crop. Field trials have been conducted, and it is hoped that golden rice will meet the regulatory conditions for its production and be on the market in 2015.

Another beneficial application of GM technology is vaccine production and delivery through GM plants. Selected DNA from hepatitis B and cholera viruses injected into banana saplings might allow the plant to produce antigenic proteins without any infectivity component. Consumption of these bananas (and some other modified vegetables like potatoes and carrots) would build up antibodies in the consumer to fight these diseases in a similar way to injecting or ingesting traditional vaccine. This may be a more efficient and less costly way of vaccinating large populations against specific diseases.

GM research with plants will accelerate in the future, and some of the outcomes may prove to be both economically and environmentally acceptable to governments and the public. Some plants and trees could be engineered for capturing large amounts of carbon, which would be sequestered in roots and stems. Perennial grasses like switchgrass and *Miscanthus* may have the best immediate potential because of their extensive root systems. Other examples are GM trees to grow faster; yield better wood, say for construction and for biofuel; resist pest invasion and extreme climatic conditions; and even detect biological attacks by developing trees that change color when exposed to biological or chemical contamination. However, environmental concerns will prevent any large scale adoption of these, particularly as pollen released from trees is uncontrollable over large areas.

GM Microorganisms

One of the first scientists to select bacteria for desired attributes was Louis Pasteur who helped to develop pure cultures for wine and beer production that are still used in the present day. Where the desired product is only produced naturally by microorganisms, difficulty in growing the bacteria on an industrial scale have resulted in low yields of the product. With today's technology the specific gene for the product can be inserted into another microorganism (a bacterium, yeast, or fungus) that is easier to culture. Thus, these GM microorganisms, sometimes called genetically engineered microorganisms, have been used for many years to produce vitamins, enzymes, food additives, and processing agents for the food industry. These include vitamins B_2 and C, xanthan thickeners, regulators of citric acid acidity, amino acids, such as glutamate and enzymes, used in the production of cheeses, baked goods, fermented beverages, and glucose. Because the final product is highly purified, like a specific enzyme, there is no altered DNA or other substances to be concerned about in the product. Because the GM organisms are contained in the fermentation vessel, there is also no release into the environment, and thus, regulatory oversight is less stringent.

However, there are relatively few examples where a GM microorganism has been approved for use in the environment including agriculture. In the agriculture area, some viruses have been genetically modified to increase their toxicity to the host, such as baculovirus containing a gene for scorpion toxin against caterpillars. *Lactococcus lactis* is a bacterium widely used for years safely in the dairy industry and is a potential vector for delivering vaccine antigens through the human mucosa. However, despite much work in this area no commercial human vaccine has yet been produced from this organism. Before their release into the environment, GM microorganisms have to be shown to be both effective and safe. These essential attributes include:

1. ability to survive and multiply in the ecosystem into which they are introduced;
2. stability of the new genetic material and low potential for this material to transfer horizontally to indigenous organisms;

3. ability of the GM microorganisms to function as designed under the different environmental conditions expected; and,
4. lack of adverse impact on the broader ecosystem where they are introduced.

The Gram-negative bacterium *Clavibacter xyli* ssp. *cynodontis* (Cxc) is a common endophyte living in the xylem of Bermudagrass (*Cynodon dactylon*) and also in a few weed species and can be made to colonize maize, rice, sorghum, oats, and white millet through artificial inoculation. The gene coding for the CrylA(c) protein from Bt ssp *kurstaki* is inserted into the chromosome of a wild-type Cxc. Maize plants inoculated with recombinant Cxc; and artificially infested with larvae sustained up to 80% less damage than plants inoculated with either wild-type Cxc or uninoculated plants. In agricultural research experiments, such bacteria have been incorporated into soil to facilitate crop growth by fixing nitrogen and applied directly onto crops to kill pests. The release of transgenic resistant to pests and pathogens could increase selection pressure on those organisms and increase the likelihood of them becoming resistant, thus rendering the GM microbial pesticides ineffective. One possible example could be Bt toxin genes introduced into a *P. fluorescens,* a common colonizer of maize plants and into several species of nitrogen-fixing *Rhizobium*. The Bt genes produce toxins against various insect pests including caterpillars, mosquitoes, and beetles.

Another application for GM microorganisms is prevention of loss of crops. Water does not necessarily freeze at 0 °C and may be supercooled in a liquid state unless there is an ice nucleator to form the ice. Ice-nucleating bacteria perform this function, which is beneficial to avoid their own intracellular freezing damage. Because these bacteria are present on crops, they can result in plant cellular frost damage. Therefore, research has been done on the development of GM microbial ice-minus bacteria (a modified *Pseudomonas syringae,* commonly found in vegetation) that can delay ice formation and death of the plants during freezing temperatures. Ice-minus technology is designed to depress the critical temperature at which frost damage begins by displacing the natural population of ice-nucleating organisms with the modified *P. syringae,* which lacks the genes for the ice-nucleating protein. These bacteria are sprayed across the leaves and other plant parts so that ice will not form unless the frost is more severe. However, after some small trials on strawberries and tree fruits, there has been no government approved initiative to apply this technology to regions that can be affected by frost. Because climate change is creating extreme weather events, seasonal damage by cold may become more frequent in areas where this has been a rare phenomenon in the past. This may have benefitted tart cherry and apple farmers in Michigan in 2012 if it had been used because an unseasonably warm March brought blossoms out early to be hit by a late frost in April. The cherry crop was almost nonexistent, and the apple crop loss was the largest since the 1940s.

In recent years, more GM microorganisms have been developed for biotechnological processes that require introduction of the modified organisms into the environment in substantial numbers. For instance, GM microorganisms have the potential for bioremediation applications in soil, groundwater, and activated sludge environments and degrading organophosphate and carbamate pesticides. A modified *Pseudomonas fluorescens* has been used in field trials, where its bacterial hemoglobin can impact polluted sites, where oxygen availability limits the growth of aerobic bioremediating bacteria. If these are effective and safe, the impact could be more land being turned over to agricultural use. Another example of a GM microorganism with gene deletions beneficial to agriculture is that used to control crown gall disease occurring in several plants caused by the soil-borne bacterium *Agrobacterium tumefaciens*. *Agrobacterium radiobacter* produces an antibiotic against the disease and is often used as a control agent. However, prolonged use of this control agent results in transfer of the plasmid that contains both the antibiotic and resistance genes. The GM microorganism *A. radiobacter* was unable to transfer this plasmid to *A. tumefaciens*is and thus became the first GM microorganism to be used in a commercially available pesticide in the 1990s.

GM microorganisms need to be tested against a range of possible targets and released only after their specificity has been established. Many of the early examples of GM microorganisms released into the environment had genes deleted from their genome, such as the ice-minus and *A. radiobacter* examples discussed above. This makes them apparently less risky than those with added genes and possibly safer than the naturally occurring microorganisms they replace. Nevertheless, each GM microorganism should be assessed according to its own particular properties. Appropriate risk assessments should be carried out before agreeing to the widespread release of these DNA-modified microorganisms. International input should be sought because even if these have been shown to be safe in one country or region, they may have a deleterious effect in a different ecosystem in another country. Unfortunately, it is almost impossible to predict long-term effects of introducing a new species into the environment. At the same time, there are many examples of introduced plants, insects, and animals, some accidentally and some deliberately, where these have gone very wrong and whole ecosystems have deteriorated. Thus, there can be both promotion of reckless introduction of GM microorganisms by researchers and industry and also overt rejection of any GMOs by consumers groups, usually with the government in the middle trying to balance the need for new technologies guided by the precautionary principle in the recognition that any release may be irreversible.

Another issue is the intentional misuse of GM microorganisms for criminal purposes, such as creating synthetic pathogens, or enhancing their virulence. Although most governments have eschewed research into 'germ warfare', the technology in the present day is available to small laboratories to generate bioterrorism weapons. Fortunately, the delivery system for mass infection is more difficult to establish, but small targeted attacks could be achievable by one or a few scientists, as seems to have been the case with the *Bacillus anthracis* attacks in 2001 where the agent was delivered by mail. In the agricultural area, a modified pathogen affecting large areas of crops could be economically devastating.

GM Animals

GM animals for food have also been developed, although none is currently in the market. In September 2010, the USFDA stated it was willing to consider approval of GM salmon, which grow twice as fast as native species because of the insertion of a gene that produces a continuously released growth hormone. GM Atlantic salmon have an added gene from the ocean pout that acts as an 'on switch' to produce the growth hormone year-round. This, therefore, shortens the time it takes to grow a mature salmon, which has the same flavor, texture, color, and odor as a regular salmon. This rapid growth should make salmon more plentiful and cheaper for the public. There are concerns, however, that GM fish might escape from growing pens and then breed with native fish, possibly causing catastrophic effects on the life cycle of wild fish, especially as GM salmon may out-compete the wild salmon population for limited food sources. If the USFDA approves the sale of the salmon, it will be the first time the government has allowed modified animals to be marketed for human consumption, and under existing guidelines, the fish would not have to be labeled as genetically modified. However, the environmental concerns would still need to be addressed.

There are other applications of GM technology to animals that are in development or close to approval. A GM pig, called enviropig, has been genetically modified in Ontario to be able to metabolize plant phosphorus more efficiently and consequently excrete less polluting phosphorus (up to 70% less) in its feces. Pig manure is high in phytate, a form of phosphorus, so when farmers use the manure as fertilizer, phosphates enter the watershed and cause eutrophication of the water by algae blooms that deplete oxygen and kill the aquatic life. The enviropig has an enzyme that allows breakdown of phytate without release of phosphorus. A transgene construct composed of the promoter segment of the murine parotid secretory protein gene and the *Escherichia coli* phytase gene is introduced into a pig embryo. Although the approval process in Canada was going ahead, funding ceased and the project is currently halted.

Another environmentally positive GM approach is to reduce flatulence from cows. During digestion of grasses, bacteria in the cow produce methane, which is a major greenhouse gas. Various research approaches in Australia, Canada, and the US are being taken to reduce release of methane in cattle by removing microorganisms that produce methane in the gut or rumen or that produce metabolic products other than methane, or modifying the grass the cattle feed on. Other applications being developed include GM cattle that produce more fat-free milk and increased amounts of casein for better cheese production.

Products Derived from GMOs

Products derived by GM microorganisms have been in use for many years. Because the final products are often highly purified, no residual DNA is present. Thus, the main issue is the specifications for the GM product. In the case of hepatitis B vaccine, the GM derived product was purer, safer, and cheaper than the original vaccine derived from human blood. As mentioned earlier, many food ingredients and processing aids, like enzymes, are produced by GM technology and have been evaluated for safety by national food safety authorities as well as by the Joint FAO/WHO Expert Committee on Food Additives. Because they are produced in closed systems, environmental concerns are minimal.

Perhaps the most infamous GM product is bovine somatotropin hormone (BST), which is a protein hormone naturally found in the pituitary gland of cattle and which is produced in cows after giving birth to initiate lactation. If BST is injected into nonlactating cow, milk production is induced without the need for a long gestation period. It can also be administered to lactating cows to significantly increasing milk production (10–25%). In the last few decades, a genetically modified source of BST has been developed in the US. Through recombinant DNA technology, a genetically modified *E. coli* bacterium is used to produce large amounts of the hormone, which is called rBST (recombinant bovine somatotropin hormone). The US is the only developed nation to permit cows to be given rBST and approximately 20% of herds use the hormone. Although the EU does not permit the use of rBST, milk produced using the technology may be imported and sold without labeling. There are various arguments against rBST use including uncertainty about its safety to consumers over a lifetime, economic reasons (too much milk may lower the price, and consumer reluctance to purchase such rBST milk or products made with the milk), and animal health reasons (increased risk of clinical mastitis, reduced fertility, and increased risk of lameness). The Codex Alimentarius Commission has not been able to achieve a consensus on the approval of rBST, especially as Canada and the EU have not approved its use for animal health reasons.

There has been recent interest in the use of GM microorganisms for the ethanol industry. Lignocellulosic producing plants such as switchgrass, straw, and various wood chips are cheap ingredients to make ethanol and reduce the biofuel industry's reliance on maize and other crops. Much work has been expended on developing GM microorganisms that convert the pentosans derived from the celluloses to ethanol. GM microorganisms that can convert xylose and other pentose sugars along with cellulosics-derived sugar constituents to ethanol would greatly improve the efficiency of such production and lower costs. Modified *Saccharomyces cerevisiae*, *Zymomonas mobilis*, *E. coli*, and *Klebsiella oxytoca* have been the most successful GM microorganisms so far, but much work has yet to be done before these lignocellulosic products can be cheaply and efficiently converted to fuel.

Medical advances may be made possible in the near future through the use of GM animals. For instance, GM hens lay eggs that have miR24, a molecule with potential for treating malignant melanoma and arthritis, and also human interferon b-1a, an antiviral drug. GM goats have been raised to produce a constituent of human milk as well as antithrombin for people whose blood needs thinning. Antithrombin, normally harvested from human plasma, is used in patients preceding surgery to stop blood clotting but carries a risk for blood-borne diseases. Other GM goats are being engineered with a gene from a spider for dragline silk to produce silk protein in their milk; this silk milk would be transformed in web-like

'biosteel' material. Another example is GM cows that produce large amounts of albumin in their milk, which can be used to treat burn patients and aid those with liver and kidney diseases.

Positions of Proponents and Critics

In the present day, GM crops and foods are a multibillion dollar industry that is controlled by the companies that produce them. Farmers who wish to plant GM seeds must pay a premium so that those who invested in the research and develop can recoup their costs and make a profit in the same way as drug companies or any research intensive business. Some potential customers feel this is a monopoly by large multinational corporations and that prices of seed and other GM products will always remain artificially high. This is particularly a concern in developing countries where the value of GM crops may be the greatest, especially if there is drought, flooding and extremes of temperatures that are exacerbated by climate change. However, many of these countries, such as Zambia in Africa, refused shipments of whole kernel GM maize because of concerns that farmers would grow the seed and jeopardize future trade with the EU.

