We illustrate the general theory for estimation of a RSF for multiple variables by defining 3 dummy variables to model the selection among the 4 vegetation types (Table 17.2). Let $w(X_i) = w(X_{i1}, X_{i2}, X_{i3})$ denote the RSF, that is, the odds or relative probability that a unit with covariate vector $X_i = (X_{i1}, X_{i2}, X_{i3})$ is selected, where the dummy variables are coded (Table 17.5). Given data from SP-A (i.e., a sample of points in the study area and a sample of selected points), we assume the RSF can be modeled by the **exponential function**

$$w(X_i) = e^{\beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}}.$$

Then conditional on the observed sample sizes, probability of use given X_i is $(\text{use} | X_i) = e^{\beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}} / (1 + e^{\beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}})$.

This is the form of a logistic regression function, and we can now examine a simulated sample of available points (coded as $Y = 0$ for the available points [dependent variable] in Table 17.5) and the sample results for the 117 used points (coded as $Y = 1$ for the dependent variable; from Table 17.2). Any **computer software package** for fitting a logistic regression function can be used to obtain estimates of the coefficients and their standard errors. Those estimates can be placed in the exponential function

Table 17.5. Independent and dependent variables coded for entry into a logistic regression computer software package. The sample of used points is coded $Y = 1$, based on the available sample sizes (see Table 17.2). The simulated sample of 20,000 available points was computed to yield the exact proportions of habitats in the study area (Table 17.2); these points are coded $Y = 0$.

Location of tracks	Depending variable Y	Sample size	Independent variables			
			X_{i0}	X_{i1}	X_{i2}	X_{i3}
Interior of burned	1	25	1	1	0	0
Edge of burned	1	22	1	0	1	0
Edge of unburned	1	30	1	0	0	1
Interior of unburned	1	40	1	0	0	0
Interior of burned	0	6,796	1	1	0	0
Edge of burned	0	2,015	1	0	1	0
Edge of unburned	0	2,073	1	0	0	1
Interior of unburned	0	9,114	1	0	0	0

$$w(X_i) = e^{\beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}}$$

to obtain the RSF, ignoring the constant β_0 . Note the coefficient β_0 is not used in the RSF for a technical reason (the fraction of used points in the sample is unknown). It is important to understand the RSF is given by equation

$$w(X_i) = e^{\beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}}$$

and not by the logistic regression function

$$w_i(X_i) = e^{\beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}} / (1 + e^{\beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \beta_3 X_{i3}}).$$

Once the logistic regression equation is fitted, values for the coefficients are estimated, and the RSF, $w(x_i)$ can be evaluated numerically.

Application of the General Theory to Categorical Data

To illustrate the estimation of a RSF for a single categorical variable, we assume the vegetation types in Neu et al. (1974) are in a GIS and that a random or systematic sample of 20,000 points was placed across the area. To that end, we assume that 34% (i.e., 6,796) of 20,000 points were in the interior of the burned habitat, 10.1% (i.e., 2,015) were in the edge of the burned habitat, 10.4% (i.e., 2,073) in the edge of the unburned habitat, and 45.5% (i.e., 9,114) in the interior of the unburned habitat to yield a simulated sample of the available vegetation types based on the reported proportions (Table 17.2). We then coded independent and dependent variables as they would be placed in a standard logistic regression software program (Table 17.5).

Estimates of the coefficients and their standard errors from a logistic regression software package were then obtained (Table 17.6). Upper and lower limits of approximate 95% confidence intervals on the coefficients can be computed from

the expressions, $\beta_i \pm 1.96(SE[\beta_i])$ or equivalently, 95% confidence intervals on the selection ratios can be obtained from $e^{\beta_i \pm 1.96(SE[\beta_i])}$. We note (Table 17.6) that 2 of the coefficients are large compared to their standard errors (95% confidence intervals will not contain 0.0). Thus, there is significant selection among the vegetation types. We elect to leave all of the vegetation types in the RSF for the categorical variable “vegetation type.”

The RSF evaluated for the type “interior of burned” is $w(X_1) = e^{-0.179(1) + 0.907(0) + 1.188(0)} = e^{-0.179} = 0.836$, where $x_i = (1, 0, 0)$; Table 17.5) and the constant b_0 is ignored. The values of the RSF were evaluated for the other vegetation types and standardized so they sum to 1.0 in the third column (Table 17.7). Note the fourth vegetation type, “interior of unburned,” is the **reference type** with $X_4 = (0, 0, 0)$. Statistical significance of the other coefficients is judged in comparison to the reference selection ratio, $w(X_4) = e^0 = 1.0$. The coefficient $b_1 = -0.179$ is small compared to its standard error, and one could conclude the “interior of burned” does not add a significant contribution to the RSF compared to the reference level, “interior of unburned.” In the terminology of hypothesis testing, there is no significant difference in selection for “interior of burned” and the reference level “interior of unburned.” Both coefficients for “edge of burned” and “edge of unburned” are positive and large, indicating there is significant selection for those 2 habitat types in comparison to the reference level “interior of unburned” or “interior of burned.”

Table 17.6. Estimated coefficients and their standard errors for the resource selection function, $w(x_i) = e^{b_1 X_{i1} + b_2 X_{i2} + b_3 X_{i3}}$, fitted to the moose data (Tables 17.2, 17.5)

Coefficient	Value	SE ^a
b_0	-5.4290	0.1581
b_1	-0.1787	0.2549
b_2	0.9073	0.2655
b_3	1.1882	0.2416

From Neu et al. (1974).

^a SE = standard error.

Table 17.7. Estimated values for the resource selection function (RSF), $w(x_i) = e^{b_1 X_{i1} + b_2 X_{i2} + b_3 X_{i3}}$, for each of the habitat types in the moose example (Table 17.2)

Location of tracks	$w(X_i)$	$w(X_i) / \sum w(X_i)^a$
Interior of burned	0.836	0.110
Edge of burned	2.478	0.326
Edge of unburned	3.281	0.432
Interior of unburned	1.000	0.132
Totals	7.595	1.000

^a Values of the RSF standardized to sum to 1.0.

The interpretation of the results (Tables 17.3, 17.7) is the probability of location of moose tracks in the “edge of burned” by the protocol used in the Neu et al. (1974) study was about 2.5 times larger than the probability of location of moose tracks in the “interior of unburned.” This interpretation is subject to the specific time, study location, density of the moose population, etc., and specific values for other independent predictor variables (e.g., the depth of snow). Extrapolation of the results to the relative probability of selection of the different vegetation types by moose depends on the additional assumptions that tracks were equally visible in the different vegetation types and that moose selected locations independent of one another (i.e., the animals have free and equal access to the entire study area).

The standardized values (Table 17.7) are the **same** as reported based on the simple selection ratios (Table 17.3). We included the analysis of the Neu et al. (1974) data by use of a computer software package for logistic regression for 2 reasons. First, we wanted to demonstrate the simple selection ratios (Table 17.3) are equivalent to fitting a more general RSF that gives the relative probability (odds) of selection among the vegetation types based on observed data. The interpretation of the values of the selection ratios, $w(X_i)$ (Table 17.7), or the simple selection ratios (Table 17.3) are in reference to each other. For example, the probability of selection for the “edge of burned” by moose was about 2.478, or 2.5 times larger than the probability of selection of the reference habitat “interior of unburned” by moose.

Second, we also wanted to provide a unified procedure for analysis of categorical data that does not depend on tedious use of formulas for the ratios of random variables (Manly et al. 2002). The above procedure using a standard computer program for logistic regression is one of the easiest ways to analyze habitat selection among categories of a single categorical variable.

Multiple Continuous and Discrete Variables

We illustrate the general theory for estimation of a RSF by analysis of resource selection by alder flycatchers (*Empidonax alnorum*) on the Innoko National Wildlife Refuge in Alaska. A complete description of the study is provided in Erickson et al. (2003). Locations of breeding alder flycatchers were gathered by walking transect surveys in the floodplain of the Innoko River during the 2000 and 2001 breeding seasons. Transects were systematically located along the Innoko River perpendicular to the general orientation of the river. The study area for breeding habitat was defined to be the area in the floodplain of the river. This example fits in **Design I**, because breeding areas were sampled for the population of alder flycatchers. **SP-A** fits, because a separate sample of selected locations is contrasted to a sample of locations in the floodplain.

Using **ArcInfo GRID** (http://home.gdal.org/projects/aigrd/aigrd_format.html), the study area polygon (flood-

plain) was converted into an image with 30-m units (pixels), coincident with **Landsat Thematic Mapper™ imagery** taken on 26 August 1991. Eleven raster layers were coregistered (measured) on each 30-m pixel in the study area and used in subsequent processing. For each pixel, the following 11 **coverages** were considered:

- coverages 1–6: spectral values of Landsat™ bands 1–5 and 7 from 26 August 1991,
- coverage 7: elevation (from U.S. Geological Survey 1:63,360 scale quads),
- coverage 8: slope (derived from elevation),
- coverage 9: aspect (derived from elevation),
- coverage 10: distance from unit to river (rivers defined from Landsat™ imagery), and
- coverage 11: distance from unit to closest lake (lakes defined from Landsat™ imagery).

There were 109 observations of breeding birds (109 “used” points) and a systematic sample of 5,094 pixels in the floodplain (of a total of 616,754 pixels). The values of each of the 11 coverages were recorded for each pixel that intersected a 105-m radius of the center of the pixel containing the observed used point. This collection of pixels formed a buffer surrounding each used point. A similarly sized buffer was defined for each of the pixels in the floodplain sample and for each pixel in the floodplain, so the estimated relative probability of selection could be mapped for the entire study area. Twenty potential predictor variables were defined for the buffer surrounding each pixel:

- variables 1–6: average of Landsat™ bands 1–5 and 7 for all pixels in the buffer,
- variables 7–12: standard deviation of Landsat™ bands 1–5 and 7 for all pixels in the buffer
- variable 13: average elevation of all pixels in the buffer,
- variable 14: average slope of all pixels in the buffer,
- variables 15–18: aspects (the percentage of pixels in the buffer defined as having north, south, east, or west aspect),
- variable 19: average distance to river for all pixels in the buffer, and
- variable 20: average distance to closest lake for all pixels in the buffer.

Twenty variables are too many to realistically fit and evaluate in a RSF using contemporary computer software. In addition, several of the variables were **highly correlated** with one another, and inclusion of ≥ 2 highly correlated variables (i.e., multicollinearity) leads to unstable coefficients in the fitted models (Neter et al. 1996). Highly correlated variables were eliminated from consideration, resulting in a set of 12 variables (Table 17.8). Because data were collected using SP-A, logistic regression can be used to estimate the coefficients in the RSF:

$$w(X) = e^{\beta_1 X_1 + \dots + \beta_p X_p}.$$

Again, we emphasize that use of the **logistic regression software is a shortcut** to obtain the coefficients in the exponential model

$$w(X) = e^{\beta_1 X_1 + \dots + \beta_p X_p}.$$

The function $w(X)$ estimates the relative probability of selection of a point in the landscape given the values of variables X_1 through X_p at that point and coefficients β_1 through β_p for variables in the model. For each selection of p variables among the 12 listed in Table 17.8, the sample of selected locations (with the dependent variable $Y = 1$) and the sample of floodplain locations (with $Y = 0$) were fitted to a logistic regression function using a computer software package. The relative probabilities of selection are calculated by taking the coefficients from the fitted logistic regression and placing them into the formula

$$w(X) = e^{\beta_1 X_1 + \dots + \beta_p X_p}.$$

rather than using probabilities generated by the computer software. Probabilities from the computer software are generated from the logistic model

$$e^{\beta_1 X_1 + \dots + \beta_p X_p} / (1 + e^{\beta_1 X_1 + \dots + \beta_p X_p}),$$

which is the “wrong” model for SP-A (i.e., independent samples of selected units and units in the study area). The logistic regression software is only a convenient shortcut to obtain the maximum likelihood estimates of coefficients in the correct exponential model.

There were 12 variables available for estimating the RSE. All 4,095 ($2^{12} - 1 = 4,095$) possible main-effect models were fitted by logistic regression of the dependent variable Y on the independent predictor variables. Quadratic variables and interaction terms were ignored for this study. These 4,095 models were then ranked according to Bayesian Information Criterion (BIC; Schwarz 1978). The top 5 models (i.e., those with the smallest BICs) from this set were reported as our final best models (Table 17.9). BIC was defined as

$$-2\log(\text{likelihood}) + p\log(n),$$

where p is the number of variables in the model, n is the number observed bird locations plus number of locations sampled in the study area, *likelihood* is the value of the logistic likelihood, and \log is the natural logarithm.

Relative probabilities of selection were calculated for each pixel in the floodplain based on weights of importance values (Burnham and Anderson 1998) for the top 5 models. For each of the top 5 models, the BIC differences were calculated as

$$\Delta_i = BIC_i - \min(BIC),$$

Table 17.8. Importance values and sign of coefficient based on importance value weighting for variables in the models for alder flycatcher, Innoko National Wildlife Refuge, Alaska

Variable	Variable description ^a	Importance value (sign of coefficient)
River	Average distance from river (m)	0.7 (–)
Lake	Average distance from lake (m)	0
Band 1	Average of band 1 in buffer	0
Band 4	Average of band 4 in buffer	1 (+)
Band 5	Average of band 5 in buffer	0
Std band 1	SD of band 1 in buffer	0.28 (–)
Std band 3	SD of band 3 in buffer	0.89 (+)
Std band 4	SD of band 4 in buffer	0.61 (+)
Std band 7	SD of band 7 in buffer	0.39 (+)
Elevation	Average elevation (m)	1 (–)
Slope	Average slope (deg)	0
Aspect	4 categorical variables: percentage in north, south, east, and west aspect	0

From (Erickson et al. (2003).

^aSD = standard deviation.

Table 17.9. Top 5 models for alder flycatcher example, Innoko National Wildlife Refuge, Alaska. Rankings based on Bayesian Information Criterion (BIC). Models based on averages and standard errors (SE) of variables in a 105-m radius buffer around each sampled point in the landscape. The floodplain sample was derived from the corridor-wide area.

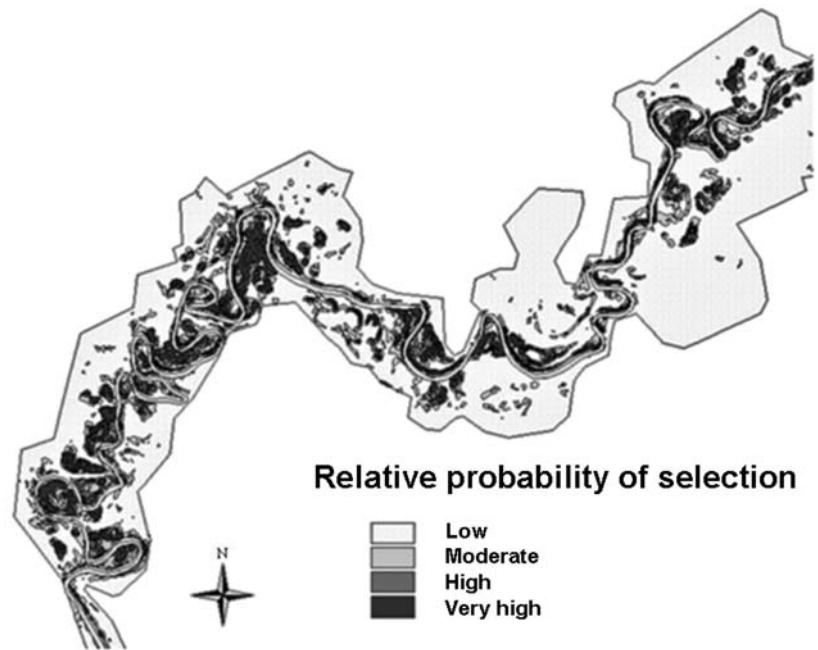

Model	BIC	Model weight	Variable ^a	Estimate	SE
1	911.36	0.376	River	–0.0008	0.00029

From Erickson et al. (2003).

^aSee Table 17.8 for descriptions of the variables.

Fig. 17.4. The weighted average of estimated relative probabilities of use by alder flycatchers based on 5 models and weights (see Table 17.9) for the southern section of the floodplain of the Innoko National Wildlife Refuge, Alaska. A general pattern of higher probability of use near the river in the southern section of the study area is apparent.

Erickson et al. (1998).

where BIC_i is the BIC for the i th model, and $\min(BIC)$ is the minimum BIC value for the 5 models. The BIC weights were calculated as

$$w_i = e^{\frac{1}{2} \Delta_i} / e^{\sum_{i=1}^5 \exp(\frac{1}{2} \Delta_i)}$$

Each model was used to predict the relative probability of selection for a pixel; a **weighted average** of the 5 predictions was then obtained using the BIC weights (Table 17.9, Fig. 17.4). This weighting procedure is similar to the use of Akaike weights (Akaike 1973, Burnham and Anderson 1998). Other model selection criteria, such as Akaike's Information Criterion (Burnham and Anderson 1998), could have been considered.

Although not described in this example, **model verification** and **validation** techniques also are recommended for further evaluation of the fit and robustness of the selected models. Model verification methods, such as Hosmer and Lemeshow's goodness of fit method for logistic regression (Hosmer and Lemeshow 1989), and validation techniques, such as those described in Boyce et al. (2002) and Howlin et al. (2003), should be conducted.

The variables elevation and the average of band 4 were included in each of the top 5 models, the standard deviation of band 3 was in 4 of the 5, and distance to river was included in 3 of the top 5. The probability of selection tends to decrease as elevation and distance to river increases (negative coefficients in the RSFs). The probability of selection tends to increase as the average of band 4 and standard deviation of band 3 increases (positive coefficients in the RSFs). Importance values, following Burnham and Anderson (1998: 326–327), for each of the variables considered, varied (Table

17.8). The variables elevation, band 4, and standard deviation of band 3 had the highest importance values. In this example, interpretation of the mean and standard deviations of the Landsat information is difficult, and other variables (e.g., quadratic effects, interactions, or ratios of bands) might have improved the models. A quality vegetation map was not available; it would have allowed for more direct interpretation of importance of different vegetation types.

SUMMARY

This chapter introduces the study of habitat use and food selection by wildlife in comparison to those resources in a study area to help identify important habitat patches and food resources. Selection is defined to exist during a study period if resources are exploited disproportionately to their availability at a given scale: geographic range of a species or home range of an individual or social group. Selection also can be defined as sites selected within a home range or as a site where food is procured. Generally, resource selection studies should consider selection at >1 scale and should be replicated in time and space.

Common field sampling protocols are introduced, followed by detailed discussion with examples of the most applicable method, SP-A: study area units are randomly sampled and selected units are randomly sampled. The sampling protocol is considered in association with the most common study designs. After presentation of field procedures for recording data on habitat units, food predictor variables, and use by wildlife, we present the estimation of RSFs as a unified theory for study of the relationships among selection of units and predictor variables measured on those units.

These functions allow one to estimate the relative probabilities that habitat units were selected and to rank units according to their value for use by wildlife for the study area, population, and time period.

Modeling of resource selection is introduced for computation of selection ratios among categories of vegetation types or food types. Logistic regression is the basic tool by which all example sets of data in this chapter are analyzed; it is used to analyze data to illustrate the concepts of relative probabilities of selection among vegetation types. Estima-

tion of RSFs using multiple predictor variables is illustrated for estimation of relative probability of selection of breeding sites by alder flycatchers on the floodplain of the Innoko River, Innoko National Wildlife Refuge, Alaska. Information theory and maximum likelihood procedures are used for selection of appropriate predictor variables for the RSFs. Finally, we illustrate the mapping of habitat to identify those areas with the highest relative probability of selection during the study period by alder flycatchers in the Innoko National Wildlife Refuge.

VISION STATEMENT

IMAGINE CROSSING GEOGRAPHIC and administrative boundaries to efficiently make policy decisions for regional fish, wildlife, and their habitats. By accessing multiple organizations' data and information, we can begin to successfully manage a region's dynamic natural systems and their inhabiting fish and wildlife. With effort and organization, we can adopt common data-management strategies that incorporate core data elements, data standards, and protocols to enhance information transferability. A data management system connecting numerous entities would create a powerful tool for effective management planning and scientific monitoring (Roger et al. 2007).

INTRODUCTION

Natural systems, including fish, wildlife, and **habitat** (habitat includes water, air, land, and other areas that species occupy), are complex, interrelated, and ever-changing. Data and information about natural systems mirror these properties, and the thing common to nearly all of these datasets is they occur somewhere in space. Currently, ecosystem information is collected across multiple programs and efforts, using many different methods, and it is maintained in many different technical systems. The result is that it is difficult—and in some cases, practically impossible—to assemble the data into ecosystem level views that cross geographic, administrative, and political boundaries. So let us all agree the Information Age has arrived, and that technology plays a large and important role in gathering, compiling, and synthesizing data. The old adage of analyzing wildlife data over “time and space” today implies use of technologies, including their integration into research and monitoring studies as well as evaluation strategies. Thus, resource managers must understand how to use these technologies, especially in regard to evaluating and assessing land at various **scales** (e.g., site, watershed, sub-basin, and basin levels). To assist resource managers with this task, this chapter explores spatial technologies and the applications that are commonly used by wildlife managers to acquire, compile, and interpret data. These include updated spatial application information from O'Neil et al. (2005). This chapter focuses on **Geographic Information System (GIS)** and **Global Positioning System (GPS)** technologies, and on using remotely sensed data, such as imagery from Landsat and, recently, **light detection and ranging (lidar)**. This chapter also serves to heighten awareness and understanding of data documentation, data accuracy, and Internet applications.

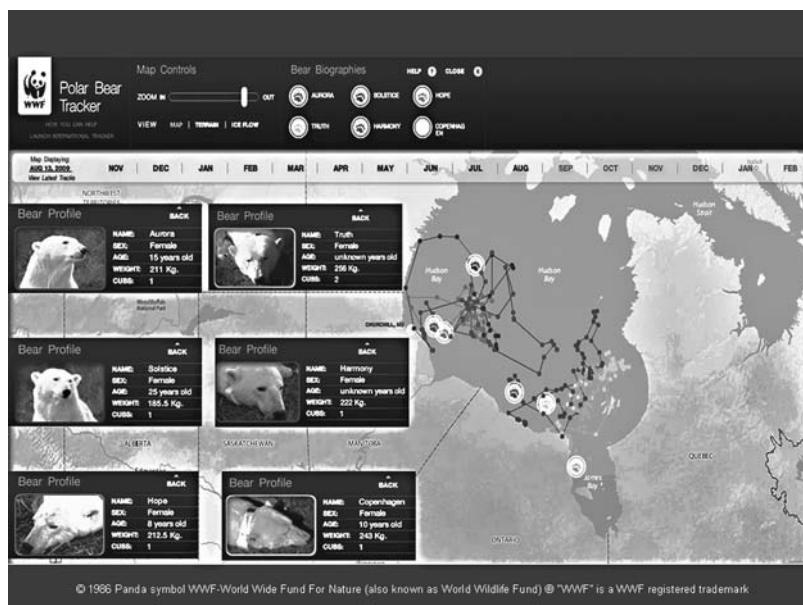

Fig. 18.1. Example of how a Geographic Information System map is combined with data collected by Global Positioning System collars to track individual movements of polar bears (*Ursus maritimus*) in Ontario, Canada.

To start, we direct your attention to Figure 18.1. This figure illustrates how to integrate wildlife species information with data from GIS, GPS, and the Internet. This kind of an approach gives people a dose of science in an easily understandable format. Thus, the primary purpose of this chapter is to get you familiar with the technology and its associated components, so that you will have a better understanding of its use, eventually enabling you to develop your own applications. To help facilitate a better understanding, a series of box inserts is included to briefly touch on key topics, concepts, or applications that might be of interest to users of spatial technologies. Included are such topics as how cartography can be manipulated to produce a great looking map that gives a false impression (Monmonier and H. de Blij 1996; see Box 18.1) and how spatial technologies can support vegetation monitoring at a fine scale. The definitions of key terms for certain technologies also are given in these boxes.

Today's issues and their complexities have a tendency to overwhelm resource managers in a sea of data. Most resource agencies are awash in data, but managers still find themselves with a lack of information. **Spatial technologies** provide tools to incorporate and analyze large datasets in a meaningful manner that produces useful information. Data can be converted or displayed by locations or across a landscape as charts, drawings, symbols, or a map. These technologies provide a way to assess and depict complex relationships among variables, which is useful for incorporating scale and hierarchy concepts into ecosystem-based management approaches (O'Neill 1996, O'Neil et al. 2008) and for helping examine environmental impact (Antunes et al. 2001). Additionally, they allow spatial depictions in 3 dimensions and can display theoretical concepts, such as total diversity

of ecosystem functions (O'Neil et al. 2005). The technologies presented here also allow others to see how decisions are made, thus leaving a trail of accountability in the decision-making process to follow. However, as with any analysis and modeling tool, spatial technologies are only as accurate and reliable as the underlying data. Spatial tools on their own cannot improve accuracy, precision, or bias of information.

Spatial technologies should be considered as tools to assist resource managers with mapping. **Maps** are as important to the manager as calculators and vehicles. Using spatial technologies can provide timely information in usable formats for aiding decision-makers, but these tools should not be viewed as making the final decisions per se. Spatial technologies, such as GIS, are frequently described in terms of **hardware** (computers and workstations) and **software** (computer programs); typically, more computing power (speed and memory) in combination with large computing **storage** (disk space) is preferred. Workstations do most of the heavy lifting in handling large and/or complex datasets. Peripherals, such as storage and retrieval systems, and CD-ROM, DVD-RAM, and USB devices are required to effectively transcribe data into and out of systems.

The first spatial technology addressed is GIS, which is a general-purpose technology for handling geographic data in a digital form. **GIS** has the ability to preprocess large amounts of data into a form suitable for analysis and evaluation; support models that perform analysis, calibration, forecasting, and prediction; and postprocessing of results to produce tables, reports, and maps (Goodchild 1993). For a more technical description on what GIS is and steps needed to maintain it, review Koeln et al. (1996) and O'Neil et al. (2005).

BOX 18.1. EXAMPLE OF WHAT NOT TO DO WHEN DEPICTING INFORMATION ABOUT A SPECIES

This example shows what can happen when depicting information about a species without understanding or taking into account the scale or level of information needed to study the problem of interest. The figure is a hypothetical example of an American marten range map depicting various levels of habitat suitability. This map represents a false-positive outcome in that it conveys the impression that we know a great deal about this species and have the ability to rate large expanses of its habitat.

Depiction of the American marten range map in Oregon to demonstrate how a map can appear to be accurate while the information it displays can be misleading. Habitat suitability requires fine scale information.

The fallacy: it is the right question at the wrong scale; maps can simply reflect that we may not know the habitat used by marten in the Oregon and Washington Coast ranges as well as we do the intermountain range. Mapping nonhabitat is confusing, because if it covers large areas in the map, value judgments of good, fair, or poor may just reflect the author's biases or narrow understanding of the information being used to construct the map. The bottom line is that such a map superficially suggests that large areas of a species habitat could be discounted or presumed to be highly unimportant in a conservation strategy, when the reality is that fine-scale elements will dictate what is suitable and what is not. A more appropriate depiction at this coarser scale would be to show just a species range without any qualifiers as to habitat suitability or to show only habitats that are generally associated with a species presence.

There is a strong tendency to want to depict more about a species or a situation than we may really know. We caution users of Geographic Information System technology to be sure that they understand the information being presented. If you are unsure, then ask the following question of someone who does understand: does this make sense?