GMOs in agriculture became a contentious issue when first shipments of GM maize and soybeans were shipped from North America to Europe. The advantages claimed by GM use proponents are: (1) more effective control of destructive insects through targeted pest control and less resistance by pests to sprayed insecticides or those delivered through irrigation; (2) much less use of actual chemical pesticides with less chance of indiscriminate dispersion in the environment including wind drift and water runoff, and destruction of beneficial insects; and (3) reduced tillage with subsequent soil erosion required to remove weeds. However, these are advantages that accrue to the farmer and not to the consumer. Consequently, the distribution of the risks and benefits is an issue in risk communication.

One of the most used GM products is the glyphosate-based herbicide (e.g., Roundup®) against weeds where farmers do not need to hoe or remove weeds mechanically or use traditional herbicides. However, there is a fear that superweeds resistant to this herbicide will eventually emerge, making crop yields less in the future. There are also concerns that pollen from GM crops will fertilize nonGM species, or seeds from GM plants will spread uncontrolled GM genes into the environment, sometimes called 'genetic contamination' or 'genetic pollution' and also lessen diversity in crops. GM crops are meant to be isolated from crops grown in nonGM areas, and if pollen transmission is limited as with maize, this is feasible. But this would be impossible if GM trees were developed, for example, to be resistant to spruce budworm and withstand drought as airborne pollen transmission by tree is often measured in kilometers.

The development and sale of GM foods has been challenged on safety, economic, and environmental grounds. Evaluation of GM foods for human food safety requires a demonstration of substantive equivalence in nutrition compared to its unmodified counterpart. To decide if a modified product is substantially equivalent, the product is tested by the manufacturer for unexpected changes in a limited set of components, such as toxins, nutrients, or allergens, that are present in the unmodified food. The manufacturer's data are then assessed by the appropriate regulatory agency. That data, along with data on the genetic modification itself and resulting proteins (or lack of protein), are submitted to regulators. If regulators determine that the submitted data show no significant difference between the modified and unmodified products, then the regulators will generally not require further food safety testing. However, if the product has no natural equivalent, or shows significant differences from the unmodified food, or for other reasons that regulators may have (for instance, if a gene produces a protein that had not been a food component before), the regulators may require that further safety testing to be carried out. In addition, special studies are required to demonstrate that the GM food contains no new proteins (or increased level of a known protein) capable of causing allergenic reactions. A standard safety test may consist of the following steps:

1. Analysis of the chemical composition of the relevant plant parts, measuring nutrients, antinutrients (those that interfere with the absorption of nutrients) as well as any natural toxins or known allergens;
2. Assess the risk of gene transfer from the food to microorganisms in the human gastrointestinal system;
3. Study the possibility that any new components in the food might be allergens;
4. Estimate how much of a normal diet the GM food would comprise;
5. Estimate any toxicological or nutritional problems revealed by this data in light of data on equivalent foods; and
6. Additional animal toxicity tests if there is the possibility that the food might pose a risk.

In this regard, two GM products failed initial safety testing because of possible allergic reactions and were discontinued. To date, no adverse health effects caused by GM products approved for sale have been documented. However, environmental concerns and labeling remain major issues for marketing GM foods.

Opponents of GM foods are demanding more rigorous environmental testing before any approvals are granted. Although public knowledge of GMO technology and GM foods is generally low, consumer acceptance of the technology is highly variable. In Canada, China, and the US, many GM foods are on the market and no special labeling is required. However, the EU, Japan, Malaysia, Australia, and other countries have taken a cautious approach to GM food and have established labeling and traceability requirements for GMOs and their derived food products. These requirements dictate a physical separation of GMOs and nonGMOs throughout the whole supply chain. At the production and raw commodity level, this requires a certification scheme; this becomes more complicated for GM ingredients, especially those which are otherwise indistinguishable from their nonGM counterparts, such a vegetable oils. In some cases, conventionally grown crops and food made from them may contain a small amount of GMOs due to cross-pollination. Current analytical methods are capable of detecting approximately 1% of GM food in a mixture, and this is used as the *de facto*

limit in most legislation. Therefore, if a product is found to contain more than 1% GMO, it is considered to be mislabeled, and subject to regulatory action, even if it poses no safety concern. Another potential problem of labeling GM food is that it could, in principle, be applied at the foodservice level. As with the term 'organic', some businesses may try to use 'nonGM' as a marketing advantage and thus further contribute to so far scientifically unfounded fears of consumers to GM foods.

The US follows a scientific, risk-based assessment appealing to the concept of substantial equivalence, and the notion that zero risk in food safety regulation is not practical, given that conventional foods are already presumed to be safe. In contrast, the EU follows a more precautionary approach to risk management of GMOs and has abandoned the concept of substantial equivalence. In 1999, the European Council formalized a moratorium on GMO approval by recommending to the European Commission an amendment to the existing regulations. The provisions of the recommendation were for the EU to take a thoroughly precautionary approach to future approval of GM crops, and that GM crops should not be placed on the market until it could be demonstrated that there is no adverse impact on human health and the environment, and that principles regarding traceability and labeling be applied. A revised regulatory framework was subsequently approved by the European Parliament and European Council in 2003. Critics of the EU's adoption of the precautionary principle argue that it has become less of an approach for risk management and more of a tool for lobby groups to influence the regulatory process, undermining the role of science in that process. The EU has already proven its willingness to reject World Trade Organization (WTO) decisions where there is scientific uncertainty regarding the potential health effects of a product and strong public support for the continued moratorium (as occurred in the case of bovine growth hormones (BGHs), where the EU has accepted the imposition of countervailing sanctions against some of its exports to maintain the moratorium on BGHs).

It has been argued that in drought-prone developing countries, especially in areas of Africa, the use of GM crops with a tolerance to limited rainfall could be the only means to stave off famine and malnutrition for millions of people. However, even there GM crops and products have become a contentious issue. In 2002, many countries in eastern and southern subSaharan Africa experienced their worst food crisis in a decade affecting 15 million persons. The governments of Malawi, Mozambique, Zambia, and Zimbabwe rejected United State food aid because of concerns over the inclusion of GM maize. GMO advocates in the US, Canada, Australia, and Argentina (all major GM food exporters), publically stated that these governments were allowing millions of their countrymen to starve because of unfounded fears of health or other concerns. GMO opponents indicated that offering GM maize to these countries was a means of encouraging African countries to adopt GM technology because the exporters were having a hard time having their products accepted in Europe. The US government stated that it did not separate GM and nonGM grains and had insufficient nonGM grains to supply these countries. The grain was not milled before being sent, the extra cost claimed to be a factor, but opponents of the aid argued this was not done so that farmers could replant some of the grain as seed and make these countries potential GM crop growers in the future.

This had been previously demonstrated in Mexico where farmers planted GM varieties received as food. This has become a contentious issue in that country where seeds are smuggled across the border from the US, the world's largest maize producer, with more than 70% of crops being from GM varieties. Some Mexican farmers in the arid northern flatlands are planting banned GM maize to reduce crop loss. In contrast, farmers in the south are concerned that pollen from these GM crops will fertilize native maize species and reduce the pool of local maize varieties, which may be as many as 10 000. However, some officials in Mexico indicate that Mexican farmers will not be able to compete without GMO crops. In 2008, Mexico, the US, and Canada lifted all maize tariffs under the 1994 North American Free Trade Agreement, and Mexico imported nearly 35% of maize for its residents. Because maize costs have risen because of the biofuel industry, there is an argument that growing and harvesting of GM crops would reduce Mexico's dependency on the US for its maize.

Eventually, South Africa milled the US GM maize and Malawi, Mozambique, and Zimbabwe accepted the milled food to be distributed as famine relief. Because Zambia continued to refuse the milled product, it became a rallying point for advocates both for and against biotechnology, using Zambia's stand as an example. The refusal by the EU to state that this GM maize were safe for African governments led the US to file a case against the EU through the WTO. As a result of the extensive publicity in Europe, nonGM producers gained much more of the EU market, and the US ended up with a surplus of GM maize, which it was unable to sell. In August 2003, the US, Canada, and Argentina took the EU to the WTO for suspending approvals for biotech products, and for six member states' national bans on EU-approved GMOs. The US claims to have suffered $200 million in lost sales for maize products alone and $100 million for soy products. European governments voted with a clear majority in 2005 to retain existing national bans on GMOs.

In 2006, the WTO Dispute Panel ruled on three aspects of the EU's regulation of GM crops: first, the EU had acted inconsistently with its obligations under the SPS Agreement (Agreement on the Application of Sanitary and Phytosanitary Measures) by applying a *de facto* moratorium on approvals on new GM crops between June 1999 and August 2003; second, in the case of specific measures delaying the approval of 24 new GM crops, the EU had breached its obligations under the SPS Agreement; and third, safeguard measures implemented by six EU member states against the import or marketing of specific GM crops were not based on any risk assessment as required by the SPS Agreement, and hence the EU had acted inconsistently with its obligations under that Agreement. However, the ruling did not consider the source of the contentious issues: (1) the safety of GM foods; (2) substantial equivalence that states that GM foods are like conventional foods; and (3) whether the GMO approval process by the EU is consistent with its obligations under the WTO. Some commentators feel that the US may have won a battle for marketing GM foods but lost the war in Europe where there is still much opposition to GMOs on the market.

However, with the WTO ruling, antiGM governments, such as Zambia's, have lost one of their arguments for not adopting the technology. Drought struck Zambia again in 2005 and some farmers would like to have had permission to plant GM crops. Among the proponents is the Biotechnology Outreach Society of Zambia, which accepted the 2003 findings of a team of Southern African scientists that GM crops pose no immediate risk to humans and animals and advised the southern African nations to embrace the technology because of its potential to increase agricultural yields. In contrast the Jesuit Center for Theological Reflections and the Kasisi Agricultural Training Center thought that GM crops would bring negligible benefits to Zambian farmers and could threaten the sustainability of small-scale farming in Zambia. The government suggested that farmers should consider alternatives to maize, such as winter maize, which grows well in dry conditions, and cassava, and to irrigate their fields with water from wetlands. Although the US leads the world in GM crops (>16% of the total planted), the recent drought in 2012, which cut the maize production by approximately 20%, may increase the desirability of GM crops. In theory, some GM varieties are able to withstand extreme climate change. However, it is interesting that the varieties planted for the 2012 maize and soybean crops in the midwest did not fare well against the recent drought.

However, another issue is the use of ingredients from GM products, such as lecithin. Maize oil and soy oil are sources of lecithin, which is widely used in processed food as an emulsifier. This is a highly purified product with no protein or DNA remaining from the GM crop source. Nevertheless, consumer concerns about genetically modified food have extended to highly purified derivatives from GM food. In 2000, the EU required labeling of food containing additives derived from GMOs, including lecithin, even though it is not possible to distinguish a GM product from a conventional one through any laboratory tests (i.e., total equivalence). Thus, industries wanting to sell lecithin in Europe have to maintain a written tracking record of all their sources if they wish to avoid any labeling infractions. Labeling may eventually be an issue in the US and Canada where national governments do not require labeling of GM foods or ingredients. However, in 2013, a proposed new law in New Mexico defines any product containing more than 1% of a genetically modified material as a product that would require a disclosure label on the 'immediate container' or wrapper and would require the label to be 'easily legible.' A referendum for a similar measure in California was defeated in November 2012.

Conclusion

As Ramjoué (2008) states: The most fundamental question to be answered is whether and to what extent a given society believes that a certain technology, in this case the use of genetic engineering in agriculture, is a useful and appropriate way forward. It seems that some countries in the world agree that GM products, like drugs, are a benefit overall, and other countries are either ambivalent or totally opposed. These past recognize that once GM crops become a part of agriculture, they cannot be eliminated, and future trade could be adversely affected. Actually, even in regions like the EU, which has many Member States opposed to GM foods, a certain proportion of GM ingredients may be permitted because of inadvertent exposure in the food chain to some GM components, and it would appear in the very long run, GM products are going to be present in all countries, coming from large farms with mass-produced monocultured crops. This will be accelerated because of more extreme weather events making growing, harvesting, and storing of crops more difficult and with fewer proportions of a society willing to work on the farm. May be this will result in cheaper food for the masses and probably no long-term health effects, but with a probable loss of the small farmer and local varieties unless the public sees value in the foods produced in the same way as wines, cheeses, and organic foods have developed their uniqueness and remained thriving industries.

Safety of Regional Specialities – Korean Fermented Foods

CH Lee and GI Lee, Korea University, Seoul, Republic of Korea

Glossary

Critical control point A processing factor of which a loss of control would result in an unacceptable food safety or quality risk.

Fermentation A kind of food processing that is the conversion of carbohydrates to alcohols and carbon dioxide or organic acids using yeasts, bacteria, or a combination thereof, under anaerobic conditions.

Food safety A scientific discipline describing the handling, preparation, and storage of food in ways that prevent foodborne illness.

Hazard A biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effect.

Hazard Analysis Critical Control Point A systematic preventive approach to food safety and pharmaceutical safety that addresses physical, chemical, and biological hazards as a means of prevention rather than finished product inspection.

Soybean Sauce and Soybean Paste

Korean-style soybean sauce (*Kanjang*) and soybean paste (*Doenjang*) are produced in a single process using *Meju*, a fermentation starter. The *Meju* is prepared from cooked soybeans. Soybeans are soaked overnight in water, cooked for 2–3 h, and mashed by pounding. The substance is shaped like a brick or a ball, dried in the sun, and stored in a stack covered during the night for several days. Through this process, molds (especially *Aspergillus oryzae*) are grown on the surface, and bacteria (typically *Bacillus subtilis*) are generated inside the *Meju*. The enzymes from molds and bacteria hydrolyze the soybean proteins into amino acids, and the carbohydrates into sugars and organic acids. The amino acids and sugars interact with each other in a browning reaction, resulting in the characteristic dark brown color and meaty flavor. Well-fermented *Meju* is immersed in an earthen jar filled with brine and ripened for several months. The brown color and meaty flavor leach into the brine. During this period, salt-tolerant yeasts grow in the mash, particularly *Saccharomyces rouxii*, which produces the aroma of soybean sauce. The liquid portion becomes soybean sauce (*Kanjang*) and the precipitates become soybean paste (*Doenjang*). Soybean sauce produced thusly is boiled once and stored in an earthen jar for years.

Gochujang, a unique hot bean paste, is one of Korea's most common and popular seasonings. It is made with *Meju* and malt made from barley. Malt powder is mixed with cereal porridge made from rice, glutinous rice, or barley. The enzymes in malt hydrolyze the starch into sugars and reduce the consistency of the mixture. *Meju* powder, red pepper powder, and salt are added to the partly saccharified porridge, with thorough mixing, to form a paste that is transferred to an earthen jar. The top is covered with salt to prevent mold growth. The jar is placed in the sun for further fermentation. The proteins in soybean and cereals are degraded into amino acids to produce a meaty flavor. During fermentation, a wonderful harmony of the meaty flavor from hydrolyzed proteins, the sweet taste of hydrolyzed starches, the pungent taste of red pepper, and the saltiness is achieved, and a new characteristic flavor stimulating the appetite of Koreans is formed.

Safety concerns of these fermented soybean products include possible contamination with mycotoxin-forming molds during *Meju* fermentation, biogenic amine formation during the aging process in brine, and contamination with *Bacillus cereus*. Much research has been conducted in Korea on these safety concerns. It has been proven that aflatoxins are degraded to 80–90% after 2 months of fermentation and degraded to 100% after 3 months of fermentation.

In addition, samples of soybean sauce and soybean paste were collected from various markets in Korea to detect aflatoxin levels. According to a report supported by the Korea Food and Drug Administration (KFDA) in 2006, aflatoxin levels were not detected in a total of 14 samples of *Doenjang*, *Kanjang*, and *Gochujang*. Another report performed in 2004–2005 showed that aflatoxin B_1 was detected in one of the seven soybean sauce samples and in 2 of the 56 soybean paste samples by enzyme-linked immunosorbent assay/high-performance liquid chromatography (ELISA/HPLC). Because the detected levels were 1.81 and 0.05–0.17 ppb, respectively,

 doi:10.1016/B978-0-12-378612-8.00307-3

they were under the permitted level (10 ppb) of Korea Foods Standards (Table 1). Although they are within safe levels, right manufacturing processes and management practices (including cultivating and storage technology) are important to minimize the contamination with aflatoxin, ochratoxin, biogenic amines, and *B. cereus* at every stage of production.

Several factors can be considered in degrading aflatoxins during fermentation. Ammonia produced during the fermentation, light, microbial competition with *Bacillus* spp., and addition of charcoal or vitamin C were reported to help reduce aflatoxins in soybean products. In addition, increasing concentrations of CO_2 or N_2 suppressed the formation and growth of aflatoxin because aflatoxin producing molds are aerobic organisms requiring O_2. The most important factor is the prevention of any mold growth, which results in aflatoxin production because any subsequent cooking will not destroy it.

Table 1 Regulatory standards for traditional Korean fermented foods

	Fermented soybean products	*Kimchi*	*Fermented fish products*
Aflatoxin ($\mu g\ kg^{-1}$)	<10 ppb (vitamin B_1) <15 ppb (total aflatoxin)	– (<10 for red pepper powder)	–
B. cereus	<10 000 per 1 g (excluding *Meju* and soy sauce)	–	–
Coliform group	Negative (limited to sterilized mixed paste)	Negative (limited to sterilized packaged products)	Negative (limited to *Jeot* and spiced/seasoned *Jeot*)
Escherichia coli	–	–	–
Harmful metals ($mg\ kg^{-1}$)	–	Lead <0.3 Cadmium <0.2	–

'–' Indicates no regulations.

Source: Reproduced from Korea Food & Drug Administration (KFDA) (2008) *Food Code*. Seoul: Korea Food Industry Association.

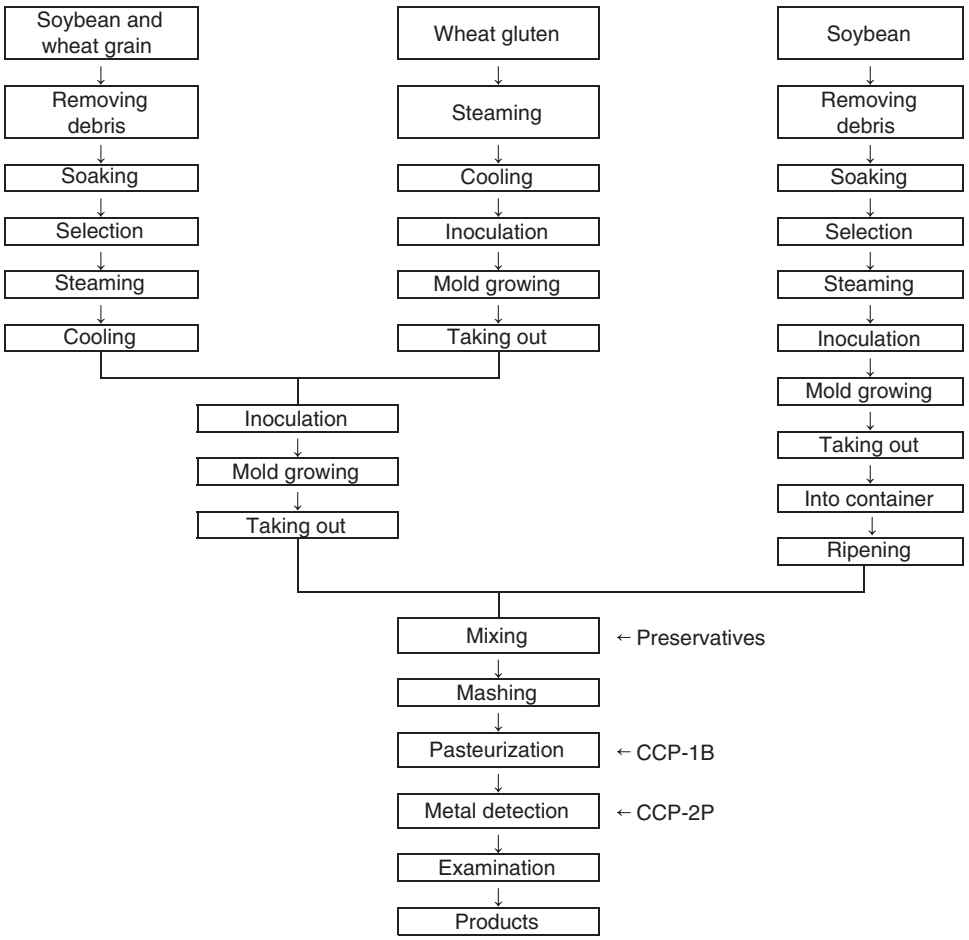

Figure 1 Flow chart of the procedure for *Doenjang*, marked with CCPs.

It was suggested that storage temperatures should be maintained at 0–7.5 °C because the optimal temperature for aflatoxin production is 25–30 °C. The food industries in Korea are therefore launching refrigerated soybean products for enhanced safety. Current refrigerated soybean paste accounts for 16% of the sales. This method was also reported to remove off-flavor and improve taste.

Adopting controlled fermentation techniques using *Koji*, a starter of Japanese soybean products, is a safe alternative to replace the traditional method. Most of the industrial production of soybean sauce and soybean paste in Korea utilizes *Koji* instead of *Meju* because *Koji* contains *A. oryzae* rather than *Aspergillus flavus*, which produces aflatoxin. However, the taste and flavor of soybean products fermented with *Koji* are not as rich as those made in traditional ways. It is thus worthwhile to introduce both these methods in the food market to meet consumer preference.

As an approach to eliminate, minimize, or prevent hazards from farm to fork, the hazard analysis critical control point (HACCP) system is highly regarded. This control system includes seven principles designed to prevent problems before they occur and to correct deviations as soon as they are found. The critical control points (CCPs) are placed in the flow chart of operational steps, where practices can be applied. The KFDA has put efforts in developing HACCP models for improving safety and reducing hazards in Korean fermented foods. The following models for soybean products are the examples. The potential hazard lists of fermented soybean products, *Doenjang*, *Kanjang*, and *Gochujang*, can be summarized as follows: biological hazards (pathogens, such as *E. coli* and *B. cereus*, yeast, and molds), chemical hazards (aflatoxin and pesticide residues), and physical hazards (foreign substances, such as grass, seeds, sticks, and wood waste). According to the HACCP model suggested by the KFDA, the CCPs of *Doenjang* and *Gochujang* are identical (Figures 1 and 2). Two CCPs (CCP-1B and CCP-2P) were noticed in their procedures. It mentions that pathogens, such as *E. coli* and *B. cereus*, should be controlled in the pasteurization step (CCP-1B) with critical limits, appropriate time, and temperature (60–80 °C). The metal detection step (CCP-2P), a procedure to remove iron and stainless steel using a metal detector just before packaging, is another critical point. The quality control for the raw material (soybean) is relatively easy in Korea because most companies purchasing it in bulk from the Korea Jang Cooperative.

Kanjang has only one CCP (CCP-1B) for a pasteurization step at 80–85 °C to manage pathogenic bacteria (Figure 3). Bacterial count of *B. cereus* should be less than 10^4 cells per gram in these soybean products after the thermal treatment.

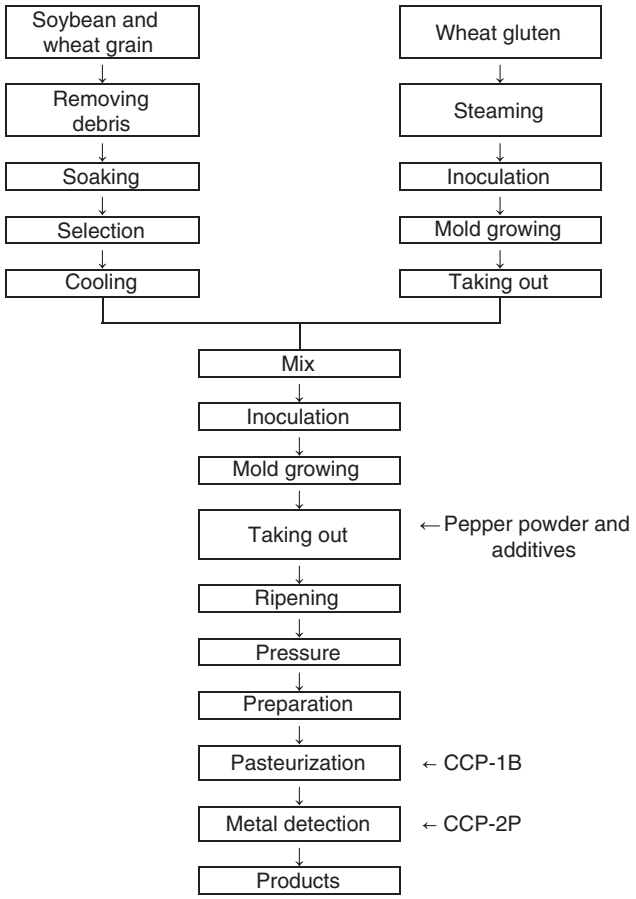

Figure 2 Flow chart of the procedure for *Gochujang*, marked with CCPs.

Fermented Fish Products

Fermented fish products in Asia are generally salt-fermented products: fish sauce, fish paste, and cured fish. When the salt concentration is higher than 20% of the total weight, growth of pathogenic and putrefactive microorganisms can be prevented. In this case, the products do not need other preservative means. The first criterion for classification in this group is the degree of hydrolysis, which is influenced by fermentation time and temperature, added enzyme sources, and the water content. The fully hydrolyzed liquid is defined as fish sauce. The cured fish is confined to represent the partially hydrolyzed fish products that retain the original shape of fish in the exuded liquid, and this form is frequently used as a side dish for rice meals. Fish paste is characterized by partially dried salted fish, which restricts the degree of hydrolysis and produces a homogeneous and solid condiment. Each type can be further subdivided by the type of raw materials, such as fish species, portion of fish, etc.; accordingly, numerous products can be named. In Korea, more than 30 products are included in the category of cured fish.

When the salt concentration is lower than 20%, the salted fish undergoes rapid spoilage, and other means of preservation is needed. Lactic fermentation by the addition of carbohydrate is an old method for fish preservation in low-salt processes. Rice, millet, flour, and even syrup (or sugar) are used as the carbohydrate source. The amount of added carbohydrate and the salt concentration primarily control the extent of acid fermentation and maintain quality. An alternative method keeps the low-salt fermented fish with vinegar at low temperatures. This method is practiced widely in the Scandinavian countries. Many Asian countries produce salt-cured and dried-fish products, for example, *Plakem* in Thailand, *Jambalroti* in Indonesia,

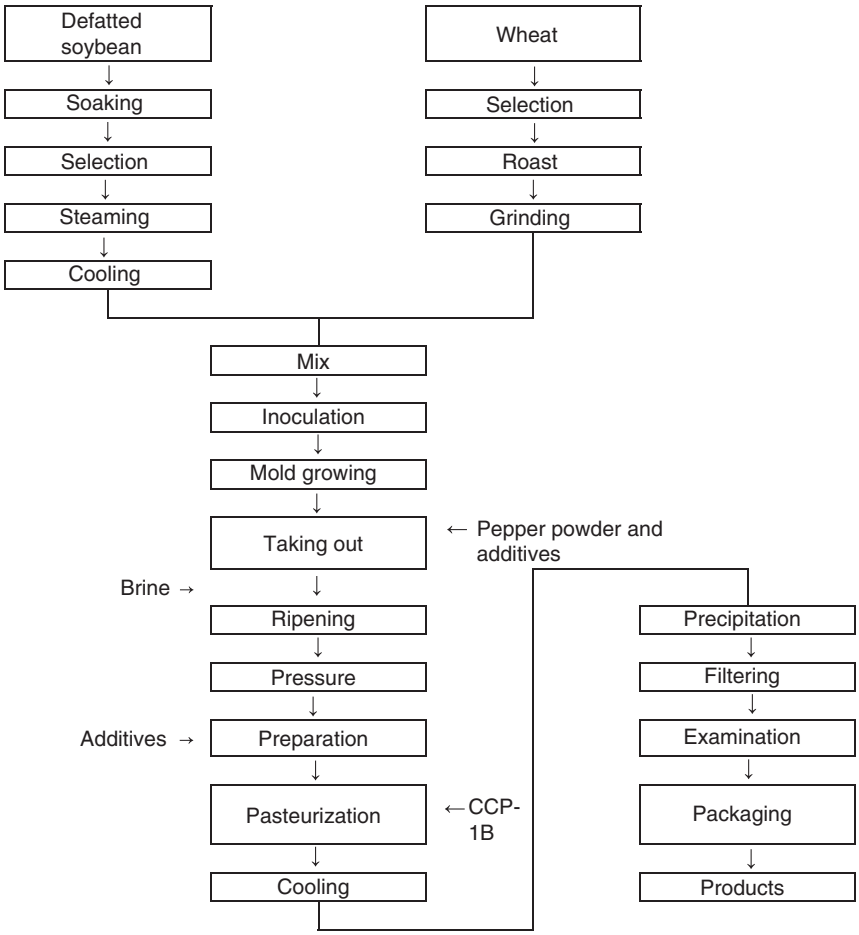

Figure 3 Flow chart of the procedure for *Kanjang*, marked with CCPs.