USING GIS IN THE FIELD OF WILDLIFE

Prior to 1950, vegetation maps were tediously drawn by hand, and wildlife biologists interpreted the maps in terms of habitat for wildlife, typically game animals. The availability of aerial photography and then satellite imagery gave biologists a way to more accurately analyze habitats across broader landscapes. For example, in the early 1970s, Schuerholz (1974) quantified forest edge habitat from aerial photographs, and Cowardin and Myers (1974) identified and classified wetland habitats from remotely sensed images. In the later 1970s and 1980s, as computers became more widely available and more capable, vegetation maps were transcribed into digital images, and habitat analyses became highly automated (e.g., Marcot et al. 1981, Mead et al. 1981, Mayer 1984, Burroughs 1986, Brekke 1988). In practice, the staff of the Chattahoochee-Oconee National Forest in Georgia developed a forest plan (U.S. Forest Service 2004) that reflected a public desire for more wilderness and recreational areas, given the Forest's proximity to the Atlanta metropolitan area. The plan acknowledged that GIS was heavily relied on, using such processes as buffering (e.g., for delineation of scenic corridors) in the development of various land classes. Today, GIS is an indispensable tool for analyzing historical, current, and potential future habitat conditions for wildlife (Fig. 18.2) and for assessing the spatial relationships among landscape features (Box 18.2).

Another case in point is an up-and-coming concept, whereby GIS supports a **habitat accounting and appraisal system** called Combined Habitat Assessment Protocols (CHAP) for evaluating and crediting habitat impacts and

mitigation (O'Neil 2010). CHAP is being used in 5 western states for projects that range from evaluating ecosystem restoration of the Los Angeles River to settle a lawsuit for a 25-year wildlife-habitat loss in Oregon for US\$133 million. This approach uses site mapping and inventory of individual vegetation types for structural conditions and fine-feature vegetation components or key environmental correlates. The field information is then linked to a peer-reviewed dataset that can tie potential fish and wildlife species to the site's vegetation inventory. Two matrices are generated—species-function and habitat-function matrices—and these values are then combined to generate the overall value of the habitat for fish and wildlife (see Fig. 18.3); the values are determined, stored, and displayed in a GIS geodatabase. GIS also is gaining in popularity for use in evaluating **cumulative effects** of management actions and potential effects of **alternative management decisions** on wildlife habitats, populations, and communities.

GIS and Modeling Wildlife–Habitat Relationships

One of the most common uses of GIS in wildlife management is in analysis of **amounts**, **patterns**, and **trends** of habitat for individual wildlife species. For example, McComb et al. (2002) used GIS to model potential habitat of northern spotted owls (*Strix occidentalis caurina*) at landscape scales in the Pacific Northwest. Dettmers and Bart (1999) applied GIS to predict forest songbird habitat in southern Ohio. Carroll et al. (1999) used presence data to construct and validate spatial habitat models of fisher (*Martes pennanti*) in central Oregon. Knick and Dyer (1997) used GIS to analyze black-tailed jackrabbit (*Lepus californicus*) habitat in south-

BOX 18.2. WHAT IS A SPATIAL RELATIONSHIP?

Spatial relationships may be important for understanding the resources of concern when developing habitat management strategies (Schroeder et al. 1999). Spatial relationships describe the association among landscape features, and they may be characterized by both topological and directional aspects. When developing the topology among landscape features, one is using methods that develop associations among landscape features. Research into spatial relationships has been driven by the work of mathematicians, cognitive scientists, and designers of software for any Geographic Information System (GIS). In a GIS, it may not be sufficient to know just the position of a landscape feature; it also may be necessary to know how the landscape feature relates to other features in the same (or other) databases. For example, it may not be sufficient to just be able to locate a patch of optimal habitat; it also may be important to locate other patches of good or optimal habitat nearby.

Some examples of spatial relationships include:

1. polygons that share a common boundary (e.g., adjacent polygons),
2. polygons of a certain type (e.g., optimal habitat) nearest to other specific polygons (e.g., proposed harvests),
3. polygons that overlap other polygons (e.g., the intersection of soils and timber stands),
4. lines that cross one another (e.g., roads that cross streams),
5. lines that logically flow into one another (e.g., stream networks),
6. lines that are within a certain distance of other landscape features (e.g., roads within a certain distance of streams),
7. points contained in polygons (e.g., bird point sample locations in timber stands), and
8. points that can be seen from certain other points (e.g., as in defining viewsheds).

Fig. 18.3. Displaying wildlife habitat values of focal habitats in a landscape.

western Idaho. O'Neil et al. (1995) depicted and mapped all of Oregon's wildlife habitat types using GIS. Following procedures used by O'Neil et al. (1995), Kiilsgaard and Barrett (2000) created the first **wildlife-habitat types map** of the entire Pacific Northwest. Many other examples can be found in the literature. These habitat relationship models use such variables as slope, aspect, and vegetation structure to provide estimates of habitat quality. Variables used are based on factors shown to influence quality of habitat selected by particular species. Research or professional judgment generally provides the knowledge necessary to develop models of habitat relationships. The challenge is to create the appropriate databases necessary to evaluate relationships in a spatial manner. Bettinger (2001) outlined many of the challenges facing integration of wildlife models with remotely sensed imagery and data related to forest structural conditions. Dussault et al. (2001) caution that existing forest cover maps may not be adequate for evaluating wildlife habitat suitability without an examination of the correlation between mapped forest features and **structural conditions** desired by specific wildlife species or species groups.

Other types of models for evaluating habitat quality also have been integrated with GIS. For example, Clevenger et al. (2002) integrated expert-based models to help identify and plan for wildlife habitat corridors, Raphael et al. (2001) integrated Bayesian belief network models of species habitat suitability into GIS analyses, Guisse and Gimblett (1997) evaluated recreation conflicts in state parks by integrating a neural network model with GIS, and Rickel et al. (1998) used a fuzzy logic model in conjunction with GIS to evaluate wildlife habitat quality. The main objective of these approaches has been to develop useful tools for resource managers charged with identifying locations of important areas for wildlife when empirical information is lacking. GIS helps facilitate this process by providing a representation of the spatial features of a landscape in the habitat quality evaluation.

Statistical analyses also have been integrated with GIS processes to evaluate quality of wildlife habitat. For example, Clark et al. (1993a) integrated a multivariate analysis of female black bear (*Ursus americanus*) habitat into a GIS model, and Pereira and Itami (1991) used results of a logistic multiple-regression study of Mt. Graham red squirrel (*Tamiasciurus hudsonicus grahamensis*) in their GIS model of habitat for the species. Software developed from a variety of organizations is increasingly becoming open to integration. As a result, almost any wildlife habitat-quality model that can be described with quantitative relationships can be integrated with GIS.

Some researchers have taken the integration of wildlife habitat relationships and GIS a step further by integrating qualitative wildlife-habitat relationships with forest planning processes. The goal is to allow features of a landscape important for describing habitat to guide development of forest plans. This innovation represents a distinct change in forest planning, because historically, forest plan develop-

ment has been guided by economic or commodity production objectives, rather than by ecological or social objectives. As a result, **wildlife-habitat relationship** models that include **spatial components** can be incorporated into forest planning processes and guide development of forest plans. Hof and Joyce (1992, 1993) and Hof et al. (1994) were among the first to attempt to integrate wildlife habitat concerns in mathematical forest-planning models. Specific examples of the integration of wildlife-habitat relationships with forest planning processes include elk (*Cervus canadensis*) in Oregon (Bettinger et al. 1997, 1999), birds in the Northwest (Bettinger et al. 2002), birds in the Midwest (Nevo and Garcia 1996), ruffed grouse (*Bonasa umbellus*) habitat in the Midwest (Arthaud and Rose 1996), red-cockaded woodpecker (*Picoides borealis*) habitat in the Southeast (Boston and Bettinger 2001), northern flying squirrel (*Glaucomys sabrinus*) in western Oregon (Calkin et al. 2002), spotted owl in Washington State (Hof and Raphael 1997), and late successional habitat in Oregon (Sessions et al. 2000). **Measures of biodiversity** also have been integrated into forest planning efforts (Kangas and Pukkala 1996). Other habitat-related concerns can be included in forest planning processes (Box 18.3), such as the desire to develop and maintain contiguous core areas of older forest (Öhman and Eriksson 1998, Öhman 2000) and development of connected habitat corridors (Sessions 1991, Williams 1998).

GIS and Modeling Populations

Spatially explicit wildlife population models consider 2 factors of importance to the estimation of populations: the species-habitat relationships and the arrangement of habitat over space and time. Spatial models can assist land managers in their decision-making processes, because landscapes are complex and dynamic. However, many of the **population models** are developed for **one (or a few) species**, and accommodating multiple species across a landscape remains a significant challenge (Turner et al. 1995). Liu et al. (1995) provide an example of the use of a spatially explicit population model in GIS to examine the impact on a nontarget species, Bachman's sparrow (*Aimophila aestivalis*), of a forest plan developed with other goals in mind. The model results allow managers to determine how sparrow population density and distribution may react to planned management activities, such as whether the populations are of a size that meets the minimum management goal for the species, or whether the populations are sensitive to certain projected landscape characteristics. Another example of the prediction of potential population densities is by Mladenoff and Sickley (1998), who used GIS to assess potential population sizes of gray wolf (*Canis lupis*) in the northeastern United States.

GIS has been used as an integral part of **population viability analysis** (PVA; Akçakaya 2000a). Kingston (1995) provides a review of the use of population viability models in a

GIS environment. This analysis uses the vital rates (survival, reproduction, and dispersal) of individuals of a species to calculate population size over time and rate of change. To model PVA in a spatial manner, information about spatial structure (size, shape, and quality) of habitat patches that a particular species might inhabit also is required. This habitat quality information for a landscape can be provided through GIS processes and applications, and it allows land managers and planners to evaluate how management practices may affect the probability of species extinction. Brook et al. (1999) compared 4 PVA processes, including ones that use spatial or mapped representations of populations, and concluded that subtle differences among models can affect results.

Beyond assessing populations and viability, Allen et al. (2001) used GIS gap analysis to model mammal populations and concluded that geographically defining minimum critical areas produced more conservative and defensible maps of species richness than did other methods. Hof and Raphael (1997) developed a geographic model to optimize allocation of northern spotted owl habitat in Washington State. Optimization model parameters included adult survival, fecundity, and occupancy of sites. Some authors have even integrated assessments of population genetics with GIS. For example, Ji and Leberg (2002) evaluated genetic diversity from a regional perspective using GIS. Finally, because intensive ground surveys cannot keep pace with the rate of land use change in some areas of the world, presence-absence models are being developed for use in GIS, in conjunction with remote sensing and other technology, to allow one to map the potential distribution of species at large spatial scales (Osborne et al. 2001, Kilgo et al. 2002).

GIS and Conservation of Wildlife Communities

Another use of GIS in wildlife management is in delineation and conservation of wildlife and ecological **communities**. Delineation of **hot spots** (areas of high species richness or centers of species endemism or rarity; Dobson et al. 1997, Griffin 1999, Ceballos et al. 1998) has become popular for specifying areas with wildlife and plant assemblages and communities needing protection. Mapping species-rich hot spots has been used to delineate potential protected areas or reserves (e.g., Bojorquez-Tapia et al. 1995). Spatial algorithms or processes used to define hot spots usually undergo rigorous evaluation. For example, Araújo and Williams (2001) discovered bias toward marginal populations when delineating complementary hot spots, and NCASI (1996) reported that results of richness hot spots can be highly sensitive to the underlying distribution maps of individual species.

The National Gap Analysis Program (GAP) took delineation of conservation hot spots further by intersecting areas of high species richness with a set of land use allocations, with the goal of identifying areas of high richness that may suffer from lack of protection (Scott et al. 1993). GAP provides an assessment of the extent of representation of na-

tive species and communities across a landscape. Those species or **communities not adequately represented** on public lands can be viewed as **gaps** in conservation networks (Pearlstone et al. 2002). The process of identifying gaps has been aided by dividing analysis areas into segments to account for geographic variation and to help cover broad geographic areas (Scott et al. 2001). For example, the Florida GAP project is a geographically extensive analysis. One of the objectives of this project is to provide interested stakeholders with GIS databases related to status of terrestrial vertebrate species and their habitats. Landsat Thematic Mapper satellite imagery is used, as are the National Wetlands Inventory GIS databases, other available databases (e.g., for soils), aerial photography, and on-the-ground surveys (Pearlstone et al. 2002).

GIS also has been used to design potential reserves or protected areas (Fig. 18.4). One of the fundamental issues for biologists and managers is selection or proposal of areas that should be conserved. A variety of techniques has been developed to determine optimal reserve designs, each using GIS databases to guide selection of reserve areas. Wildlife-habitat relationships can be used to delineate areas of special concern, such as the **corridor suitability** GIS database created for Maryland's Green Infrastructure Assessment (Weber and Wolf 2000). For this assessment, GIS databases representing land cover, stream networks, roads, slope classes, aquatic community conditions, and other traits were used to create a database that described the suitability of areas to act as corridors of wildlife movement. This database was then used as input for a model that determined the least-cost pathway between core wildlife management areas.

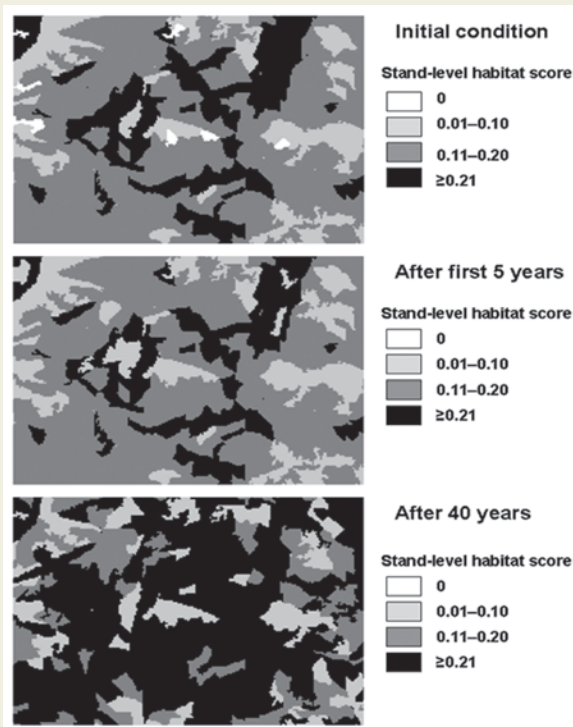

Other researchers (e.g., McDonnell et al. 2002, Nalle et al. 2002) have devised mathematical algorithms to most efficiently design nature reserve systems to meet biodiversity objectives. In addition, reserve area redundancy (ReVelle et al. 2002), complementarity (Williams et al. 2000a), and representativeness (e.g., Mackey et al. 1988, Powell et al. 2000a, MacNally et al. 2002) have been discussed in the literature and demonstrated through use of GIS processes. Dobson et al. (2001) advocated integrating strategies and objectives to meet multiple needs for people and species.

Efficient identification of potential reserve areas with GIS processes has allowed policy-makers to consider a number of management issues. For example, should reserve areas represent an array of community, productivity, or ecosystem classes, as Stokland (1997) suggested for bird and insect conservation in boreal forest reserves of Norway? Should reserve areas be established mainly for species richness, species rarity, or for other objectives, such as balancing requirements of rare species conservation with a broader biodiversity conservation perspective? Williams et al. (2000a) suggested that more biodiversity could be protected if the few species that attract the most popular support (flagship

BOX 18.3. AN EXAMPLE OF INTEGRATING HABITAT RELATIONSHIPS INTO A FOREST PLANNING PROCESS

We illustrate the potential to integrate habitat relationships into a forest planning process with an example provided by Bettinger and Boston (2008). Wildlife habitat goals can be qualitatively or quantitatively defined. Quantitative goals also can reference spatial information provided by Geographic Information System (GIS) databases, allowing spatial goals to be developed. Spatial goals may include configurations, such as required minimum patch sizes or complementary habitat types, and thus may indicate that, for optimal benefit to a particular species, one type of habitat should be placed next to (or in some proximity of) another. Great gray owls (*Strix nebulosa*), for example, prefer early seral stage forests (clearcuts) for foraging, yet these areas should be adjacent to single-story open-canopy forests containing snags or large trees with broken tops.

One can use spatial relationships to guide the development of a forest plan that seeks to provide the greatest amount of habitat over time while achieving other economic or commodity production goals. Bettinger and Boston (2008) illustrate a planning process where commodity production goals in the Pacific Northwest can influence spotted owl (*Strix occidentalis*) habitat capability levels. The process also was used to constrain scheduled activities such that owl habitat capability levels do not fall much be-

Spatial arrangement of spotted owl habitat on a portion of the landscape.

species) had distributions that covered the broader diversity of organisms across a landscape. Should some level of **redundancy** be built into reserve areas to guard against potential losses from major disturbance events? Finally, should reserve areas be complementary to one another to efficiently and cost-effectively set aside the least amount of land area with highest biological opportunity cost? Each of these questions can be addressed with the appropriate GIS databases and reserve selection processes.

GIS and Wildlife Conservation in a Risk Assessment Context

GIS lends itself well to modeling wildlife populations, habitat relationships, and ecological communities in a spatially explicit risk-assessment framework. Such an approach generally entails overlaying maps of the occurrence of wildlife species or communities and habitats (Glenn and Ripple 2004) with **natural and anthropogenic stressors**, such as disturbance events (e.g., fire or climate change) and patterns

of land use, and then evaluating potential changes in conditions that could serve as conservation threats. As an example, Barve et al. (2005) developed a GIS-based procedure for assessing threats to a wildlife sanctuary in India. They mapped current and projected threats from roads and accessibility, human settlements, and livestock density in the sanctuary and devised a composite threat index expressed on a 5-category ordinal scale of intensity. They found that **threat intensity** negatively correlated with tree species diversity and concluded the threat index is a useful protocol that could be applied to other areas.

Integrating remote sensing and GIS tools with risk analysis (evaluating potential threats, their costs or implications, and their probabilities) has long been established in spatial fire risk models. For example, Sturtevant et al. (2009) used GIS with a landscape disturbance and succession model (LANDIS) to estimate fire risk and to help guide management of fire-prone forests in wildland-urban interface areas. Lehmkuhl et al. (2007) combined fire risk and wildlife habi-

low grow-only (no activity) levels, and then to describe the subsequent impact on timber harvest levels. The spatial aspect of the planning process involved the timing and placement of management activities; it included a landscape-level home-range analysis for spotted owl habitat quality. In the latter of these 2 concerns, the forest structure within 2,400 m of each stand was assessed to understand how scheduled activities would affect overall habitat quality. Each stand of trees, in essence, received a habitat score based on the planned activities in other stands within a 2,400-m radius. Stand-level habitat scores were then weighted by the size of each stand, and a landscape-level average was determined. The landscape-level average was then used to control the timing and placement of activities. Although mainly performed using vector GIS data, this process is similar to the moving window approaches commonly used in conjunction with raster GIS data. A few practical constraints also were added to the planning process. These included constraints on minimum harvest age and on maximum clearcut size (48.6 ha).

A heuristic planning technique (i.e., one that determines good, feasible problem solutions that are not necessarily optimal), threshold accepting, was used to develop the forest plan. Threshold accepting is a stochastic neighborhood search process based on accepting, during a search, subsequently lower quality solutions only if they are

within some threshold quality of the best solution located during the search. The plans developed were thus informed by the spatial arrangement of scheduled activities and the resulting landscape-level habitat quality (the figure on page 436). When assessing the competing goals, trade-off curves (the figure below) were used to help visualize how the goals interact. The relative effects of policies can then be considered by policy-makers and managers in the assessment of a gain (or decline) in one measure compared to the decline (or gain) of another.

Trade-offs among spotted owl habitat and commodity production goals when the minimum harvest age is altered.

tat models to spatially depict potential benefits for fire hazard reduction and wildlife conservation from alternative fuel-reduction treatments at the landscape scale.

Risk analysis approaches to evaluating wildlife communities typically entail dealing with incomplete information and use of expert judgment. GIS and **remote sensing** information and tools can be used to integrate limited data with expert knowledge and to map uncertainties (Bojorquez-Tapia et al. 1995, Jones and Thornton 2002). Johnson and Gillingham (2004) developed a procedure to evaluate the reliability of predictive species-distribution models when based at least in part on expert opinion. They found that expert-based predictive models can vary according to opinions used and provided a means of mapping such uncertainties of species distributions. The uncertainty maps can provide managers with explicit information on the reliability of expert opinion as the basis for species distribution models (also see Murray et al. 2009). More generally, GIS tools for denoting and representing expert knowledge are being applied in various

conservation venues (Bojorquez-Tapia et al. 2003, Gao et al. 2004).

GIS-based tools have been developed for evaluating connectivity of wildlife habitat and for delineating potential wildlife dispersal corridors in the landscape (Clevenger et al. 2002). One such ArcGIS-based tool using a cost distance approach is CorridorDesigner (<http://www.corridordesign.org/>; Beier et al. 2008). Other approaches to identifying potential wildlife habitat corridors combine GIS models with landscape genetics. Epps et al. (2007) evaluated landscape genetics of desert bighorn sheep (*Ovis canadensis*) in a least-cost GIS model to predict probable movement corridors, evaluate potential connectivity among populations, and determine effects on connectivity from anthropogenic barriers and translocated populations.

Other GIS-based risk assessment tools have been developed to evaluate and help delineate biodiversity hot spots for potential conservation consideration. For example, Hunter et al. (2003) used GIS to merge anthropogenic threats (hous-

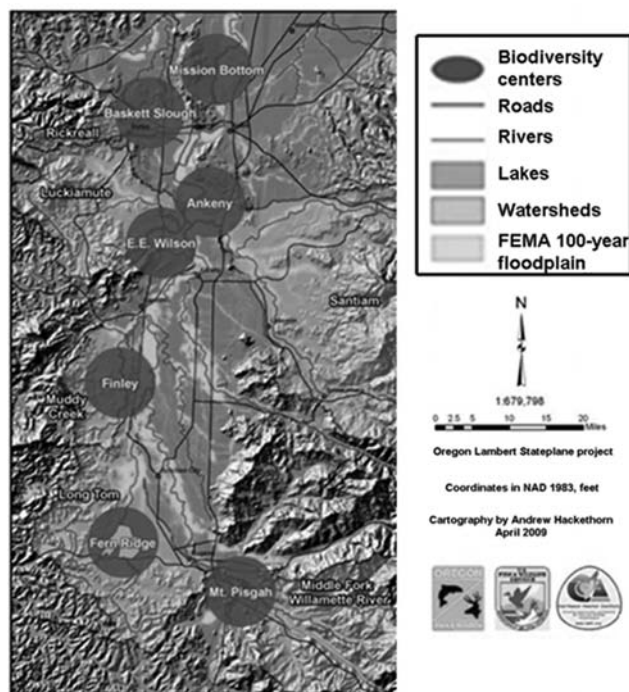

Fig. 18.4. Willamette Valley conservation strategy that links centers of biodiversity (i.e., U.S. Fish and Wildlife Service wildlife refuges, state wildlife management areas, or community conservation areas) with Willamette River 100-year floodplain and 4 watersheds. Land conservation by easements or acquisitions is targeted first in the biodiversity center buffers or in or near the 100-year floodplain, and then in watershed. FEMA = Federal Emergency Management Agency.

ing density) with indicators of biological richness from the Utah GAP to map biodiversity hot spots with high potential threat levels that might require mitigation or conservation, and biodiversity hot spots with low threat levels that could serve as new reserves.

Other examples of using GIS in risk analysis for wildlife conservation and to inform and support natural resource management decisions include the following. Llewellyn et al. (1996) developed a map-based decision-support system to help prioritize sites for restoration on the Mississippi River floodplain; McDonald and McDonald (2003) presented a GIS-based wildlife risk assessment method using resource selection models; and Goparaju et al. (2005) used GIS tools to evaluate effects of forest fragmentation risk on ecological communities.

One promising area of remote sensing and GIS application is community-based, participatory resource inventory and environmental decision-making, empowering local communities with tools they can use to evaluate, economically value, and plan for use of their local natural resources, including wildlife. Such GIS applications were presented by Lewis (1995a), Kearns et al. (2003), Guralnick and Neufeld (2005), and Jankowski (2009). These approaches would likely prove fruitful if used with increasing public interest in **citi-**

zen science participatory programs for wildlife observation (Lepczyk 2005), such as Cornell Lab of Ornithology's Project FeederWatch (www.birds.cornell.edu/pfw/).

Another use of GIS is in crafting optimal or satisfactory solutions to delineating potential protected areas across landscapes. Over the years, several GIS-based spatial allocation models have been developed and used, such as SITES (Roberts et al. 2003), Marxan and Marzone (Christensen et al. 2009), Ecospace (Pauly et al. 2000, Christensen et al. 2009), SELES (Fall and Fall 2001), and network flow models of dispersal corridors (Phillips et al. 2008). Such approaches usually entail identifying species richness or key areas of biological diversity, determining existing or desired land-allocation boundaries, and developing a cost-function layer that denotes various aspects of potential wildlife dispersal filters and other real or assumed costs of conservation and land allocations. Results are maps with protected area polygons typically denoting optimal or satisfactory solutions to habitat conservation that meet lowest-cost criteria.

GIS AND THE INTERNET

The rapid development of GIS networks has been concurrent with the ever expanding capabilities of the Internet. GIS technologies have become more complex, growing from isolated workstation-based solutions to fully integrated multi-user enterprise systems that connect many people and organizations to dynamic data and web-based application tools. The Internet has served to disseminate data; support software applications; document the enormous volumes of data being created today; and facilitate professional networking and collaboration among scientists, resource managers, and the public. The Internet is a valuable resource without which any modern GIS user cannot fully function.

When beginning a GIS project, analysts may first need to compile initial geospatial datasets that are pertinent to their location of interest. There is an ever-growing amount of geospatial data being served online via the Internet; one can find, free of charge, the appropriate datasets to support both the analysis and reporting protocols being implemented for any given project. These data are being served by a variety of methods, from simple data clearinghouses, such as the Oregon Geospatial Enterprise office (<http://www.oregon.gov/DAS/EISPD/GEO/index.shtml>), to complex dynamic representations, such as **Google Earth** or Microsoft's **Virtual Earth**.

There are many sources of data available on the Internet that are collected and maintained by private organizations and are available for a fee (or are free), and public data are available from federal, state, and local governments and various nonprofit sources. A prominent source of data on the Internet in the United States is the Natural Resources Conservation Service Spatial Data Gateway (<http://datagateway.nrcs.usda.gov/>). Users can select the geographic areas of interest, usually by county and state, and can view the avail-

able data, such as imagery, topographic maps, **digital elevation models (DEMs)**, soil hydrology, and geographic information. Most, if not all, of the 50 states in the United States operate websites to disseminate GIS data; so they are a great place to start looking. They are usually easily located on the Internet by using a search engine with the state name and "GIS data" as keywords.

Data **clearinghouses** are usually simple websites that offer GIS data files, premade maps, and metadata (data about data) for download just by clicking on the appropriate links. This type of site exemplifies a static concept of data delivery. Files that are available for download from this type of site are rarely or only periodically updated; they represent data that do not regularly change, such as geologic or topographic information. Users simply click on a file to download it and save it to their hard drive. Files are usually served in one or more formats compatible with modern GIS software, such as **Earth Systems Research Institute (ESRI)** shapefiles and coverages and .e00 exchange files. The various incarnations of ESRI geodatabases, such as the Microsoft Access®-based Personal Geodatabase, the standalone file geodatabase or the multi-user geodatabases that run on third-party **relational database management system** platforms, such as SQL or Oracle, are becoming more popular for direct data transfer. Static data delivery requires little server side maintenance or hardware requirements, as long as the data do not change often. Every time there is a change in a dataset, it is necessary to regenerate statistics, metadata, and hyperlinks on the webpage. Users also do not have the option of defining their own areas of interest. Instead, they are forced to download and handle a dataset that is either geographically larger than needed or to piece together multiple smaller files to cover the project area. These types of data are increasingly being served via dynamic websites that provide greater flexibility for users.