Maldive fish in Sri Lanka, and *Gulbi* in Korea, but the role of fermentation in these products is not fully understood.

Fermented fish products can be divided on the basis of the enzyme hydrolyzed versus the microbial fermented. The products are subdivided into four groups depending on the enzymatic hydrolysis: (1) hydrolysis in >20% salt, (2) hydrolysis in salt + drying, (3) hydrolysis at low temperature, and (4) hydrolysis at low pH. The products preserved by microbial fermentation are subdivided into two groups: (1) fermented with added carbohydrate and (2) fermented without added carbohydrate.

The major potential hazard associated with proteinaceous foods, such as fermented fish, is from the growth of pathogenic bacteria such as *Vibrio* spp., presence of parasitic worms, and the production of physiologically active amines. Of particular concern for unheated foods in anaerobic conditions is the possible growth of *Clostridium botulinum* and its toxin production.

It is evident that neither the high-salt nor the low-salt lactic fermented fish products will cause the growth of any pathogenic bacteria once they are prepared with the appropriate salt content and/or low pH. However, the improper storage of raw fish before salting and insufficient acid production in a very low-salt fermentation can cause an outbreak of botulism. The botulinum toxin is destroyed relatively easily by cooking, but it is very stable in salty and acidic environments. The fermented fish products most frequently incriminated in *C. botulinum* type E poisonings are *Sushi* (a type of *Narezushi*) and *Kirikomi* (a type of Shiokara) in Japan, and salmon egg cheese (fermented crushed salmon roe) among British Columbia First Nation Peoples and Alaska Indians.

The physiologically active amines, such as histamine formed by the bacterial decarboxylation of histidine, may be produced in amounts sufficient to cause poisoning in certain fishes. *Jeot-gal* is the generic name of high-salt fermented fish products, which are used not only for side dishes but also for additives in making *Kimchi*. *Jeot-gal* contains large amounts of precursor amino acids of biogenic amines because it is made from the muscles and viscera of seafood and salts. It is therefore important to reduce the biogenic amine content. Several studies suggested that the addition of garlic and glycine can inhibit amino acid decarboxylase activity in *Myoelchi-jeot* (made of anchovies). In fact, the cadaverine and tyramine contents were reduced by up to 18.4% and 30.9%, respectively, in the culture treated with garlic extract. Glycine has the greatest inhibitory activities on biogenic amine production. The contents of putrescine, cadaverine, histamine, tyramine, and spermidine were reduced by 32.6%, 78.4%, 93.2%, 100%, and 100%, respectively, compared with the control. Therefore, there is no doubt that these findings can help improve safety. Nowadays, many people are trying to reduce sodium intake because they

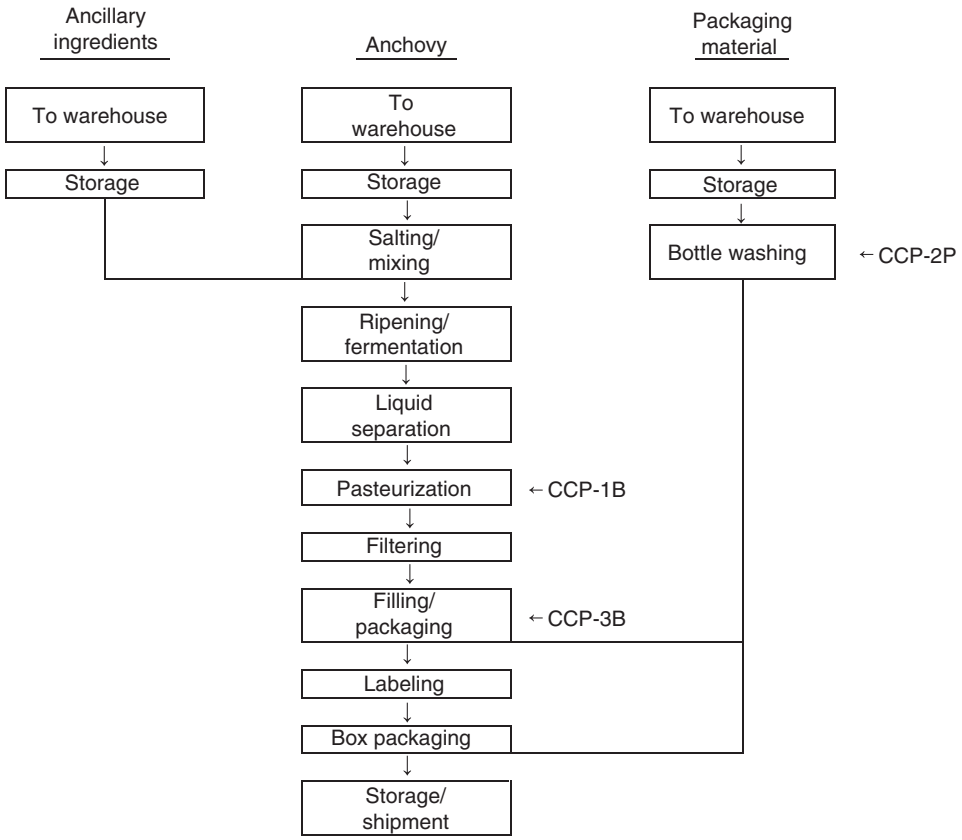

Figure 4 Flow chart of the procedure for liquid fermented anchovy, marked with CCPs.

are paying attention to their health and well-being. Keeping this in mind, companies are investing in cooling systems to produce refrigerated products with less salt. Following the HACCP, plan for liquid fermented anchovy is based on products that are produced not in a cooling system but in a traditional way (Figure 4). The possibility of pathogen growth results in a CCP at the pasteurization step (CCP-1B). Sufficient bottle washing is required to eliminate debris inside the bottle (CCP-2P). Proper filling and a packaging system (CCP-3B) are essential to prevent decomposition and microbial contamination due to poor sealing.

Fermented Vegetable Products

Kimchi is a unique fermented vegetable product with a long tradition in Korea. It is a common side dish served with cooked rice and other dishes. There are more than 50 varieties of *Kimchi* classified by the use of raw materials, processing methods, and the season and locality of preparation. Korean cabbage and Korean radish are the most popular vegetables for making *Kimchi*; but cucumber, carrot, onion, and even eggplant can be used as the primary vegetable. Fermented fish sauce is an important subingredient providing enzymes and flavor substances for fermentation. Salt, garlic, and red pepper play an important role in controlling the type of microflora in *Kimchi*. Production of organic acids at the cost of carbohydrates and resultant pH reduction contribute to maintaining freshness of the vegetables during the storage period.

A recipe for the simplest *Kimchi* may include Korean cabbage 100 g, garlic 2 g, green onion 2 g, red pepper powder 2 g, and ginger 0.5 g with an optimal salt content of 3.0%. Whole (or cut) cabbage is salted with 15% brine for 3–7 h, washed twice with fresh water, and drained. Other minor ingredients are chopped, combined, mixed with the treated cabbage, placed in containers, and tightly sealed. The length of time for completion of the fermentation depends on the salt content and temperature, 3 or 4 days at 20 °C and 2–3 months at 5 °C.

The content of reducing sugar decreases rapidly at the beginning of *Kimchi* fermentation, whereas the total acidity increases. The optimal pH and acidity for the best taste is 4.2 and 0.6% (as lactic acid), respectively. The number of aerobic bacteria decreases rapidly at the beginning of *Kimchi* fermentation, when anaerobic bacteria dominate. However, at the later stages of fermentation, surface film-forming aerobic bacteria start to grow, and texture softening and taste deterioration take place. During *Kimchi* fermentation, the type of microflora changes. The number of *Leuconostoc mesenteroides* decreases after 10 days of fermentation in a 3.5% salt content at 14 °C, whereas *Lactobacillus plantarum*, which is considered to be a key to the *Sauerkraut* production process, reduces the quality of *Kimchi*. It

is also worthwhile to note that there is a considerable increase in the vitamin B group during winter *Kimchi* fermentation. That is, the amounts of vitamin B_1, B_2, B_{12}, and niacin may reach as high as twice the initial amounts at the optimal maturation of *Kimchi* and then decrease as the taste of *Kimchi* deteriorates due to overfermentation. Vitamins A and C are reduced slightly during the fermentation, but it is an excellent way of preserving these vitamins during the winter season.

There have been several controversial debates on the safety of *Kimchi* in terms of nitrate, nitrite, secondary amines, and biogenic amines. It was reported that the levels of nitrate in the vegetable decrease rapidly over 4 days of fermentation at 20 °C, whereas the contents of nitrite and secondary amines increase slightly and before decreasing. The change in nitrate reductase activity during *Kimchi* fermentation follows the same pattern as the change in nitrate concentration. This indicates that *Kimchi* fermentation reduces the nitrate level in vegetables through the action of microorganisms without increasing the concentrations of nitrite or secondary amines to any significant level.

The formation of nitrite and secondary amines during *Kimchi* fermentation was of great concern to many researchers in Korea in the 1970s. However, it was found that the amounts of nitrite and secondary amines in *Kimchi* were very low compared with those in sausages and fish. The possibility of nitrosamine formation during fermentation was investigated because fresh cabbages contain large amounts of nitrate varying from 55 to 2500 ppm. However, the levels of nitrate are reduced rapidly from 135 to 70 ppm after 4 days of *Kimchi* fermentation and further down to 50 ppm after 10 days of fermentation at 20 °C. Thus, the subject is of less concern.

To examine the biogenic amine contents in commercial *Kimchi*, eight types of *Kimchi* products were analyzed by HPLC. The biogenic amine contents were between 0 and 150 mg kg^{-1}, which is an acceptable level for human health. The putrescine and cadaverine levels seem to be slightly high in the *Baechu Kimchi* sample compared with those of other samples. To reduce these amines, addition of *Jeot-gal* can be adjusted because the biogenic amines in *Jeot-gal* are transferred to *Kimchi*.

It is well known that *Kimchi* has strong antipathogenic and antimicrobial activities. In fact, *Clostridium perfringens* disappeared after 2 days of *Kimchi* fermentation; *Staphylococcus aureus* and *Salmonella typhimurium* after 4 days; and *Listeria monocytogenes*, *Vibrio parahaemolyticus*, and *E. coli* after 5 days, whereas the number of lactic acid bacteria increased from 10^5 to 10^8. This antimicrobial effect of *Kimchi* appears to result from the combined effects of the organic acids and bacteriocin produced during fermentation, and the *Kimchi* ingredients (garlic, onion, ginger, etc).

Contamination with parasite eggs in *Kimchi* imported from China was a big scandal in Korea in 2005. The types of parasite

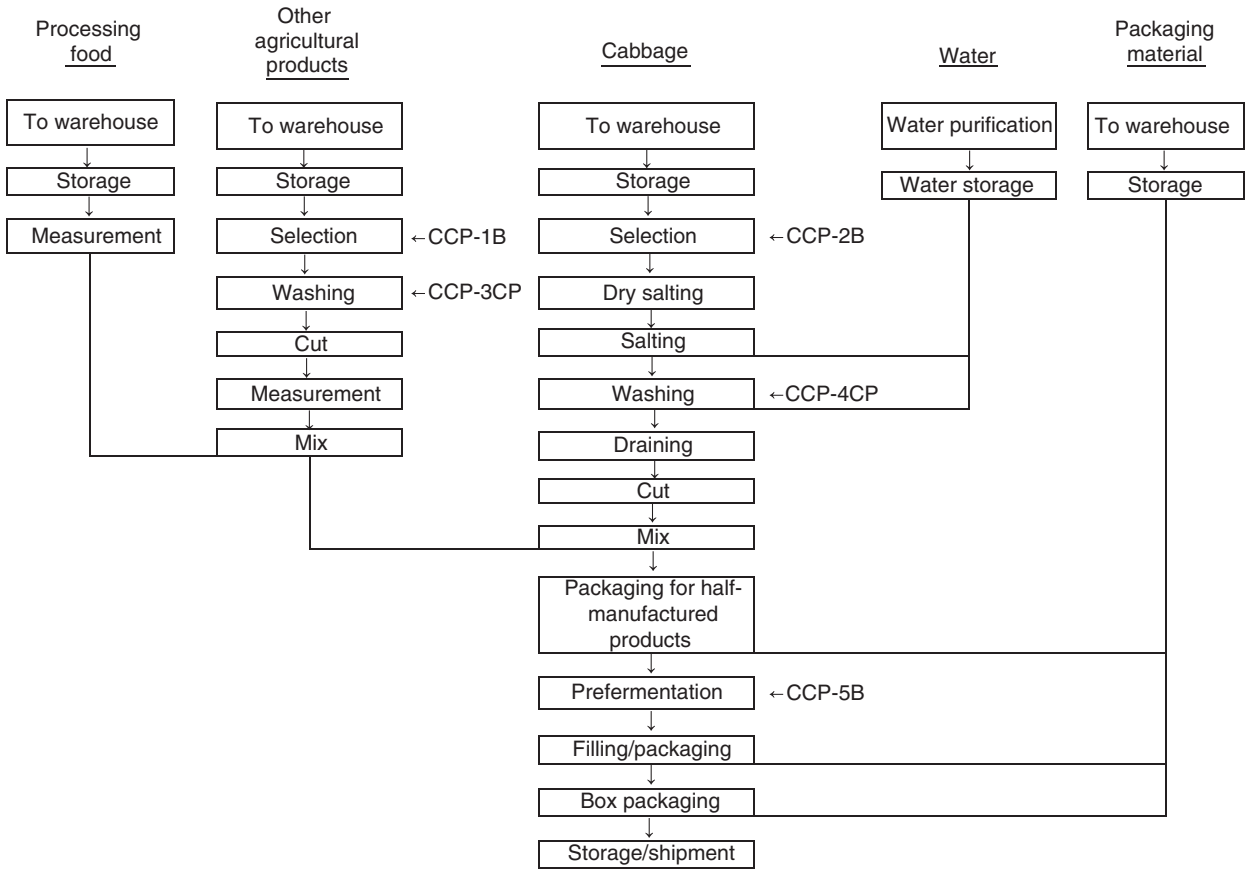

Figure 5 Flow chart of the procedure for *Baechu Kimchi*, marked with CCPs.

eggs found in *Kimchi* were *Ascaris lumbricoides* (roundworm), *Ancylostoma duodenale* (hookworm), *Trichostrongylus orientalis*, and *Isospora belli*. Although parasite eggs are mostly inactivated in *Kimchi* juice, which contains 3–5% salt, 0.8% organic acids (mainly lactic acid and acetic acid), and CO_2, the KFDA considered this issue as a safety incident at that time. It created a severe trade conflict with China, and the import and export of *Kimchi* were severely damaged.

To identify potential problems and possible corrective actions in the production of *Kimchi*, the KFDA has suggested the HACCP model, as shown below (Figure 5). Several CCPs (CCP-1B, CCP-2B, CCP-3CP, CCP-4P, and CCP-5B) have been identified by the analysis of biological, chemical, and physical hazards. Because *Kimchi* is a ready-to-eat product, a hazard analysis must be conducted to determine whether there are food safety hazards that are reasonably likely to occur. Among these items of hazard analysis, both microbiological evaluation and detection of pathogens of cabbages, ingredients, instruments, utensils, employees, and working area are essential. Therefore, the selection steps CCP-1B and CCP-2B (choosing good raw materials and removing decomposition and spoilage parts from materials) in the beginning of the HACCP plan is very significant for preventing pathogens, molds, parasites, and other contaminations from the raw materials to the final products.

The next step to consider is the washing procedure for other agricultural products and cabbages (CCP-3CP and CCP-4CP). Sufficient washing in accordance with the standard operating procedure (SOP) can help to remove the pesticide residues and foreign substances. Unlike other HACCP plans, the prefermentation step (CCP-5B) can be a critical point in making *Kimchi* because inappropriate temperature and time can result in abnormal fermentation.

Another example of pickled vegetable products, *Danmooji* (also known as *Takuan* in Japan), can be introduced. It is made from radish and used widely in Korea and Japan. In addition to being served alongside other types of Korean dishes, it is also used as a filling for *Kimbab* (rice roll in laver sheet). *Danmooji* is made by first salting radish, desalting it, and seasoning it with vinegar and sugar. The finished *Danmooji* is usually yellowish because food industries use coloring agents for this effect. The HACCP plan for *Danmooji* suggested by KFDA indicates five CCPs (CCP-1C, CCP-2CP, CCP-3B, CCP-4B, and CCP-5B) (Figure 6). They include proper seasoning preparation (CCP-1C) not to exceed the limits of food additives, proper washing (CCP-2CP) to remove the pesticide residues and foreign substances, proper filling/packaging (CCP-3B) to prevent decomposition and microbial contamination from poor sealing, and proper pasteurization (CCP-4B) and proper cooling (CCP-5B) to ensure microbial contamination and growth at the final stages. The amount of free chloride (more than 1 ppm) is required to maintain microbiological control in cooling water.

HACCP systems introduced in this article are one of the models that verify the safety of traditional foods. To ensure the validity and the good performance of a HACCP system, the system must be applied in combination with other food safety

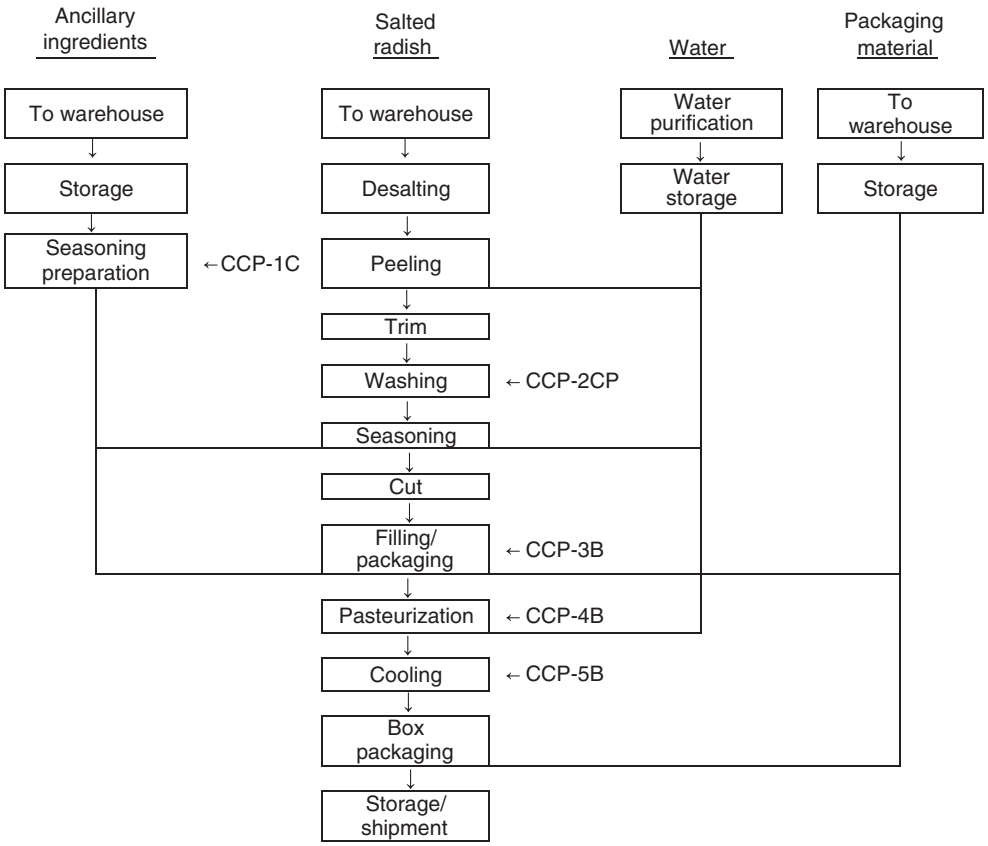

Figure 6 Flow chart of the procedure for salted radish (*Danmooji*), marked with CCPs.

assurance systems, such as good manufacturing practice (GMP), good handling practice (GHP), as well as personnel training. In fact, quite a number of industries have already obtained certification schemes, such as good agricultural practice (GAP), GMP, GHP, and International Organization for Standardization (ISO) standards. In addition, international standards, such as Codex standards, can facilitate the global trade of traditional foods as free trade agreement is increasing between countries. *Kimchi* was first registered in Codex in 2001, followed by *Gochujang*, *Doenjang*, and *Ginseng* in regional Codex 2009. Having Codex standards for more traditional foods will facilitate exports.

Safety of Human Milk: Microbiological Aspects

RM Lawrence, University of Florida College of Medicine, Gainesville, FL, USA
RA Lawrence, University of Rochester, Elmwood Avenue, Rochester, NY, USA

Glossary

Bioactive factors These factors are constituents of human milk that have specific functions for the infant in addition to nutrition. Example: Lactoferrin binds iron and suppresses the growth of *Escherichia coli*.

Breast milk Milk produced by the human breast stimulated either by infant suckling or mechanical pumping by hand or machine.

Breastfeeding To feed human infant at his/her mother's breast. To suckle.

Colostrum First milk produced after delivery.

Donor milk Milk pumped by a mother to be given to an infant not her own

Risk/benefit ratio The risk of a contamination versus the tremendous benefit of breastfeeding or receiving human milk.

Species specificity With respect to mammary secretion each species provides a milk specific for the offspring of that mammalian species and its nutritional and growth needs.

Introduction

Lactation is the physiologic completion of the reproductive cycle and occurs in all mammalian species including the human. Of more than 4000 mammalian species, each one produces a milk that is carefully engineered to meet the nutritional needs of that specific species as determined by the offspring's maturity at birth, the rate of physical growth and especially the rate of brain and neurological growth. The process of lactation is designed so that the offspring receives the feeding directly from the gland that produces the nutrient thus eliminating any intervention by the mother or utilization of equipment. There is no opportunity for invasion of infection. This discussion of human feeding will, however, also include situations where milk is removed from the breast and fed to the infant using man-made devices with and without any processing of the liquid. It will also include a description of human milk banking.

The Value of Human Milk

Any discussion of human lactation and breastfeeding requires first an understanding of the uniqueness of human milk and the importance of breastfeeding to both mother and infant. When specific issues are discussed such as maternal infection, medications, or complications of the infant it is the risk/benefit ratio that is the issue. What is the risk of a maternal infection to the nursling for example compared to the tremendous value of being breastfed. Thus, the answers are complex and multifunctional.

The most compelling reason to promote breastfeeding is species specificity. Human milk is designed for the nutritional needs of the human infant who will be exclusively nourished by it for 6 months and then continue to receive mother's milk for months to years while weaning foods are added to the diet. Human milk supports growth of brain and body as the sole nutrient. The human infant is the most immature of all mammals at birth except for the marsupials thus brain growth is the most significant need of the human newborn. The biochemistry of human milk includes nutrients not found in other species' milk especially the cow and the goat. Cholesterol, docosahexaenoic acid (DHA), and taurine are essential to human brain growth for instance but do not occur in cow milk. The micronutrients in human milk are easily absorbed by the human infant. The milk also contains enzymes that contribute to the digestion and absorption of all macro- and micronutrients.

There are a number of infection protection constituents in human milk (Table 1). Lactoferrin is an excellent example of a constituent with multiple roles. Lactoferrin binds iron to make iron unavailable for *Escherichia coli* that depends on iron for growth. When lactoferrin binds to iron, *E. coli* cannot flourish and the physiologic flora of the newborn gut thrives. The normal flora of the breastfed infant is *lactobacillus bifidus* (*Bifidobacterium bifidum*). The small amount of iron in human milk is totally absorbed by the infant. Only 10% of the iron in formula is absorbed in contrast.

Bioactive Factors

The proteins in human milk are not only a vital nutrient but also prevent infection and inflammation as well as promoting growth.

 doi:10.1016/B978-0-12-378612-8.00323-1

Table 1 Component functions in human milk

Function	*Component*	*Process*
Biosynthesis of milk components in mammary gland	Phosphoglucomutase	Synthesis of lactose
	Lactose synthetase	Synthesis of lactose
	Fatty acid synthetase	Synthesis of medium-chain fatty acids
	Thioesterase	Uptake of circulating triglyceride fatty acids
	Lipoprotein lipase	Uptake of circulating triglyceride fatty acids
Digestive function in infant	Amylase	Hydrolysis of polysaccharides
	Lipase (bile salt-dependent)	Hydrolysis of triglycerides
	Proteases	Proteolysis (not verified)
	Xanthine oxidase	Carrier of iron, molybdenum
	Glutathione peroxidase	Carrier of selenium
	Alkaline phosphatase	Carrier of zinc, magnesium
Preservation of milk components	Antiprotease	Protection of bioactive proteins (i.e., enzymes and immunoglobulins)
	Sulfhydryl oxidase	Maintenance of structure and function of proteins containing disulfide bonds
Anti-infective agents	Lysozyme	Bactericidal
	Peroxidase	Bactericidal
	Lipases (lipoprotein lipase, bile salt-dependent lipase)	Release of free fatty acids that have antibacterial, antiviral, and antiprotozoan actions
Anti-inflammatory agents	Vitamins A, C, and E	Scavenges oxygen radicals
	Catalase	Degrades hydrogen peroxide
	Glutathione peroxidase	Prevents lipid peroxidation
	Platelet-activating factor acetylhydrolase	Degrades platelet-activating factor
	α1-antitrypsin	Inhibits inflammatory proteases
	α1-antichymotrypsin	Inhibits inflammatory proteases
	Prostaglandin 1	Cytoprotective
	Prostaglandin 2	Cytoprotective
	Epidermal growth factor	Promotes gut growth and function
	Transforming growth factor-α	Promotes epithelial cell growth
	Transforming growth factor-β	Suppresses lymphocyte function
	Interleukin 10	Suppresses function of macrophages and natural killer and T cells
	Transforming growth factor-α receptors I and II	Binds to and inhibits transforming growth factor-α

In: Lebenthal E (ed.) *Textbook of Gastroenterology and Nutrition in Infancy*, 2nd edn. New York: Raven, and Hamosh M (2001) Bioactive factors in human milk. Breastfeeding 2001, Part I: The evidence for breastfeeding. *Pediatric Clinic of North America* 48: 69.

Leukocytes are present in milk in very high levels in colostrum and in lesser amounts continually throughout lactation. Specific antibodies and other antimicrobial factors protect the infant from infections. The immunologic benefits of human milk are numerous covering soluble factors, cellular components and those that are hormone like (Table 2). These bioactive properties of human milk range from proteins (i.e., lacotoferrin and lysozyme) hormones (such as erythropoietin, prolactin, and insulin) growth factors, neuropeptides (TNF, alpha, Il-6) anti-inflammatory agents (enzymes, antioxidants), and nucleotides (see Table 2). It is not only the presence of these factors that explains the immunologic properties of human milk but also their dynamic actions that affect infection protection in the normal development of the infants immune system. Although the fetus receives some maternal antibodies across the placenta, the newborn infant depends on the transport of secretory IgA (sIgA) immunoglobulins in colostrums and mature milk. sIgA provides local protection to the mucous membranes of the GI tract from birth throughout lactation.

Although the protective properties of human milk can be divided into cellular facts and humoral factors, it is important to recognize that the constituents of human milk are multifunctional, interactive, and complementary and have not been duplicated in artificial infant feedings. The nonimmunoglobulin antipathogen factors in human milk are shown in Table 3. This is a long list of specific antipathogens that have been demonstrated to protect against specific bacteria, viruses, and toxins.