Rapidly changing, extremely large datasets that require multiple users to edit them are not suited to distribution by the type of static websites described above. Users of high-resolution aerial imagery, for instance, often require only a portion of an image to cover a site of interest. Downloading an entire set of imagery may be too time consuming and would require extensive clipping or excessive display times. Dynamic data delivery is a model that incorporates server and GIS technologies to reduce the maintenance of the data delivery system by automatically updating linkages to existing datasets while simultaneously reducing data storage redundancy. Instead of constantly having to deal with updating frequently changing datasets or separate copies for multiple users, managers can store, back up, and maintain a single dataset that incorporates input from all users. This system results in a much more robust method of handling large amounts of data, but it is not without high initial costs associated with the hardware, software, and personnel required to run such a system. Dynamic data delivery systems

are often supported in an organization's information technology department to facilitate seamless data analysis and dissemination of information while sharing the costs among many departments or agencies. Data managers can link with source data, manipulate changes, and instantly have those changes reflected in the data being served to the public by a single action rather than by having to copy the data to an export file and updating the website code to point to the new file(s). Dynamic mapping applications, such as ESRI's **ArcGIS** Server, also can be set up to automatically incorporate various GIS datasets to provide interactive maps that can be imbedded in websites.

Dynamic web services can be configured to provide this imagery for download or streaming directly to a GIS application. The Oregon Imagery Explorer (<http://oregonexplorer.info/imagery/>) is a good example of a dynamic web service that allows users to stream or download 0.5-m **National Agriculture Imagery Program** data directly to a GIS application, such as **ArcMap**. The data storage requirements of these datasets alone would require prohibitively large storage servers and/or download times.

Finding where to access some of these data also can be confusing at times. The most popular search engines for quickly locating websites, as determined in a 2006 Nielsen NetRatings survey (http://www.google.com/search?q=2006+Nielsen+NetRatings&rls=com.microsoft:en-us:IE-SearchBox&ie=UTF-8&oe=UTF-8&sourceid=ie7&rlz=117SUNA_en), are Google (49.2%), Yahoo (23.9%), and MSN (9.6%). Although these search engines may not directly link to spatial data sources, they often do point to viable data centers or other Internet resources. The Geography Network (<http://www.geographynetwork.com/>) is a good example of a place to start looking for geographic datasets. Other resources include user groups and help forums. The Society for Conservation GIS (<http://www.scgis.org>) is an example of an active user group that can help link many organizations in the natural resources field. ESRI operates a support website (<http://support.esri.com/>) that can be invaluable to GIS users in providing analysis solutions and identifying software bugs. ESRI also hosts many online training opportunities at its training site (<http://training.esri.com/gateway/index.cfm>) that can help users learn about the basics of GIS analysis and new functionality that is constantly being added to GIS tools. Much of this training is offered free of charge. Another source of online geographic data is the U.S. government's **Geospatial One Stop** website (<http://www.geodata.gov>). This website contains linkages to many federal, state, and local data sources.

GIS in the International Community

Numerous ongoing efforts are under way to consolidate and enhance spatial information studies at the global level, such as the various United Nations programs to enhance biodiversity and information exchange; the World Wildlife

Fund; and *Diversitas*, an international program to promote biodiversity. Several governmental and nonprofit agencies have developed forums (websites that allow users to interact with one another in a bulletin board-like setting) to create, analyze, and disseminate spatial information. Such groups as the American Geological Institute, **United Nations Environmental Program's (UNEP) Global and Regional Integrated Data (GRID)** program, and the **Global Spatial Data Infrastructure (GSDI)** lead the way in connecting scientists and the public to data and information regarding the status of geophysical and biological resources of the planet.

UNEP-GRID is a good example of the coordination of many entities at the global or regional scale. UNEP-GRID is headquartered in Nairobi, Kenya, and provides global leadership in coordinating environmental data management, disseminating GIS decision support tools, and providing GIS training. UNEP-GRID centers around the world coordinate regional data on climate change, vegetation coverage, temperature maps, elevation data, and many other key datasets. In addition to housing regional datasets, each GRID center has additional research responsibilities and interests. For instance, the UNEP-GRID node in Arendal, Norway, is responsible for polar research, and the Sioux Falls, South Dakota, site houses global landcover data collected from U.S. satellites. Currently there are 7 GRID sites around the world, with 5 more being proposed. As more regional centers come on line, there will be further opportunities for every country to participate in the global area of environmental data management.

GSDI is a nonprofit organization dedicated to enhancing and facilitating the development of spatial data to build sustainable social, economic, and environmental systems and fostering informed and responsible use of geographic information. Many groups, including UNEP-GRID, are members of GSDI. Other major players in the global spatial data arena provide similar services to scientists and resource managers around the globe. Another UN group, the **World Conservation Monitoring Centre** provides a great deal of spatially derived data, such as biodiversity information, species databases, and international environmental agreement protocols.

Other sources of information certainly do exist to address global issues in GIS. ESRI hosts an annual international GIS user's conference in San Diego, California. This conference draws well over 10,000 participants from all over the globe. Attendees can hear presentations by GIS users in many different fields and have access to hundreds of hours of training in GIS technologies. There are often opportunities to receive complimentary or discounted registration passes from ESRI if the applicants are affiliated with educational or nonprofit organizations or are students. There also are projects that address species-specific issues at the global scale. For instance, the **Global Owl Project** (<http://www.globalowlproject.com/>) incorporates scientists and resources from many different countries in an effort to conserve and protect world

owl populations. Another great source for global spatial information is the **National Biological Information Infrastructure (NBII)** and the **Global Biodiversity Information Facility**. They offer global biodiversity information through a coordinated effort of international scientists. Becoming aware of these data sources will certainly help connect disparate scientific studies to the global context of biodiversity and conservation of wildlife in the future.

USING GLOBAL POSITIONING SYSTEMS

In recording wildlife and related natural resource information, a fundamental component is location. No tool has shaped the nature of location gathering, navigation, and field geographic data collection more than the United States' **Global Positioning System (GPS)**. GPS provides accurate 3-dimensional locations (latitude, longitude, and elevation) 24 hours a day to users who have a GPS receiver. Various types of GPS receivers for consumers, mapping professionals, surveyors, and other users requiring high accuracy are available. Manufacturers include Garmin, Trimble Navigation, Topcon, Novatel, and Magellan. A larger list of manufacturers and system integrators can be found in the **GPS World Buyer's Guide** (<http://www.gpsworld.com>). As users, we are not required to pay a subscription fee to access GPS signals; thus, GPS is often viewed as "free of charge." In fact, the U.S. government via the taxpayers pays the bill, and current maintenance of the GPS is in the neighborhood of US\$750 million per year.

GPS also is known as the **Navstar** system, and it is managed by the U.S. Department of Defense, specifically, the U.S. Air Force. There is no doubt that GPS is primarily a military tool, but its expansion and has created a huge multibillion dollar commercial industry. The Air Force Space Command is required to maintain at least **24 GPS satellites** in orbit, which is considered the baseline constellation; in actuality, the system is currently maintaining ≥ 30 operational satellites. The system is dynamic, and the GPS constellation and individual satellite status is updated daily (<http://www.usno.navy.mil/USNO/time/gps/current-gps-constellation>). The system is designed for use anywhere in the world, although the military does maintain control of it and could shut it off or scramble civilian use in any region of the world if they deemed it in the United States' best interests to do so.

As there are other international "GPS" systems in various phases of development, it now becomes good practice to consider the wider term **Global Navigation Satellite System (GNSS)**. GNSS is the standard generic term for all satellite navigation systems that provide autonomous geospatial positioning with global coverage. GNSS systems include the U.S. Navstar GPS, the Russian Global Navigation System (GLONASS), the European Galileo system, the Chinese Beidou system, and others. The viable operation and

future expansion of all of these systems relies on many political and long-term funding factors. It is undeniable the proven and fully operational U.S. Navstar GPS system is, and will be for some time, the benchmark GNSS system. Because of this system's status and its familiarity, we continue to use the "GPS" acronym throughout this section.

GPS technology and how it works is well documented. More in-depth study of GPS, its inner workings, and highly technical material on signal processing, etc., are available. There are several self-help guides (Letham 1998, Anderson 2002a, Kennedy 2009), if one desires a more detailed understanding. Many manufacturers also are good providers of overviews of the technology. For example, Trimble Navigation's GPS tutorial can be found at their website (www.trimble.com/gps/) and provides a good basic understanding of the technology without overstressing the technical details. Such magazines as GPS World (gpsworld.com) have a great deal of coverage of the GNSS/GPS industries.

GPS satellites transmit signals at specific frequencies in the microwave energy range that GPS receivers can **track and receive**. In simple terms, receivers range (determine their distance to the satellite transmitting the signal) by calculating the signal travel time and rate of speed, which is the speed of light. The signals also provide critical almanac and ephemeris data that tells our receivers exactly where the satellites are positioned in their orbital planes. If the GPS receiver can simultaneously track 3 satellites (4 if elevation is required), it can **triangulate** these ranges and calculate its position (Fig. 18.5, Box 18.4). How accurately the receiver can calculate its position depends on a variety of factors we summarize below.

Fig. 18.5. Three satellites are used for triangulation; the fourth satellite takes another measurement to check the other 3.

BOX 18.4. GLOBAL POSITIONING SYSTEM SATELLITES

Navstar GPS was developed by the U.S. Department of Defense and manufactured by Rockwell International. These 24 satellites are placed in 6 orbital planes 20,200 km (10,900 nautical miles) above Earth. Each plane is inclined 55° relative to the equator. They weigh about 710 kg and are 5.2 m wide with solar panels extended. Their orbital period is about 12 hr, and they pass over one of the ground stations twice a day. The lifespan of these satellites is planned at 7.5 years. Using ≥ 4 satellites can yield 3-dimensional estimates of location, whereas using 3 satellites can only generate 2-dimensional observations.

How Accurate Is GPS?

As selective availability (the government's intentional dithering of the GPS signal) has been discontinued since May 2000, we will discount its potential error effect (≥ 100 m) in the unlikely event that selective availability were ever turned back on. For practical discussion, all GPS receivers can typically provide 2-dimensional positioning (i.e., x, y) to within approximately 15.2 m in autonomous mode, that is, without the aid of any other correction augmentation sources. In fact, in autonomous mode, your US\$100 recreational hunting receiver and a US\$20,000.00 survey-grade rover really are not that far apart. Of course, 15.2-m accuracy is not going to cut it in many applications, including those in natural resource research that demand higher integrity in mapped locations. Thus, it is important to understand that **GPS accuracy** is based on 3 main aspects:

- the **type and quality** of the GPS receiver being used,
- the **quality of the signals** being tracked, and
- the **differential correction**, with another GPS receiver (known as a base station) collecting simultaneous GPS positions on a known geodetic survey point.

Types of GPS Equipment and Common GPS Uses

Although the accuracy of a position determined in autonomous (i.e., no correction augmentation) mode is not much different among GPS receivers, the type and quality of a given GPS receiver and antenna will yield significantly different results when accurate correction data are applied (we explain more about corrections in the section on differential GPS below). Thus, the user's receiver—also known as the rover—is the first (but not only) critical bottleneck in the quality of the positions one can expect. It is true that an inexpensive consumer-grade receiver can improve on the pre-

sumed 15.2 m inaccuracy of autonomous GPS by means of correction augmentation, but not to a typical accuracy of much better than 3.0–4.6 m, assuming good GPS conditions. If we need better than that, we need to use better receivers!

There are 3 common grades of GPS receivers. The first is consumer grade receivers, which are the least expensive and provide the least accurate positional information. The second is mapping grade receivers, which generally cost between US\$1,000 and US\$10,000 and are frequently used to develop information for GIS databases. The wide dispersion in cost of mapping grade receivers reflect a variety of accuracy capabilities, depending on make and model. However, many mapping grade applications focus on receivers that can achieve at least 1 m or even 0.3 m horizontal accuracy, which is far superior to what a consumer grade GPS receiver can achieve. As one would expect, these high-accuracy mapping grade systems will be at the higher end of this cost spectrum. Finally, the third grade is survey grade receivers, which are the most expensive and may require more data collection time, yet they can provide centimeter-level positional accuracy. Antennas can be self-contained, as in the case of many consumer and mapping grade receivers, or external, allowing them to be mounted on a pole, a backpack, a truck, or a person.

The choice of GPS receiver generally centers on, foremost, its accuracy capability for the project. Time occupation required (i.e., the efficiency of GPS collection) and cost considerations to achieve this accuracy must be weighed.

Quality of Signal

GPS is a **line of sight technology**. If the GPS receiver cannot “see” (track) the signals from the satellites, then it cannot calculate positions. If it can see them, but the signals are mitigated in their flight, we will not get accurate positions. The quality of these signals is critical to accurate positioning. There are 2 key aspects to signal quality, described below.

Geometric Configuration of the Satellites

If the tracked satellites are spaced apart sufficiently in the sky, the receiver will have better inputs to perform the math required for accurate positioning. If the opposite is true, we get greater dilution of precision (DOP) and our accuracy suffers. The DOP is used to describe the strength of a satellite configuration and its impact on the accuracy of the data being collected. Positional DOP (PDOP) is most commonly used indicator, and it represents the mean of the vertical DOP and the horizontal DOP. A major benefit of many higher quality GPS receivers is their ability to filter or set masks for DOP thresholds, ensuring only low DOP data is used (low DOP implies more accurate positions). Most consumer-grade GPS receivers do not allow the user to set a DOP mask and thus cannot filter out this high dilution of precision.

Satellite Signal Strength and Direct Flight Path

Strong signals from direct observable satellites in view yield better positioning results. A satellite directly overhead that is tracked by our receiver without being hindered by ground obstructions (trees, buildings, canyon walls, etc.) is an excellent input to the location calculation. Satellite signals can pass through forested canopies, yet they can be blocked by tree trunks or other landscape features. This blockage may lead to either no reception of the signal or reception of a multipathed signal. Other sources of error include atmospheric interference, problems involving the synchronization of clocks (satellite and receiver), and other receiver errors.

In forested conditions, mapping-grade receivers can obtain accuracy levels of ≤ 3 m after differential correction is applied (Wing 2008, Danskin et al. 2009). Depending on the model, consumer-grade GPS receivers may obtain accuracy levels of ≥ 5 m (Wing et al. 2005). Positional accuracy seems to increase as slope position increases, is better in the winter time (under leaf-off conditions), and can be improved slightly when the Wide Area Augmentation System (see below) is available. Further, differential correction significantly improves positional accuracy (Wing et al. 2008, Danskin et al. 2009). GPS test sites have been developed in Oregon (Clackamas GPS test network), Pennsylvania (Ridley Creek test network), and Georgia (Whitehall Forest GPS test site) to help study and publish the performance characteristics of different receivers under forest canopy (Box 18.5).

Critical Role of Differential GPS

Differential GPS (DGPS) is **mission critical** to driving our GPS systems to better accuracy beyond what receivers can do alone (i.e., autonomous mode). Simply explained, differential GPS is correcting our rover receiver's answers relative to another GPS receiver that is calculating locations at the same time. We call this second receiver a **base station**. What is so great about this base station? Well, technologically, not a whole lot. Base stations are basically subject to the same kind of **GPS errors** as ordinary receivers. However, they are

BOX 18.5. GLOBAL POSITIONING SYSTEM GROUND STATIONS

Known as the control segment, these stations monitor each satellite's functionality and exact position in space. They correct ephemeris errors, such as clock offsets, and transmit corrections to the satellites. There are 5 stations worldwide: Hawaii and Kwajalein in the Pacific Ocean; Diego Garcia in the Indian Ocean; Ascension Island in the Atlantic Ocean; and Colorado Springs, Colorado, which is the master ground station.

placed in excellent GPS conditions, such as on a tall building or tower (above any potential for signal obstructions). What really makes them so useful is they are stationary and placed on known survey locations. So, even when the base station is calculating imprecise GPS autonomous locations, our base station and correction systems can detect it and can correct the same errors that our rovers are seeing! Errors the base station detects, which are common to our rover data, such as atmospheric errors, can be effectively eliminated. DGPS cannot get rid of all errors from our rover, but it gets us closer to perfect data, depending on the quality of receiver and signals we are using, as described in the section above.

Post-Processing versus Real-Time Correction of DGPS

DGPS corrections can be delivered from the base station in 2 main ways, **post-processed** and **real-time**. Post-processing delivers the correction result after the rover has collected its data from the satellites. This method is adequate for applications where the data is being collected for map production or GIS database updates. The data accuracy is not critical in the field, but may be for the end-product. Real-time DGPS systems allow us to obtain our DGPS corrected accuracy (again, relative to the device type and quality of inputs) on the spot. This speed may be key in mission critical navigation, where autonomous accuracy will not bring us close enough to the desired target. For example, if our navigation map shows us the precise location of a buried well head that we need to excavate, a 15.2-m navigation circle around the exact location is a lot of wasted digging and is not practical! If we instead can use a sub-meter or better mapping-grade receiver with real-time corrections, we can drill into the target area within the standard size of an excavator's bucket.

Post-Processing

Not all GPS receivers support post-processing. To post-process, you will need the following.

- A GPS rover's receiver with internal software that supports collection of raw satellite information.
- Access to correction data collected by a GPS base station, preferably one dedicated to collecting GPS data on a known, verified surveyed position. The U.S. National Geodetic Survey runs a huge network of base stations that provides correction data for post-processing free to the GPS public (<http://www.ngs.noaa.gov/CORS/>).
- A post-processing software or post-processing service provider that is compatible with the data from your receiver. This would generally be sourced from the manufacturer of your receiver. Users also can use the National Geodetic Survey Online Positioning User Service at their website (<http://www.ngs.noaa.gov/OPUS/>).

Real-Time DGPS Corrections

Real-time DGPS opens up the ability to obtain your receiver's corrected accuracy right in the field. In the early days of GPS, real-time DGPS stations were more than likely limited to private companies, for example, a large surveying outfit or multimillion dollar mining or drilling operation. However, the real-time DGPS options and infrastructure have been expanding. There are a number of real-time sources, many free of charge, that one can use, depending on receiver capabilities. It should be noted that real-time DGPS depends on acquisition of the corrections by one's receiver hardware (typically by radio or satellite). One needs to determine whether the available real-time source will be blocked by obstructions or natural topography.

Wide Area Augmentation System

Because of GPS utility to fix an airplane's location in real time, the Federal Aviation Agency (FAA) has developed a plan called **Wide Area Augmentation System (WAAS)** that would **extend coverage for DGPS for the entire United States**. WAAS is a critical component of the FAA's strategic objective of a seamless satellite navigation system for civil aviation. This system improves the accuracy, availability, and integrity of GPS, thereby improving the system's capacity and safety. Ultimately, WAAS allows GPS to be used as a primary means of navigation from takeoff through Category I precision approach (i.e., very close to the runway, but not zero visibility; Category 3 landings are zero visibility). The ramifications of the FAA to maintain this system go well beyond aviation; because of its design, the system helps ensure that DGPS corrections will be accessible to all who need them. WAAS takes a consumer grade GPS to about 4.6-m accuracy, and with the right piece of mapping grade equipment, you can achieve about 0.6–0.9-m accuracy. Users working in closed canopy conditions will find it quite difficult to consistently obtain and hold the WAAS satellite signal. If you want to know more about WAAS, see the Garmin website (<http://www.garmin.com/aboutGPS/waas.html>).

U.S. Coast Guard DGPS

The **original** real-time DGPS source, the **U.S. Coast Guard** and other international maritime and navigation agencies, have established radiobeacons that transmit corrections to compatible receiver hardware. It is likely you would require a dual-frequency beacon receiver along with your GPS receiver. The radios transmit usually in the 300 kHz range. For information about the Coast Guard DGPS system, go to their website (<http://www.navcen.uscg.gov/dgps/Default.htm>).

Real-Time Kinematic and Their Networks

As discussed above, WAAS and the Coast Guard beacon DGPS systems have provided a great augmentation infrastructure primarily to our consumer grade and mapping grade receivers. However, WAAS and the Coast Guard bea-

cons cannot directly achieve survey grade accuracy. If you are going to use survey grade GPS, your receiver and its base station will need to be capable of **real-time kinematic (RTK)** to effectively incorporate real-time centimeter positioning. Because the base station requirements in a RTK network require very proximal access to the base station (typically baselines ≤ 20 km), it has been very common for surveyors and other high precision users to set up their own base stations, transmitting corrections to their RTK rovers on a radio broadcast (e.g., 450–470 MHz).

There is now a push for many areas to fill in RTK networks. These are the RTK correction equivalents to WAAS and the Coast Guard beacons. Because of the short baselines, RTK networks require many more receivers to cover DGPS for a user base. However, we are seeing cooperative infrastructure that is building large RTK networks. The networks also are taking advantage of virtual reference station technology. A virtual reference station can greatly extend the baseline distances allowed to obtain quality RTK corrections to your rover. It also allows for redundant corrections to be applied from multiple base stations in the network to maximize the quality of results. RTK corrections from these networks can be “broadcast” over an Internet connection, making it possible for a user to subscribe to a data cell phone plan and obtain RTK corrections from the cell phone connected to the RTK rover.

A significant by-product of these RTK networks is they eliminate the need for users in the coverage area to set up their own RTK base stations, cutting down significantly on capital expense and operation setup time. Along with survey-grade RTK systems, some of today's sub-meter mapping-grade GPS devices (connected to a compatible data modem or cell phone) can accept RTK corrections from these networks as well. This capability provides a more affordable solution for users that do not need centimeter real-time positioning, but want to navigate to features to within as good as 0.2 m! An example of a sub-meter real-time capable solution is Trimble's 2008 GeoXH[®] device (<http://www.trimble.com/>).

GPS Uses in Wildlife Biology

Now that a cursory understanding has been given of what GPS is and how it functions, you may be wondering what its practical applications are in the field for wildlife. Two areas of use are predominant: (1) tracking and recording wildlife movements and (2) inventorying, mapping, and/or surveying wildlife habitats or specific wildlife use areas (Box 18.6). A **GPS tracking collar** can be used to track and record wildlife movements (Fig. 18.1) and provide more accuracy than other tracking systems can (Rempel and Rodgers 1997). Since 1994, there are a number of GPS collars available, and some use the Navstar GPS (e.g., those from Lotek, Telonics, and Televilt). For example, GPS collars have been used to successfully track moose (*Alces alces*; Rodgers et al.

BOX 18.6. GLOBAL POSITIONING SYSTEM RECEIVERS

GPS receivers can be carried by hand or installed in airplanes, boats, cars, or trucks. These receivers detect, decode, and process GPS satellite signals. Typically, hand-held receivers are about the size of a cellular phone or palm computer, and they are getting smaller all the time.

1997), grizzly bears (*Ursus arctos horribilis*; Servheen and Waller 1999), caribou (*Rangifer tarandus*; Dyer 1999), mountain lions (*Puma concolor*; Bleich et al. 2000) and wolves (Merrill and Mech 2000).

These collars now come in different sizes that can be used on small, medium-sized, or large mammals. The weight varies from 100–2,100 g (depending on the collar size), and the collars can store typically up to 10,000 locations non-differentially corrected or 5,000 locations differentially corrected, depending on recording frequency and battery configuration (Box 18.7). They can operate in temperatures ranging from -30°C to 50°C , and the data can be retained in the collar at temperatures ranging from -50°C to 75°C . Collars can be configured to allow periodic data downloads, or all the data can be transferred to a computer when the collar falls off. A source of concern, however, in using GPS collars lies with locating an animal, such as an elk, in a forest of varying density and topography. Rumble and Lindzey (1997) found that nearly 50% of attempted GPS locations failed in stands with $>70\%$ overstory canopy cover; in stands with less canopy cover, the percentage of GPS location attempts that failed was lower. Attempts to model the effects suggested a positive linear relationship ($P \leq 0.01$) between percentage of GPS location attempts that failed and the tree density, tree basal area, and index of diameter at breast-height times tree density. Dussault et al. (1999) and Gamo et al. (2000) also noted that **vegetation can block signals** from satellites to GPS radio collars. Therefore, a vegetation dependent bias to telemetry data may occur, which, if quantified, could be accounted for. As this technology evolves, steps to increase GPS efficiency in a forested environment may enhance its usability in these habitat types.

GPS technology also can be used to inventory, map, and monitor marine, fish, and wildlife habitats. For instance, GPS has been used to delineate coral reefs (Field et al. 2000), wildlife habitat types (Kiilsgaard 1999, O'Neil and Barrett 2001) and fish habitats (Martischang 1993, Threlhoff 1994, Waddle et al. 1997). GPS is first a **navigation tool** (Ander-

BOX 18.7. DEFINITION OF TERMS FOR DATA CAPTURING STANDARDS

Base station—a stationary receiver at a known location that provides the data used in the differential corrections of GPS data acquired by a moving receiver; a rover (field) receiver should be 500 km from the base station when using differential corrections. Depending on the accuracy requirements of your application and the equipment you are using, your baseline (distance between the base station and rover field unit) will be a key consideration in achieving effective corrections. For example, for some survey-grade receivers to achieve centimeter accuracy, they may need to be 10 km from a base station (and collect ample occupation points), whereas for an appropriate mapping-grade receiver to achieve submeter accuracy may allow a more liberal baseline of 150 km or more. Review the manufacturer's specifications for the accuracy requirements of your project.

Datum—a smooth mathematical surface that closely fits the mean sea-level surface, for example, the North American Datum of 1983 (NAD83), a geodetic data system used in satellite navigation systems to translate positions indicated on their products to their real position on Earth.

Elevation mask—a filter that ensures that the rover (field) receiver is using the same set of satellites as the base station. For distances 500 km to the base station, use 15°, for distances 1,000 km, use 20°.

Kinematic mode—the mode in which data points are collected at time intervals that vary, depending on the rate at which you are collecting data. Measurement interval will usually be ≤ 1 second; these data are stored in the receiver for later downloading and post-processing.

Positional dilution of precision (PDOP)—an indication of the quality of the geometry of the satellite constellation. The lower the PDOP value, the better the receiver can triangulate the satellite positions to provide accurate readings. However, other GPS errors can mitigate accuracy even when a good PDOP is being calculated by the user's receiver; thus, PDOP is just one indicator GPS users should evaluate in the field and in the office. Quality receivers can ignore (filter) satellite readings with unacceptably high PDOP; these receivers provide significant quality control improvements to the user who needs to validate GPS conditions relative to their reported positions.

Signal to noise ratio (SNR)—a measure of a signal's quality at the Global Positioning System (GPS) receiver. The higher the SNR value, the stronger the desired signal is compared with associated noise. A low value would indicate a weaker signal and/or higher levels of noise; for example, a SNR of 6 indicates a signal that should not be used.

Spheroid—a spheroid of best fit over the surface of Earth; for example, the Geodetic Reference System 1980 (GRS1980) is a geodetic reference system consisting of a global reference ellipsoid and a gravity field model.

Static mode—the mode in which data points are collected at 1-second fixed intervals; a general guideline is to collect point positions at 1-second intervals. The amount of data collected varies with the type of receiver.

son 2002a) that allows researchers to accurately track their movements and guide themselves to an exact location (e.g., a coral reef) and then record the delineation of the location on a map. These wildlife habitat maps require the developers to interface GPS with a map database that would permit storage of information directly on the map (Box 18.8). Further, the maps need to display the GPS receiver's current position in real time, creating a moving map. By displaying their positions in real time, researchers can be sure of their locations and the location of what they are classifying.