The Mucous Membranes as Barriers

The mucosal immune system in the infant is immature but stands ready to respond to the stimulating factors in human milk. The primary function of the mucosal surfaces is immunologic even though it may perform other functions. The mucosal surface of the gut also serves to absorb nutrients. These barrier mucosal surfaces with their large surface areas

Table 2 Immunologically and pharmacologically active components and hormones observed in human colostrum and milk

Soluble	*Cellular*	*Hormones and hormone-like substances*
Immunologically specific	Immunologically specific	Epidermal growth factor
Immunoglobulin	T lymphocytes	Prostaglandins
sIgA (11S), 7S IgA, IgG, IgM IgE, IgD, secretory component	B lymphocytes	Relaxin
		Neurotensin
	Accessory cells	Somatostatin
	Neutrophils	Bombesin
T-cell products	Macrophages	Gonadotropins
Histocompatibility antigens	Epithelial cells	Ovarian steroids
		Thyroid-releasing hormone
	Additional cells	Thyroid-stimulating hormone
Nonspecific factors	Stem cells	Thyroxine and triiodothyronine
Complement		Adrenocorticotropin
Chemotactic factors		Corticosteroids
Properdin (factor P)		Prolactin
Interferon		Erythropoietin
α-Fetoprotein		Insulin
Bifidus factor		Cytokines
Antistaphylococcal factor(s)		Interleukins
Antiadherence substances		
Epidermal growth factor		
Folate uptake enhancer		
Antiviral factor(s)		
Migration inhibition factor

and constant exposure to microorganisms, foreign proteins, and chemicals predisposes the membrane to damage and infection. The infant's immune system is developing the ability to respond to and protect against invasive pathogens as well as learn to tolerate other commensal organisms that exist on these surfaces. The bioactive factors in human milk supplement this immune protection of the mucosa while limiting inflammation. This functional barrier also includes the actions of enzymes, chemicals, acidity or pH, mucus, immune globulins, and indigenous flora. Secretary immune globulins sIgA and IgM behave at the epithelial surface without inflammation but by limiting adherence and transmigration yet facilitating phagocytosis of potential pathogens.

Study of the microbial colonization of the intestinal tract has resulted in the demonstration of the effects of probiotics that are found amply in human milk. A number of probiotic or healthy bacteria that exist in the human body to protect against the growth of pathogens are defined as microorganisms that can exist within a host while affording benefits for the organism and the host. The best known of the probiotics are *Lactobacillus rhamnosus* GG, *Bifidobacteria infantis*, and *Bifidobacteria bifidus*. Many others are considered to be on this list and are even available commercially. Human milk promotes their growth and is an important protective mechanism associated with breastfeeding.

It is well established that human milk is effective in controlling bacterial infection. Numerous articles have been published demonstrating this protection. The Agency for Healthcare Research and Quality (AHRQ) investigated the values of human milk and published two reports of their findings. A review of the literature reveals a long list of antibodies present in human milk against bacteria including *E. coli*, *Bacteroides fragilio*, *Colostridium tetani*, *Haemophilus pertussis*, *Diplococcus pneumonia*, *Corynebacterium diptheriae*,

Table 3 Nonimmunoglobulin antipathogen factors in human milk

Antipathogen	*Pathogen*
Ganglioside GM_1	Cholera toxin Labile toxin of *Escherichia coli* Toxin of *Campylobacter jejuni*
Globotriaosylceramide	*Shigella* toxin I Shigalike toxin of *E. coli*
GM3	Enteropathogenic E. coli
Fatty acids	Enveloped viruses *Giardia lamblia*
Chondroitin sulfate	HIV
Sulfatide	HIV
Glycoprotein (mucin)	Inhibition: rotavirus *in vitro* and *in vivo*
Glycoprotein (mucin, glycosaminoglycan)	HIV
Lactadherin	Rotavirus
Mucin	Adherence: S-fimbriated *E. coli*
MUC 1	Poxviruses, HIV
Glycoprotein (mannosylated)	*E. coli* intestinal adherence
Large macromolecule	Respiratory syncytial virus
Macromolecule-associated glycans	Norovirus, *P. aeruginosa*
Oligosaccharides	Adherence: *Streptococcus pneumoniae* and *Haemophilus influenzae*, enteropathogenic *E. coli* *Listeria monocytogenes*
Fucosylated oligosaccharide	Adherence, invasion, *C. jejuni*, stabie toxin of *E. coli* stable toxin *in vivo*, *Vibrio cholera*
Sialyllactose	Cholera toxin, *E. coli*, *Pls. aeruginosa*, Influenza virus *Aspergillus fumigates*, Polyomavirus, *Helicobacter pylori*

Table 4 Nonantibody, antibacterial protective factors in human milk

Factors	*Proposed mechanisms of action*	*Organisms affected*	*Effect of heat*
Bifidus factor	Inhibits replication of certain bacteria in GI tract by causing proliferation of lactobacilli	Enterobacteriaceae, including shigellae, salmonellae, and some *E. coli*	Stable to boiling
Complement components	Opsonic, chemotactic, and bacteriolytic activity	*E. coli*	Destroyed by heating at 56° C for 30 min
Lysozyme	With IgA, peroxide, or ascorbate, causes lysis of bacteria	*E. coli* Salmonellae	Some loss (0%–23%) at 62.5° C for 30 min; essentially destroyed by boiling for 15 min
Lactoferrin (nutrient binders)	Binds ferric iron	*E. coli* *Candida albicans*	Two thirds destroyed at 62.5° C for 30 min
Lactoperoxidase	Oxidizes bacteria	*E. coli* *Salmonella* Typhimurium	Presumably destroyed by boiling
Nonantibody proteins: receptor-like glycolipid or glycoprotein	Inhibit bacterial adherence	*Vibrio cholerae*	Stable to boiling for 15 min
Gangliosides (GM1-like)	Interfere with attachment of enterotoxin to GM1 cell membrane ganglioside receptors	*E. coli* and *V. cholerae* enterotoxins	Stable to boiling
Nonlactose carbohydrate factors	Prevent action of stable toxin	*E. coli* stable toxin	Stable at 85° C for 30 min
Milk cells (macrophages, polymorphonuclear leukocytes, B- and T-lymphocytes)	By phagocytosis and killing: *E. coli*, *S. aureus*, *S. enteritidis* By sensitized lymphocytes: *E. coli* By phagocytosis: *C. albicans* lymphocyte stimulation by *E. coli* K antigen		Destroyed at 62.5° C for 30 min

Table 5 Nonantibody, antiviral, and antiprotozoan factors in human milk

Factors	*Proposed mechanisms of action*	*Organisms affected*	*Effect of heat*
Lipids (unsaturated fatty acids and monoglycerides)	Inactivate lipid-enveloped virus	Herpes simplex	Stable to boiling for 30 min
		Semliki Forest virus	
		Influenza	
		Ross River virus	
Macromolecules	Inhibit attachment and penetration	Herpes simplex	Most stable at 56 °C for 30 min
		Coxsackievirus B_4	Destroyed by boiling for 30 min
		CMV	
		Rotavirus	
α_2-Macroglobulin protein	Inhibits hemagglutinin activity	Influenza	Stable to boiling for 15 min
		Parainfluenza	
α_1-Antitrypsin	Trypsin-dependent inhibition	Rotavirus	Stable to boiling for 10 min
Bile salt-stimulated lipase	May generate fatty acids and monoglycerides that inactivate organisms	*Giardia lamblia*	
		Entamoeba histolytica	
Nonlipase macromolecule	Unknown	*G. lamblia*	
Milk cells	Induced interferon by virus or phytohemagglutinin; induced lymphokine by phytohemagglutinin; induced cytokine by herpes simplex virus; lymphocyte stimulation by rubella, CMV, herpevirus, measles, mumps		Destroyed at 62.5° C for 30 min

Source: Modified from May JT (1984) Antimicrobial properties and microbial contaminants of breast milk: an update. *Australian Paediatric Journal* 20: 265, and Pickering LK and Kohl S (1986). Human milk humoral immunity and infant defense mechanisms. In: Howell RR, Morriss Jr., RH, and Pickering LK (eds.) *Human Milk and Infant Nutrition and Health*., Springfield, IL: Thomas.

Salmonella shigella, *Chlamydia trachomatis*, *V. cholera*, *S. Aureus*, and several strains of Streptococcus. Human milk also contains other protective nonantibody properties (Table 4).

Protection against viruses in human milk has also been vigorously investigated. Antibodies have been demonstrated against polio virus, coxsachievirus, echovirus, enterovirus, influenza virus, Reovirus, RSV, Rotavirus, and rhinovirus. In tissue culture, human milk will inhibit the growth of these viruses. The various factors associated with the protection against viruses and protozoa in human milk are demonstrated in Table 5.

In summary, it is well established that human milk has many properties that protect against bacteria, viruses, and protozoa. These factors act in many ways including the stimulation of the mucous membranes to develop ongoing protection.

In addition to the infection protection and immune properties of human milk, there are many other unique constituents that enhance brain growth, mature the nervous system, provide enzymes that facilitate the digestion and absorption of nutrients, and provide hormones that enhance physiologic processes. Of particular interest are the hormones associated with appetite control, Leptin adiponectin, Grelin, Insulin-like growth receptor (IGF), Resistin, and obstatin; these hormones are associated with the fact that breastfed infants cannot be overfed. Breastfeeding is associated with a normal growth curve and not obesity. The growth curves developed by the World Health Organization using only healthy breastfed children demonstrate a more physiologic Body Mass Index (BMI). The BMI is calculated as follows: weight (kg)/height $(m)^2$ = BMI (metric).

The Process of Human Milk Feeding

When an infant receives his mother's milk directly by suckling at the breast, the milk he receives is clean. Mid-stream cultures of human milk contain no bacteria. The flora on the mother's skin includes benign staph and diptheroids thus the infant does receive some skin bacteria while suckling. The infant is sterile at birth but is quickly colonized by his environment. It is ideal if the infant is colonized with his mother's bacteria that serve to protect the infant from being colonized by pathogens in the environment. The mother should always wash her hands before breastfeeding. There is no need to wash her breast, however, because human milk contains many antibacterial components as noted in Tables 3–5. If milk is pumped by the mother and left in a clean container for 8 h at room temperature, there are fewer bacteria per milliliter than the number retrievable at the time of expression because the milk destroys these bacteria. Unaltered human milk is safe for the infant suckling at the breast.

Extracting the milk from the breast and feeding the milk to infant by the bottle and nipple introduces some possibilities for contamination as any time an infant receives bottled milk. Extracting the milk by hand, as all mothers should be taught to

Table 6 Storage of human milk for home use

Breast milk	*Room temperature*	*Refrigerator*	*Freezer*
Freshly expressed into closed container	6–8 h (78 °F or lower)	3–5 days (39 °F or lower)	2 weeks in freezer compartment inside refrigerator 3–6 months in freezer section of refrigerator with separate door 6–12 months in deep freeze (0 °F or lower)
Previously frozen Thawed in refrigerator but not warmed or used	4 h or less (i.e., next feeding)	Store in refrigerator 24 h	Do not refreeze
Thawed outside refrigerator in warm water	For completion of feeding	Hold for 4 h or until next feeding	Do not refreeze
Infant has begun feeding	Only for completion of feeding; then discard	Discard	Discard

Developed from Recommendations of the Milk Banking Association of North America, Inc. and current literature. *2011 Best Practice for Expressing, Storing and Handling Human Milk in Hospitals, Homes and Child Care Settings.* © Human Milk Banking Association of North America, 3rd Edition, 2011.

Table 7 Suggestions for milk storage for infant at home

Wash hands thoroughly
Polyethylene bags are acceptable for home use
Refrigerate or freeze milk after expressing
Use fresh milk whenever possible
Freeze milk that will not be used within 2 days
Use milk stored in a self-defrosting freezer within 3 months (top of refrigerator)
Use milk stored in a deep freezer within 12 months
Use the oldest milk first. Date container at time of collection

do, provide clean milk. She should also wash her hands before handling her lactating breast and before manually expressing milk. If she chooses to use a mechanical pump to express the milk, all of the pump parts that touch the breast or the milk should be chemically cleaned between pumpings and should be sterile when she first uses the equipment. No one else should use these disposable parts although the mechanical parts of the pump that do not touch the breast or the milk may be shared if cleaned with soap and water between individuals.

The containers where the milk is placed in for storage should be sterile if the infant is sick or hospitalized. The milk should be refrigerated as soon as possible unless it is immediately fed to the infant. If it is going to be stored for more than 4 days it should be frozen as soon as it is cooled, although it has been shown that it can be used if stored up to 8 days. These guidelines apply to milk saved for a healthy baby by a healthy mother (Tables 6 and 7).

Guidelines for saving milk for mother's sick and/or premature infant are much more rigid. Sharing stored, unpasteurized milk with other infants is not recommended. One concern in refrigerating milk for days is not bacterial growth but the possibility that the lipase normally present in human milk will begin to break down the lipids. An occasional mother produces large amounts of lipase that digests her milk if stored rendering it rancid and rejected by the infant. Brief scalding before storing has prevented this action by reducing the amount of lipase for these women.

Human Milk Banking

Human milk banks have been operating for more than 100 years. During this time the 'rules and regulations' have been developed. The Human Milk Banking Association of North America (HMBANA) has been the organization in North America that has standardized milk banking as it is not controlled by any agency, state, or federal. The guidelines start with the selection of donors who must be healthy, their infants must be healthy, their obstetrician and pediatrician must approve of their patient being a donor. Screening tests are also required. The donor must follow instructions for milk collection, storage, and transport. The milk bank pools the samples, pasteurizes the fluid, stores in sterile individual containers and freezes it. Its use is limited to infants whose physicians prescribe it. There is a fee to cover the processing. Donors are not paid for milk. The supplies are limited to sick infants in Neonatal Intensive Care Units and their graduates, i.e., medical need. Pasteurization carried out by heating at 62.5 °C for 30 min (Holder method) is commonly used. High temperature, short-term (HTST method) requires 72 °C for 15 s. It has been thoroughly studied and is considered more effective with less impact on the milk constituents. This method is used by commercial milk banks. This donor milk has proved to be not only safe but also life-saving for infants who receive it.

Careful study including both before and after cultures have shown that some are not removed by pasteurization so that the commercial milk banks utilize filtration. Of particular concern is *Bacillus cereus* that has been reported in one neonatal intensive care unit from contaminated ventilator equipment in one outbreak. Twenty two other cases are reported in the literature of infants in NICUs. This bacillus is anaerobic, spore-forming, gram positive, or negative bacterium found in dust, air, and water. In adults it has been associated with foodborne gastroenteritis. The magnitude of this problem or risk of cereus being a problem for banked human milk is not known. It is known to be a problem in powdered, artificial cow-milk-based formula.