Mobile GIS

Making useful decisions based on geographic information requires more than just accurate positions and GPS. We need GIS technology, but in the past, GIS was relegated to our desktops. We would collect data in the field and return it to our office computers to make decisions. In fact, for much of our field collection, we may have used paper maps and written capture data notes on paper. This process is very inefficient and leads to errors, not to mention extremely slow turnaround of the data back to our field people that

BOX 18.8. DESKTOP AND MOBILE VEGETATION MANAGER (VEMA) SOFTWARE RELATIONAL DATABASE

Resource managers require effective sampling tools to collect, archive, and report the data they use to make their management decisions. Desktop VEMA is a customized Microsoft Access(R) relational database that helps record, calculate, and report vegetation performance based on user-determined performance thresholds. The database was largely designed around a vegetation monitoring protocol developed by a team of agency and academic plant ecologists and expert practitioners to help standardize and automate vegetation monitoring and reporting at mitigation and reference sites. The database enables users to record vegetation data and measure the outcomes against peer-reviewed performance criteria and default or user-determined performance thresholds.

Now, with mobile VEMA, the data collection protocol is handled on a mobile personal digital assistant (PDA). Mobile VEMA was developed to complement desktop VEMA by allowing users to capture vegetation data in the field electronically and to capture the Global Positioning System (GPS) coordinates (decimal degrees) where the data is collected. The field data recorded in mobile VEMA can then be transferred to desktop VEMA using a universal series bus (USB) enabled cradle for the GPS or PDA device, ActiveSync software, and a the embedded Vegetation Table Manager. Automated field data collection helps eliminate many data entry errors, because information is collected and entered into database only once. Although VEMA data can be manipulated and represented in Geographic Information System (GIS) software, as both shapefiles and feature classes in geodatabases, it is not yet a true geodatabase at the outset. We are continuing to strive to increase VEMA's efficiency, GIS compatibility, and field utility. Mobile VEMA is an excellent example of how mobile GIS is increasing field user's efficiency and extending office capabilities into the field.

rely on it. **Mobile GIS** is the extension of GIS from the office into the field. Mobile GIS integrates one or more of the following:

- mobile devices (e.g., personal digital assistants [PDAs]),
- GIS software,
- GPS technology, and
- wireless communications for Internet GIS access.

These technologies allow our field-based users to not only capture GIS features with accurate GPS devices, but also to access existing GIS data (GIS layers, aerial photography, and other necessary supporting data) when and where the decisions have to be made. O'Neil et al. (2007) drove over 80,467 km, visually inventorying and mapping wildlife habitats in the Willamette Valley of Oregon using a GPS device connected to a laptop with GIS data. Such extensive surveys are why mobile GIS is so critical. Now, field professionals could collect positions (from the GPS or other measurement device) and provide detailed database descriptions about the observations. They also can update existing GIS databases directly in the field, virtually eliminating the slow turnaround of paper edits to these databases. They can immediately notify authorities of mission critical events by submitting, from their wireless PDAs, emailed reports or automatic incident updates to the GIS.

ArcPad by ESRI (Redlands, CA), SOLO CE (<http://www.timbersys.com/products/handheld-systems/solo-forest>), and TerraSync Professional (<http://www.trimble.com/terrasync>

.shtml) are examples of **mobile GIS platforms**; they feature map displays, **interface to GPS** and other measurement systems, and supply data collection and editing capabilities. ArcPad, which is a particularly GIS function- and feature-rich mobile GIS also is customizable for special projects that require particular work flows, data entry and edit forms, and even special tool bars.

USING REMOTELY SENSED DATA

Landsat Imagery

The **Landsat** series of satellites has been in operation since 1972, when Earth Resources Technology Satellite 1, later renamed Landsat 1, was launched. There is a rich historical description of the Landsat program and usage of its data in a variety of published articles (e.g., Cohen and Goward 2004, Williams et al. 2006). The interested reader should refer to those and related articles for a historical perspective. Landsat's contributions to **study of Earth** as a system are legendary, owing largely to its observation characteristics, which have steadily improved with each successive launch. These include global coverage, multiple monthly observations of the same location, excellent radiometric calibration and georegistration, approximately **30-m spatial resolution**, and multispectral sensors that include shortwave-infrared wavelengths.

The latest satellite in the series (number 8), the Landsat Data Continuity Mission (LDCM), is slated for launch in

December 2012. In keeping with the historic character of the Landsat program, the Operational Land Imager (the LDCM sensor) is an improvement over the existing Landsat 5 and 7 Thematic Mapper-class sensors. The existing 2 satellites are being managed for minimum fuel consumption, and hence maximum life span, with the hope their utility can be extended into the LDCM era. If successful, there will be no data gap, and the user community will be extraordinarily fortunate. If either or both Landsat 5 and 7 fail before the launch of LDCM, the sudden lack of new Landsat data will cause a scramble for other current datasets as a replacement.

As the name implies, LDCM is about **data continuity** (http://landsat.usgs.gov/documents/ldcm_factsheet.pdf). Thus, the specifications for both spacecraft and reflectance sensor have qualities at least as good as those of their predecessors. For example, there will be a minimum cross-track swath width of 185 km at the equator; multispectral band spatial resolution of 30 m; panchromatic band spatial resolution of 15 m; about 12 m spatial accuracy; essentially the same 6 spectral reflectance bands and panchromatic band, with 2 additional bands for coastal studies, aerosol detection, and cirrus cloud detection. There is currently no thermal sensor being built for LDCM, but the platform will have a place for it, and current negotiations suggest there will be a thermal sensor on the LDCM satellite, as a separate sensor from Operational Land Imager.

There is one major advancement, or even revolution, in the Landsat program associated with the new data policy. For the first time, all Landsat data acquired by LDCM will be **available free** to all users on a nondiscriminatory basis. Given the anticipated demand for data, to accomplish this goal, a single product recipe will be offered, which includes 30-m (**multispectral**) and 15-m (**panchromatic**) spatial resolutions, Level 1T (terrain corrected) data in GeoTIFF format, Universal Transverse Mercator (UTM) projection (except for Antarctica), World Geodetic System (WGS) 84 (used in satellite navigation systems to translate positions indicated on their products to their real position on Earth) datum, cubic convolution resampling, and web-enabled delivery.

Another extremely important change in the program is the archive of U.S. Geological Survey data from all previous Missile Defense, Thematic Mapper, and Enhanced Thematic Mapper+ sensors. All Thematic Mapper and Enhanced Thematic Mapper+ data in the U.S. archive are now available at no cost in the above standard recipe to everyone (Landsat Science Team 2008). Technical issues with the MSS portion of the archive are delaying the ready release of these data in a timely manner using the standard recipe. It is expected this problem will be solved within the year. Moreover, negotiations with international receiving station countries are expected to lead to a similar data policy for data in their archives.

Beyond LDCM, there is a plan for a National Land Imaging Program; http://www.ostp.gov/pdf/fli_iwg_report_print

[_ready_low_res.pdf](#)). The National Land Imaging Program is intended to provide a long-term strategy for Landsat-class observations of Earth in perpetuity. At the current time, there is no traction in the program, but the Landsat Science Team is strongly advocating it at appropriate places in the U.S. government. This effort is important, because the road from declaration of a new satellite to actual launch can be long and circuitous.

Landsat Change Detection: 40 Years and Counting

Over the years, a variety of approaches has emerged for using Landsat data to characterize **land cover change** (see review by Coppin et al. [2004]). Most approaches involve 2 dates of imagery, or a series of images at intervals generally >3 years. These interval-based datasets were necessitated largely by the relatively high cost of Landsat data per image and data storage and computation limitations. With the availability of free Landsat data in a highly processed format, inexpensive storage space, and improved computing capabilities, several approaches for characterizing cover change with annual (Kennedy et al. 2007, Schroeder et al. 2007) or near annual (Healey et al. 2006, Powell et al. 2008, Vogelmann et al. 2009, Huang et al. 2010) Landsat time series are emerging.

Landsat Detection of Trends in Disturbance and Recovery

To describe this new time series class of Landsat change detection approaches, we provide a description of the LandTrendr algorithm (Kennedy et al. 2010). The LandTrendr algorithm is based on the concept of **trajectory-based change** detection, first presented by Kennedy et al. (2007).

With LandTrendr, the goal is to assemble an annual stack of images that has been geometrically registered, atmospherically corrected, and radiometrically normalized (Fig. 18.6). Then, for each pixel, the spectral response over time for a given band or spectral index (the pixel's temporal trajectory) is examined, and a set of statistical and knowledge-based rules is imposed to fit segments with consistent trends. This analysis results in a single trajectory being segmented into 1 to n segments, depending on the number of distinct breaks in the trajectory identified by the algorithm. For example, in Figure 18.6, the fitted line for the forested pixel identified as having been clearcut between 1985 and 1986 has 2 segments: 1 for the clearcut and the other for the slower process of vegetation recovery after the disturbance. In contrast, the green fitted line is associated with a forested pixel that has 3 distinct segments: 1 stable segment where spectral response was essentially constant between 1985 and 1991, at which time the forest was thinned (trees were cut to make them less crowded), and a third segment associated with the recovery after thinning.

Temporal trends in pixel trajectories can be noisy (Fig. 18.6), due to sun angle, atmospheric effects, and phenologi-

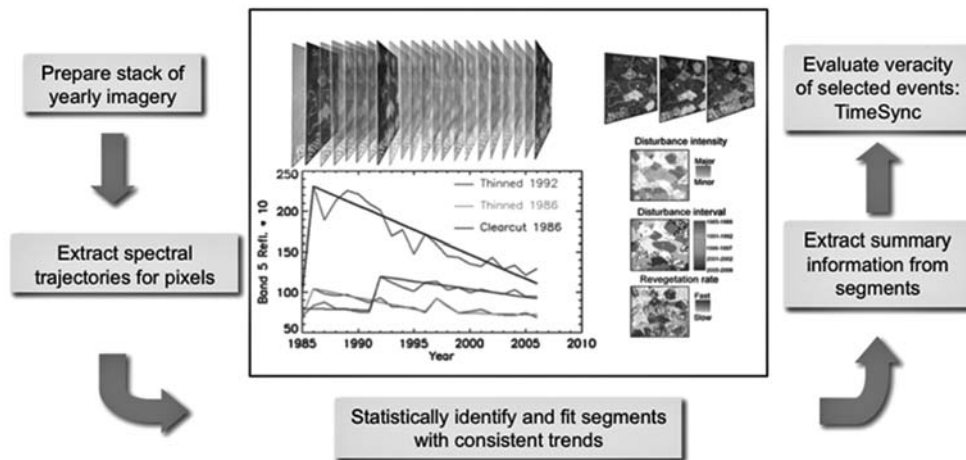

Fig. 18.6. Schematic of how the LandTrendr algorithm works.

cal state differences among images used to create a given stack. For example, the recovery segment for the clearcut pixel response (red fitted line) shows a fine temporal grain instability, whereas the longer-term trend is clearly directional. The statistical fitting rules examine multiple temporal scales of spectral response to best select the break points in the trend (vertices) and thus properly segment the full trajectory.

The map output from LandTrendr is rich and must be summarized for practical utility. The most basic information

is maps of disturbance interval and magnitude, in terms of relative or absolute vegetation loss (Fig. 18.7). The vegetation loss is relative if in terms of degree of spectral change, or it is absolute if the spectral band or index has been statistically related to a biophysical variable, such as percentage cover. Most disturbances are of the event type, whereby a sudden change occurs in a 1-year observation period. However, as is usual for recovery, some disturbances also occur over multiple years. This time frame is common for forest insect damage, for example, and leads to several other possible map summaries,

Fig. 18.7. Sample output maps from LandTrendr for areas disturbed by fire and harvest.

such as disturbance and recovery duration and recovery magnitude. Because different types of disturbance (e.g., insects or harvests) have different characteristic durations and spatial patterns, it should be possible to identify different disturbance agents using the LandTrendr algorithms. This possibility is being explored and improved as the algorithm matures (Kennedy et al. 2010).

With LandTrendr and related algorithms that focus on an annual time step, clouds can be a persistent problem in some locations. Moreover, the Landsat 7 Enhanced Thematic Mapper+ instrument developed a problem in 2003 that has led to “wedges” of missing data in every image collected since that time. With the ready availability of free data, it is now possible to operationally composite images in such a way that pixels covered by clouds (and their shadows) and those that contain no data (Landsat 7 from May 2003 to present) are replaced with suitable image data from another relevant time period. Compositing is an important feature of the LandTrendr algorithm.

Creating a set of rules to derive maps of **land and/or vegetation cover** from Landsat data can be expensive and time consuming. But more often than not, it is highly desirable to know not just that an area changed, but also that it changed from one cover type or quality to another. Thus, the typical approach of developing 2 separate land cover maps (1 for each of 2 dates) and comparing them was developed long ago and persists today. Scene-level radiometric normalization procedures (e.g., Canty and Nielsen 2008) were developed to address this issue by facilitating more meaningful application of the same classification rules to 2 dates of imagery, but scene-level normalization procedures are a relatively crude solution for the problems associated with variable sun angle-viewing geometries, atmospheric conditions, and phenological conditions among image dates, which can be pixel specific.

LandTrendr uniquely addresses this issue by performing a pixel-level normalization based on the trajectory itself (Fig. 18.8). Given that annual time series express the inherent noise of Landsat imagery even after scene-level normalization, but that meaningful changes in spectral direction are confidently detectable (Fig. 18.6), the LandTrendr approach uses the fitted trajectory segments to normalize a pixel's spectral trajectory. In other words, the spectral response for all bands and/or indices, over time for a given segment, are expressed as the fitted values for that segment rather than as the original (or scene-level normalized) values. This format allows for a more meaningful use of classification rules developed for a single year of Landsat imagery to be applied to other years of imagery. Furthermore, because we have an annual time series, those rules can be applied to all images in the series, resulting in an annual time series of land and/or vegetation cover maps that express stable class labels for unchanged areas and new labels for changed areas as the times series progresses (Fig. 18.9).