Storage of human milk at home for one's own infant should follow the guidelines developed by the Academy of Breastfeeding Medicine who has developed a specific protocol

for choosing the container, collection, and storage. The details of storing and warming are included in the protocol which can be accessed on the Academy of Breastfeeding Medicine website at: http://www.bfmed.org/Resources/Protocols.aspx. One is cautioned not to refreeze thawed breast milk, not to warm it in a microwave, milk left in the feeding container after the feeding is completed should be discarded.

The use of banked donor human milk has been shown to be safe if processed by HMBANA guidelines. Many sick infants have benefited by its use. See table of Definition 7.

Prematures fed human milk (either mother's milk or donor milk) have a lower incidence of infection especially necrotizing enterocolitis. They also have shorter hospital stays compared to infants with comparable problems who do not receive human milk.

Summary

Breastfeeding by a healthy woman for her own baby is safe when suckled directly from the breast. Milk extracted from the breast for later feeding is safe if simple guidelines are followed the infection protective constituents of human milk magnify that safety. Donor human milk is safe if the simple guidelines are followed the infection protective constituents of human milk magnify that safety. Donor human milk is safe if the simple guidelines for donor selection, collection, pasteurizing, storing, and dispensing the milk are followed. Human milk has such tremendous benefits for the human infant that issues of maternal problems rarely outweigh the benefits.

There is a theoretic concern if the breastfeeding mother is ill, infected or takes certain medications. The magnitude of the concern is determined on an individual basis often described as the risk/benefit ratio. What is the risk of the problem compared to the tremendous benefit of human milk and being breastfed. Most local infections of the breast or a case of mastitis are usually not an indication to interrupt breastfeeding. However, it is recommended that a mother with HIV should not breastfeed in developed countries. In developing countries such as Africa it is safer to breastfeed in this case because the risk of infection and diarrhea that breastfeeding protects against is so high. Most maternal medications are safe or a safe alternative drug can be utilized. Radioactive medications used therapeutically would be contraindicated if they have a long half life such as Iodine 118. Here again a specific case should be discussed with the physician who can consult the Library of Medicine database, LactMed at http://toxnet.nlm.nih.gove/cgi_bin/sis/htmlgen?LACT. Consultation is also available at the Lactation Study Center at the University of Rochester School of Medicine (585) 275-0088 daytime, weekdays.

Safety of Human Milk: Chemical Aspects

GG Moy, Food Safety Consultants International, Geneva, Switzerland

Glossary

Endocrine disruptor Any exogenous chemical, or mixture of chemicals, that can interfere with any aspect of hormone action.

Toxic equivalency factor (TEF) Relative toxicity of an individual congener of TCDD, TCDF or dioxin-like PCB to the most toxic congener, 2,3,7,8-TCDD (which is assigned a TEF value of 1.0).

Toxic equivalent (TEQ) TEQs are used to report the toxicity-weighted mass of mixtures of dioxin-like chemicals based on their toxic equivalency factors (TEFs).

Introduction

Human milk is the natural and best food for infants because it contains the optimal composition to meet their nutritional needs in early life and provides significant immunological and psychological benefits. Evidence for the health advantages of breastfeeding has continued to increase. Recent studies confirm that the singular intestinal flora of the newborn is supported by the oligosaccharides in human milk so as to exclude potential pathogens. It is well established that breastfeeding reduces child mortality and has health benefits that extend into adulthood. The World Health Organization (WHO) recommends exclusive breastfeeding for 6 months, followed by continued breastfeeding with appropriate complementary foods.

Unfortunately the wholesomeness and safety of human milk has been compromised by the presence of exogenous chemicals, which may pose a health risk for the infant. To some extent, the contamination of human milk is a reflection of living in the modern world where chemicals play a large role. For example, pharmaceuticals are essential health technologies, but they may also be contraindicated during the lactation period because they can be excreted in human milk. Similarly, inhalation or dermal absorption can also result in the contamination of human milk. For example, dermal absorption of personal care products has resulted in the presence of triclosan, ultraviolet filters, and musk fragrances in human milk. However, the most widespread route of exposure to potentially toxic chemicals that appear in human milk is through food. Although an exogenous chemical may be present in human milk, this does not automatically mean that the chemical represents a health risk for the breastfed infant. For this purpose, the risk analysis framework is used to assess the potential impact of these chemicals on health. Yet, even this scientific approach has proven to be challenging because of uncertainty in assessing long-term health effects on the infant. At present, only in very rare situations involving high levels of contamination has it been prudent to advise mothers to limit or terminate breastfeeding.

Human milk is a unique biological matrix because it can provide exposure information not only about the breastfed infant, but also about the mother and the highly vulnerable fetus. The noninvasive method for the collection of human milk is simple and relatively free of risk, in contrast to the collection of blood or adipose tissue. Human milk is considered to be one of the most important biota for the monitoring of so-called persistent organic pollutants (POPs), such as dichlorodiphenyltrichloroethane (DDT) and dioxins, which are known to accumulate in the food chain. Consequently, human milk monitoring can also yield information about the levels and trends of POPs in the environment as well as the food supply. Better understanding of sources of harmful environmental chemicals can aid in the management of such chemicals by eliminating or reducing emissions or by establishing limits for their presence in specific foods. Although this article mainly addresses POPs, many of the principles and practices can be applied to other chemicals that may be found in human milk. Note that this article is the counterpart of another article in this encyclopedia.

Hazard Identification and Characterization of POPs in Human Milk

POPs are a group of chemicals which have been intentionally or inadvertently produced and introduced into the environment. Owing to their stability and transport properties, they are now widely distributed around the world, and are even found in places where they had never been used, such as the Arctic regions. Given their long half-lives and high fat solubility, POPs tend to biomagnify in the food chain and are particularly high in long-lived predatory species. POPs appear

at higher concentrations in fat-containing foods, especially meat, eggs, milk, and certain fish. POPs also bioaccumulate in the human body and are found in human milk. The original concerns about POPs were related to the organochlorine pesticides, such as DDT, but more recently, the focus of attention has been on POPs of industrial origin, most notably polychlorinated biphenyls (PCBs), and industrial by-products, especially polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs). However, not all POPs are transmitted through food. For example, in the case of polybrominated diphenyl ethers, which are flame-retardant chemicals sprayed on cloth and used in plastics, the main exposure is through dust. As a group, POPs are of concern because many of these chemicals have been identified as endocrine disruptors.

Since 1963, the WHO Panel of the Joint Food and Agriculture Organization of the United Nations (FAO)/WHO Meetings on Pesticide Residues evaluated the safety data for a series of POP pesticides and established corresponding acceptable daily intakes (ADIs) for their use on food crops. The ADIs were deemed to present no appreciable risk when consumed over a lifetime. These included DDT, aldrin, dieldrin, endrin, heptachlor, and lindane. At the same time, the FAO Panel recommended a large number of Maximum Residues Limits (MRLs) for residues of these pesticides on food and animal fodder, which were subsequently adopted by the Codex Alimentarius Commission. Later when many countries withdrew the agricultural uses for these pesticides because of environmental and safety concerns, the WHO Panel reevaluated these pesticides as environmental contaminants and converted the ADIs to tolerable daily intakes, which were sometimes lower than the original ADI. Similarly, the FAO Panel converted the MRLs into Extraneous Maximum Residue Limits, setting many of these at the limit of prevailing methods of analysis.

Other pesticides that fall within the POPs category include chlordane, mirex, and toxaphene, but these were not approved for use on food crops. Hexachlorobenzene was approved as a fungicide on seeds, but proved to be extremely toxic and persistent in the environment, with a half-live of over 20 years. It is still one of the most commonly detected POPs in food in many countries that used this pesticide. In addition to these pesticides, alpha- and beta-hexachlorocyclohexane which occur as contaminants in the production of technical-grade gamma-hexachlorocyclohexane, i.e., lindane, are also POPs of concern. However, as all uses of lindane have been prohibited (except for medical treatment of head lice and scabies), these contaminants are no longer entering the environment.

POPs that are industrial chemicals or by-products have been evaluated by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) as contaminants in food. For example, JECFA has established tolerable intakes for PCDDs, PCDFs, and dioxin-like PCBs. In its most recent evaluation in 2001, JECFA established a provisional tolerable monthly intake for dioxins, dibenzofurans, and dioxin-like PCBs of 70 picograms (pg) (expressed in WHO toxic equivalents (WHO-TEQ)) per kg body weight per month, which is one of the lowest tolerable intakes ever set. In doing so, JECFA noted that mean exposure estimates for many populations approached or exceed this value.

Numerous environmental studies in wildlife and in laboratory animals have provided evidence that POPs may be involved with altered endocrine function, reproductive and immune dysfunction, neurobehavioral and developmental disorders, and cancer. More recently, some authors have implicated exposures to POPs in reduced immunity and increased infections, developmental abnormalities, and neurobehavioral impairments in infants and children as well as reproductive impairments, aspects of metabolic syndrome, and cancer in adults. Some POPs are being considered as a potentially important risk factor in the etiology of human breast cancer. More detailed discussions of these issues are provided elsewhere in this Encyclopedia.

Exposure Assessment of POPs in Human Milk

Since its establishment in 1976, the WHO Global Environment Monitoring System/Food Contamination Monitoring and Assessment Programme (or simply, GEMS/Food) has collected information on the levels and time-trends chemicals in food and human milk. In 1998, GEMS/Food published a literature search and health assessment of certain organochlorine pesticides and PCBs in human milk, which raised a number of health concerns. However, generally little information was available on the donors and frequently, basic information was not provided.

In regard to PCDDs, PCDFs and dioxin-like PCBs in human milk, WHO conducted a series of three surveys covering the periods 1987–88, 1992–93, and 2000–03, which included a number of countries in Europe. To ensure reliability and to improve comparability, WHO GEMS/Food carried out interlaboratory analytical quality assurance studies with a mixture of organochlorine pesticides. Only a few laboratories consistently performed well. Some laboratories failed to detect the presence of a chemical, whereas others reported chemicals that were not present. For the third round of WHO-coordinated exposure studies, the State Laboratory for Chemical and Veterinary Analysis of Food (CVUA) in Freiburg, Germany was the only laboratory to qualify as a WHO reference laboratory for these POPs in human milk based on stringent preagreed criteria. Since that time CVUA has also been designated as the European Union reference laboratory for dioxins. In the intervening years, the quality of analysis for PCDD/Fs has generally improved in terms of both capability and capacity and other quality parameters, possibly driven by demanding limits set for regulating foods by the EU following food scares, in particular, the dioxin incident in Belgium in 1999. Cost of analysis has also decreased significantly. Food is the most important source of exposure to POPs for those who are not occupationally exposed.

Stockholm Convention on POPs

In 2004, the Stockholm Convention on POPs was ratified by over 150 governments to decrease environmental and human exposure to initially 12 priority chemicals in this class. Subsequently in 2009, nine additional POPs were included under the convention and in 2011, endosulfan was added.

Table 1 Persistent organic pollutants included in the Stockholm Convention

Chemical name	*Pesticide*	*Industrial chemical*	*By-product*
Aldrin	X		
Chlordane	X		
DDT	X		
Dieldrin	X		
Heptachlor	X		
Mirex	X		
Toxaphene (over 200 isomers)	X		
Hexachlorobenzene	X		
Polychlorinated biphenyls (209 isomers)		X	
Polychlorinated dibenzodioxins (75 isomers)			X
Polychlorinated dibenzofurans (135 isomers)			X
Included as of 2009			
Chlordecone	X		
Alpha-hexachlorocyclohexane	X		X
Beta-hexachlorocyclohexane	X		X
Lindane (gamma-hexachlorocyclohexane)	X		
Hexabromodiphenyl		X	
Hexabromodiphenyl ether and heptabromodiphenyl ether		X	
Pentachlorobenzene	X	X	X
Perfluorooctane sulfonic acid, its salts, and perfluorooctane sulfonyl fluoride		X	
Tetrabromodiphenyl ether, and pentabromodiphenyl ether		X	
Included as of 2011			
Endosulfan (technical grade)	X		

A complete list of Stockholm Convention POPs along with their original sources (pesticide, industrial chemical, or by-product) is given in Table 1. Of particular relevance to human milk monitoring was Article 16 which requires periodic effectiveness evaluations of the convention. In this regard, experts convened by the United Nations Environment Programme (UNEP) considered how to implement these evaluations and recommended that a global survey of human milk be carried out in close collaboration with the WHO. This was later approved by the Stockholm Convention's Conference of Parties and in 2005, a memorandum of agreement was signed by the WHO and UNEP to formalize the arrangement.

WHO-Coordinated Global Survey of Persistent Organic Pollutants in Human Milk

In responding to the needs of the Stockholm Convention on POPs, WHO GEMS/Food developed a new protocol for the 4th WHO-coordinated global survey of POPs in human milk that would meet the combined health, food safety, and environmental objectives of WHO, UNEP, and their member counties. The protocol for survey included all 12 POPs initially covered by the Stockholm Convention and was designed based on the advice of international experts in the field and on extensive experience gained in previous surveys. To promote reliability of the data and comparability across time and among countries, participants are encouraged to adhere as closely to the protocol as possible. Given that breastfeeding reduces child mortality and has health benefits that extend into adulthood, every effort was made to protect, promote, and support breastfeeding in the context of these studies.

Analysis of Pooled and Individual Samples

Because of the high cost and analytical difficulty, the protocol uses pooled samples to monitor levels of PCDDs, PCDFs, and dioxin-like PCBs in human milk. This also avoids some ethical issues that may arise if the concentrations are known in the milk from a particular individual. These analytically complex POPs require ultrapure solvents and sophisticated equipment (high resolution gas chromatograph with two high resolution mass spectrometers coupled in tandem) and therefore have been analyzed at the WHO reference laboratory at CVUA. However, basic pesticide POPs and certain marker PCBs (analytically simple POPs) are analyzed in individual samples because of the lower cost and ease of analysis, which uses a gas chromatograph with an electron capture detector. This type of equipment is available in many developing countries. The analysis of the analytically simple POPs in developing countries was supported by periodic analytical proficiency testing. Table 2 provides a list of analytically complex and simple POPs and, where appropriate, their residue definitions, included in the 4th WHO-coordinated survey.

Results for Analytically Complex POPs

This was the 4th WHO-coordinated human milk survey of these chemicals undertaken since 1987. The current levels of PCDD/Fs were in the range of 4–10 WHO-TEQ (pg g^{-1} fat). However, perhaps the more important issue for human health and the environment is that levels have continued to show a decreasing trend over the past 20 years. Data for those countries that participated in three or more of the surveys is given in Figure 1.

The current levels of dioxin-like PCBs were in the range of 5–11 WHO-TEQ (pg g^{-1} fat). As with PCDDs and PCDFs,

Table 2 Analytically complex and simple pops and their residue definitions included in the 4th WHO-coordinated survey of persistent organic pollutants (POPs) in human milk

Analytically complex POPs
Polychlorinated dibenzodioxins (PCDDs) (total to be expressed in WHO-TEQs)
2,3,7,8-tetrachlorodibenzodioxin (TCDD)
1,2,3,7,8-pentachlorodibenzodioxin (PeCDD)
1,2,3,4,7,8-hexachlorodibenzodioxin (HxCDD)
1,2,3,6,7,8-HxCDD
1,2,3,7,8,9-HxCDD
1,2,3,4,6,7,8-heptachlorodibenodioxin (HpCDD)
1,2,3,4,6,7,8,9-octachlorodibendioxin (OCDD)
Polychlorinated dibenzofurans (PCDFs) (total to be expressed in WHO-TEQs)
2,3,7,8-TCDF
1,2,3,7,8-PeCDF
2,3,4,7,8-PeCDF

levels of dioxin-like PCBs have fallen over time as shown in Figure 2.

Results for Analytical Simple POPs

The new WHO protocol included analytically simple POPs, which basically are comprised of organochlorine pesticides. However, data on such POPs using the new protocol were available from only Belgium, Finland, Norway, and Sweden (see Table 3). Additional data collected with the WHO protocol will become available when the results of other countries are tabulated.

Although the first studies of DDT in human milk go back to the 1950s, the levels reported in such studies are only considered indicative because some reports were highly variable and few details on the sampling and methods of analysis were provided. The WHO conducted a literature search and prepared a risk assessment of the exposure of infants to some of these analytically simple POPs, which can be a useful point of reference. It should be noted that some of these POPs are extremely stable in soil and consequently, levels in food and in human milk may continue for many years. In developing countries where many of these POPs have been banned more recently and where some of these POPs, for example, DDT and lindane, are still used, levels in human milk are expected to be higher.

Risk Characterization of POPs in Human Milk

The risk characterization of POPs in human milk is hampered by the lack of consensus on health-based reference values that would protect nursing infants. JECFA has stated that the ADIs it establishes do not apply to infants under the age of 12 weeks. Although epidemiological studies suggest that exposure of the developing fetus to POPs can lead to significant long-term health effects, the additional exposure of the infant through contaminated human milk needs further study. However, measuring the levels of chemicals in human milk can provide the needed information, which is essential for understanding the risk posed by certain chemicals at critical

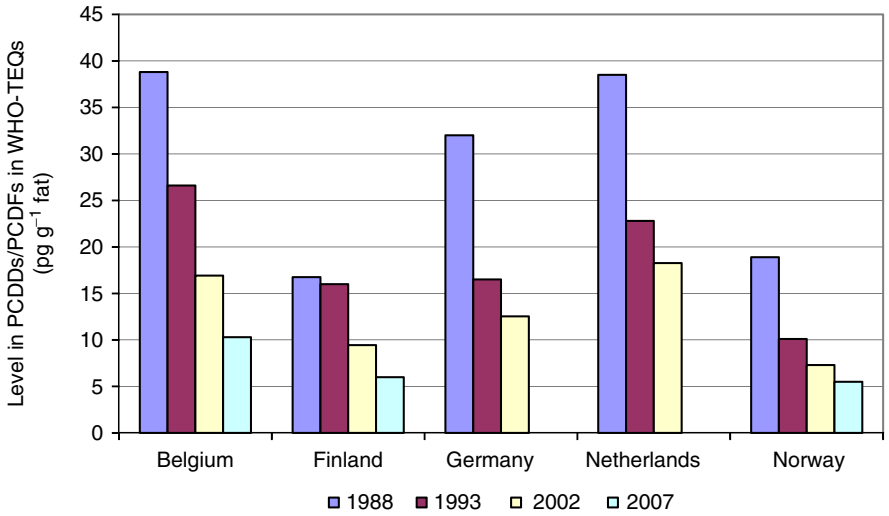

Figure 1 Trends in levels of PCDDs and PCDFs in human milk in selected countries.

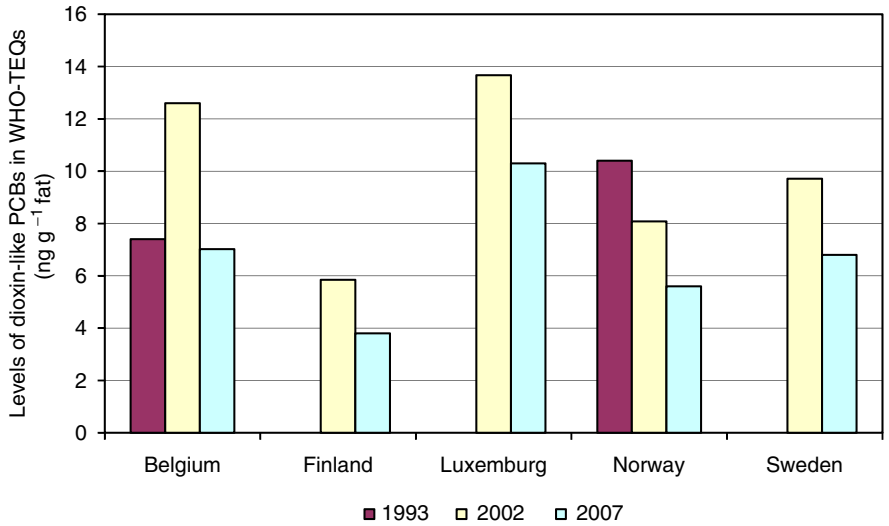

Figure 2 Trends in levels of dioxin-like PCBs in human milk in selected countries.

periods of development and for generally reducing exposure from food and the environment.

Risk Management of POPs in Human Milk

Because of health concerns raised by exposure to POPs *in utero* and through human milk, the risk management of POPs should be considered by both governments and individual mothers to reduce the risk of possible harm to the infant.

Primary preventive measures to eliminate and reduce the introduction of POPs in the environment are the most effective long-term way to control exposure to these chemicals. When possible, the use and emissions of POPs should be further reduced, including assuring the safe disposal of existing stocks.

Because food is the main source of exposure for the vast majority of individuals, responsible authorities should examine their food monitoring and control programs to assess whether greater attention should be paid to foodstuffs potentially high in POPs. It is also important to geographical areas with potential for increased infant exposure levels resulting from highly contaminated foodstuffs or other sources.

Maximum limits in foods and animal feed ingredients that are high in POPs should be considered. Limits established by the European Union for PCDD/Fs include milk and milk products, including butter fat – 3 pg g^{-1} fat; hen eggs and egg products – 3 pg g^{-1} fat; liver and derived products – 6 pg g^{-1} fat; fish oil – 2 pg g^{-1} fat; and, fish (flesh) 4 pg g^{-1} fresh weight.

Girls and young women should limit their intake of foods known to contain high levels of POPs in order to reduce their body the burden of POPs. Dietary advice for girls and women of child-bearing age should be promoted including consumption of less contaminated foods, for example, certain organic foods.

Epidemiological studies linked to POPs in food and human milk are urgently needed to assess the possible

Table 3 Levels of analytically simple POPs in human milk in selected countries

Basic POPs (ng g^{-1} fat)	*Belgium*	*Finland*	*Norway*	*Sweden*
Aldrin	ND	ND	ND	ND
Chlordane group	7.8	1	3.6	2.2
Dieldrin	6.7	1.5	2.5	1.8

Endrin group	ND	ND	ND	ND
Heptachlor group	5.3	0.55	0.6	0.8
Hexachlorobenzene	15.0	2.7	16.9	7.1
Hexachlorocyclohexane (HCH) group				
Alpha-HCH	ND	ND	ND	ND
Beta-HCH	12.0	4	5.8	6.6
Gamma-HCH	0.7	1.3	0.5	0.9
Toxaphene (Parlar) group	2.3	1.9	3.7	2.4
Mirex	ND	ND	ND	ND

Abbreviations: DDT, Dichlorodiphenyltrichloroethane; ND, not detected; POPs, persistent organic pollutants.

long-term health risks to the newborn and growing infant from the intake of POP-contaminated breast milk. This will enable the provision of adequate advice on the best breastfeeding practice for mothers at risk, such as the maintenance of body weight during the lactation period. Of course, it also must be acknowledged that there is a large body of literature on endocrine disruptors that indicates that early life exposures can induce diseases that do not manifest until puberty or adulthood. Thus, epidemiology studies must consider this long timeframe implicated in many POP-associated human diseases.

Responsible authorities should consider incorporating mechanisms to assess potential health risks posed by contaminants in human milk into their national risk assessment procedures, as is already done for pharmaceuticals. In this regard, health-based reference values for exposure to POPs in human milk contamination will be required.

Decision-making for any contemplated intervention should take into account the well-established benefits of breastfeeding as well as socioeconomic factors. Except in the most extreme cases, mothers can and should be reassured that breast milk is by far the best food to give their babies.

Risks Posed by Lead in Human Milk

Whereas lead is toxic to essentially all organs of the body, it is particularly dangerous for infants and young children as it can cause blood and brain disorders. Lead has been demonstrated to irreversibly reduce the intelligence quotient of children at extremely low levels of exposure. It is also associated with learning, attention, and more recently, to violent behavior. Lead will accumulate in the bones of girls and young women through exposures from food, water, soil, and other environmental sources. During lactation, maternal bone lead stores from these past exposures may be mobilized along with calcium as part of the normal changes during pregnancy.

As with POPs, the early studies of lead in human milk lack sufficient details on the sampling and analytical quality assurance and methods to understand if the reported levels are accurate and representative. Very large ranges of values have been reported, but the elimination of lead in paint and fuel for motor vehicles in many countries has contributed to the decline of lead levels in human milk. Levels of lead in human milk reported from a number of countries are given in Table 4.

Table 4 Lead levels in human milk in selected countries

Country	*Year*	*Number of samples*	*Lead in milk (μg l^{-1})*
Australia	1998	9	0.7 $\pm$ 0.7
Canada	2003	25	2.08 $\pm$ 1.67
China	2008	1600	5.11
Brazil	2009	92	2.90 $\pm$ 1.7
Greece	2005	95	0.15 $\pm$ 0.25
Iran	2009	44	10.4 $\pm$ 4.7
Nigeria	2002	89	1.77 $\pm$ 0.24
Mexico	2004	310	1.4 $\pm$ 1.1
UK	2004	255	1.5 $\pm$ 1.2
Spain	2011	100	15.56
Sweden	1995	75	0.7 $\pm$ 0.4
Turkey	2005	143	2.34 $\pm$ 1.0
USA	2002	15	6.1 $\pm$ 1

As with POPs, the exposure to lead by girls and young women should be avoided. However, exposure to lead is possible from food, water, soil, or air. In some cases, traditional medicines and cosmetics can contain lead. It is also important to prevent the mother from immediate exposure to lead. Because there is a linear relationship between lead in human milk and maternal blood, monitoring maternal blood during pregnancy can be used as a screening tool. For example, maternal blood lead levels of 100 μg l^{-1} generally translate to approximately 5 μg l^{-1} in human milk, concentrations that are considered of little or no concern. In general, levels below 10 μg l^{-1} are considered acceptable for human milk. However, if levels are excessive, interventions may be considered. For example, a study in Mexico in 2004 indicated that lead mobilization can be minimized if the mother has a diet that is adequate in calcium. In 1994, The US National Institute of Health Consensus Conference on Optimal Calcium Intake recommended that for pregnant and lactating women the optimal daily intake of calcium should be 1200 mg day^{-1}.

Further details on lead are provided elsewhere in this encyclopedia.

Risks Posed by Mercury in Human Milk

Both organic and inorganic mercury can be present in human breast milk. Organic mercury in the form of methyl mercury is more hazardous for children, although inorganic mercury is also of potential concern. Methyl mercury, like lead, is a neurotoxin and can cause deficits in learning and memory. Methyl mercury levels in human milk are relatively low because it is tightly bound to protein and is not subject to mobilization. However, if the maternal diet is high in methyl mercury, human milk can become contaminated as the compound is metabolized. Because methyl mercury is readily absorbed in the intestine of a nursing infant, exposure through human milk may place the infant at risk. Serious adverse health effects have been documented in cases where the mothers of breastfed infants were exposed to high levels of methyl mercury via consumption of fish.

The second form, inorganic mercury, is more easily transmitted through human milk but less than 15% is absorbed by the gastrointestinal tract of the infant. Mercury levels in milk are generally three times lower than the levels in the mother's blood. Therefore, *in utero* exposure is probably more important than lactational exposure to mercury.

The average levels found in human milk are far below those that cause acute poisonings. Most mothers are exposed to methyl mercury through fish consumption, particularly consumption of predator fish such as swordfish, shark, and tilefish that are known to be high in methyl mercury. Other sources of mercury include coal burning, incineration, chlorine manufacturing, and mining, as well as some natural sources. Inorganic mercury exposure primarily comes from cereal grains, which are consumed in large amounts.

In most studies, total mercury is analyzed because of the difficulty in differentiating between organic and inorganic species. Data on the levels of total mercury in human milk are limited because hair and maternal blood are preferred matrices for biomonitoring. Table 5 provides reports on levels of total mercury in human milk in a number of countries.

Because of the established adverse neurological effects of mercury, both pregnant and nursing women should avoid the consumption of fish that are high in methyl mercury. Various education programs for women of child-bearing age have been developed as countries attempt to address other environmental emissions. As noted earlier, the biomonitoring of maternal blood and hair can also provide useful markers of exposure that can be used to assess the safety of human milk. Further details on mercury are provided elsewhere in this Encyclopedia. In addition, a recent opinion of the European Food Safety Authority (EFSA) on mercury and methyl mercury in food includes consideration of human milk.