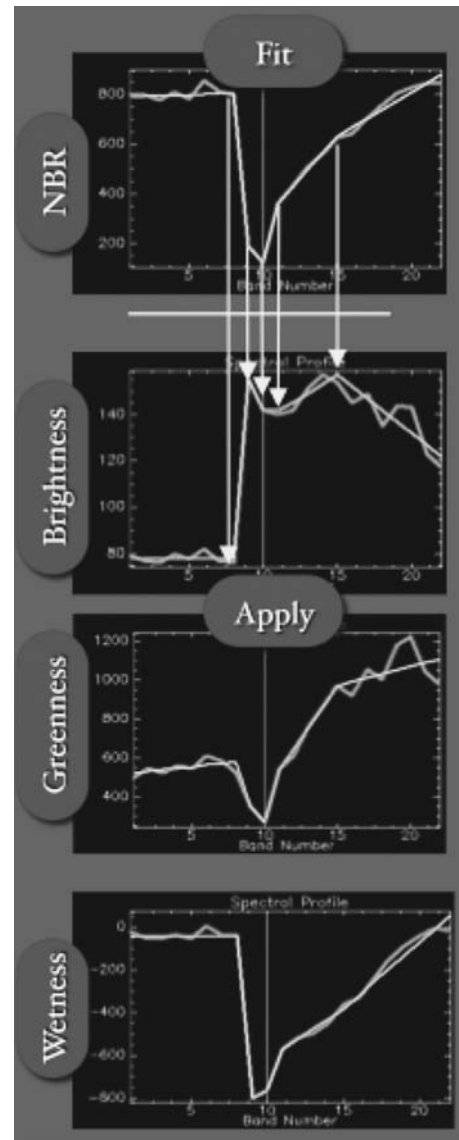

Fig. 18.8. Example of how LandTrendr fits the temporal spectral trend of a given pixel (the magenta line). The fitted line (gray) is based on regression for each segment of a given band or index (in this case the normalized burn ratio [NBR]). The vertices for each segment were derived from the fitting of the NBR, and the same vertices are transferred to the other indices or bands (in this case brightness, greenness, and wetness). Fitting is repeated for each band or index of interest.

Validation of Landsat Time Series Maps

Maps of **forest change** that have an annual time step and are for large areas are **difficult to validate**. As we cannot visit areas today and clearly determine their history, we must rely on extant datasets. Extant datasets are commonly for a single point in time; even for areas visited more than once, it would be the exception rather than the rule they were visited on an annual basis over the period of interest.

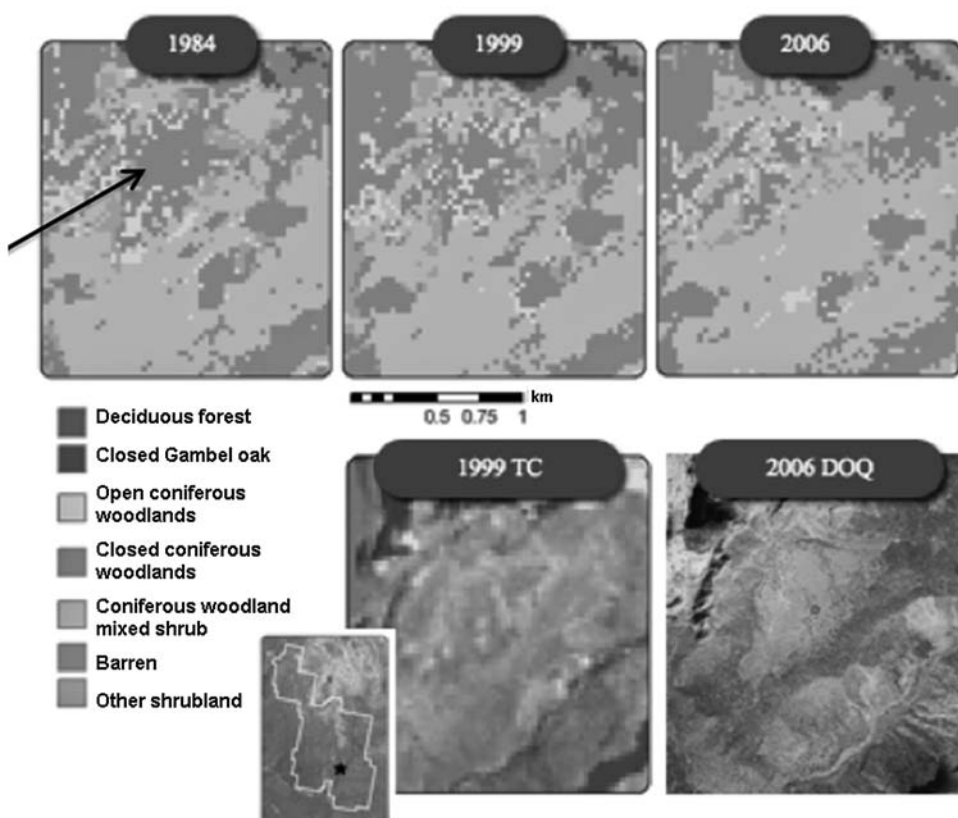

Fig. 18.9. Example of how LandTrendr fitted time series is used with a set of classification rules. Shown are three dates from a time series, where classification rules were applied to fitted imagery. The arrow points to an area that changed from barren to coniferous woodland mixed shrub between 1984 and 2006 in Zion National Park, Utah. Also shown are a 1999 Tasseled Cap transformation (TC) image and a 2006 high-resolution digital orthophoto quadrangle (DOQ) photo. The TC transforms 6 Landsat Thematic Mapper™ data channels to 3 data channels with known characteristics (soil brightness channel, vegetation greenness channel, and moisture content of soil and/or vegetation [wetness] channel).

Moreover, given that maps are spatially explicit at a 30-m resolution, there are large areas where no extant datasets exist. For Landsat change detection in forested areas, this problem was addressed by Cohen et al. (1998). They found that by observing and interpreting the Landsat images, one can unambiguously detect forest stand replacement disturbances visually in relatively dense forests. This was verified by comparing visual Landsat assessment with **air-photo interpretation** and polygon databases from a federal agency. In the era of time series maps developed over large areas, the problem of validation is exacerbated by the temporal richness and spatial extent of the maps. To address this issue, Cohen et al. (2010) developed a Landsat time-series visualization tool, TimeSync. Similarly, Thomas et al. (2011) have developed a different tool for the same general purpose.

TimeSync derives its name from the concept of syncing automated and human interpretations of Landsat time series. TimeSync has 4 main components a: chip window, trajectory window, Microsoft Access database, and a Google Earth interface. For an area of interest (a 3-pixel \times 3-pixel plot), TimeSync displays an image chip series in the chip window and the spectral time trajectory for any Landsat band or vegetation index of interest. For a plot that is spectrally stable, the image chip series will reveal a stable spectral response, and the trajectory in various bands and indices will reveal the normal noise associated with time series, but will

show no meaningful breaks in spectral trend (Fig. 18.10). For changed areas, both the chip and trajectory windows will reveal those changes (Fig. 18.11). As the plots are interpreted, the analyst uses the TimeSync interface to enter data into the database that contains the interpretations made on the series of plots under investigation. Because of the dense time series, as with LandTrendr, TimeSync facilitates interpretations of both high and low intensity disturbances and assessments of recovery trajectories.

Google Earth is used to examine a high-resolution **geo-referenced image** of plot. This image serves to assist the analyst in describing the plot trajectory, as the date of the image displayed in Google Earth is commonly time stamped. Moreover, the newest version of Google Earth has historical imagery for many locations, facilitating a direct interpretation of change independent of the Landsat imagery.

Using TimeSync, one can design a statistically valid sample that covers the full time period of interest at an annual resolution whenever a Landsat time series was developed for analysis by an automated algorithm. Once the data have been collected with TimeSync, they can be summarized and compared to map output (Fig. 18.12). **Ancillary datasets** from forest harvest records, for example, can still play an important role in the map validation process. Using these data, we can assess the level of consistency between the TimeSync interpretations and the information in the extant databases. When the whole approach is integrated, one has

Fig. 18.10. TimeSync visualization, showing a set of image time series chips (upper right) and the spectral trajectory for Landsat band 5 for the 3-pixel \times 3-pixel area (plot) at the center of the chips. This plot was unchanged throughout the time series.

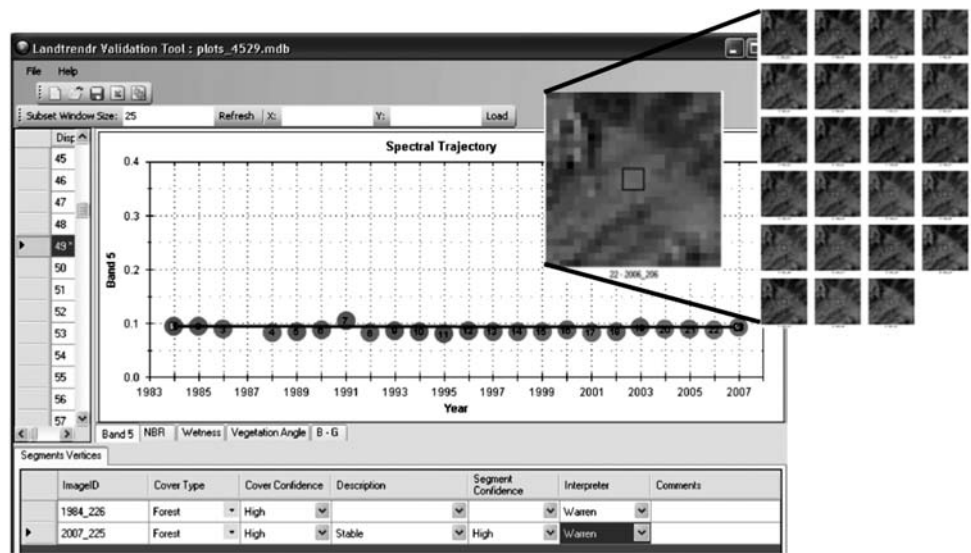

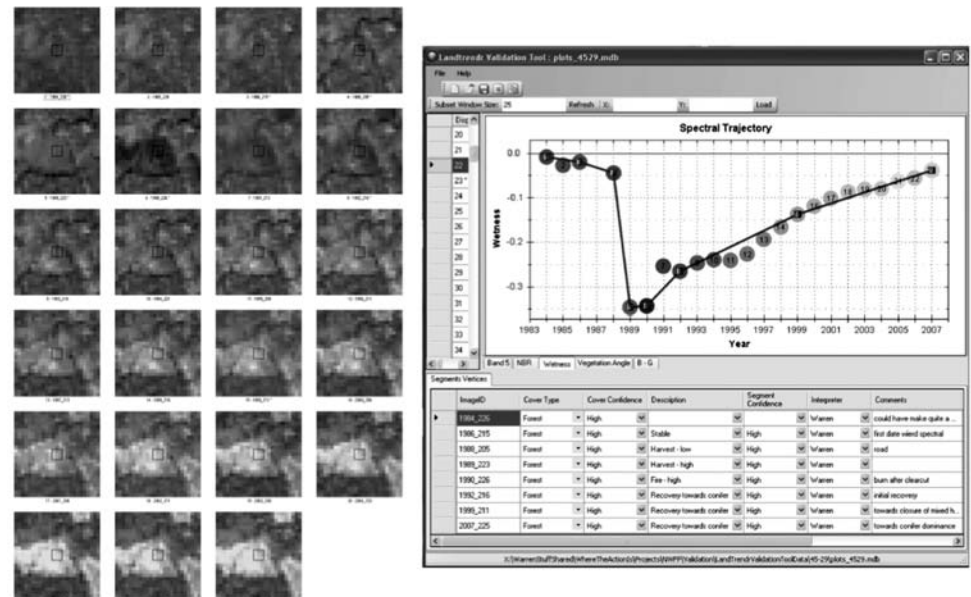

Fig. 18.11. A TimeSync example for a 3-pixel \times 3-pixel plot that was disturbed.

a statistically valid assessment of map quality via TimeSync and an independent assessment of TimeSync observation quality. Although it is tempting to call this process an accuracy assessment, in reality, there are errors in all component observations, interpretations, and databases, and it may be best to consider the result a series of agreement analyses. For a further review of how Landsat imagery works and for data sources see O'Neil et al. (2005).

Lidar—Light Detection and Ranging Characterizing Habitat with Lidar

Lidar (light detection and ranging) is an optical remote-sensing technology and geospatial mapping tool that allows for the fine-grained yet broad-scale collection of high reso-

lution, accurate terrain surface data that can provide valuable information about the 3-dimensional structure of terrestrial and aquatic ecosystems (Lefsky et al. 2002, Vierling et al. 2008). Although **lidar** technology has been around for >2 decades, recent advances in lidar technology over the past 5 years have revolutionized mapping and have the potential to contribute greatly to our understanding of wildlife-habitat associations. Providing better vertical resolution and sampling density than can be achieved by traditional field assessments, lidar is a powerful tool for investigating questions in wildlife ecology at multiple spatial scales using new, previously unmeasurable, habitat features. Particularly in **remote, rugged, and otherwise inaccessible terrain**, lidar has the potential to become a viable, and in many cases su-

Fig. 18.12. Results of a comparison between LandTrendr output and TimeSync observations for approximately 500 plots. Shown are percentage agreement on disturbance for a variety of TimeSync-observed disturbance agents and intensities.

terior, surrogate for assessing wildlife habitat features traditionally measured in the field.

Lidar data and their applications are young, but are rapidly gaining recognition. Although many researchers have quantified habitat features of relevance to wildlife, few studies have actually used lidar data to aid our understanding of wildlife–habitat relationships, and there are many applications that have yet to be explored. Moreover, the technology is ever-changing, and the possible trajectories of advances make it difficult to predict the dominant and useful applications of lidar to wildlife science in the future. It will be well worth monitoring how the field advances to seize opportunities to better inform wildlife and conservation science.

Despite the recent rapid advances in the ability to achieve high-density lidar data, it is highly important to recognize that **not all lidar datasets are equal**. Differences in **acquisition specifications** (e.g., flight altitude and sensor settings) and **ground truthing** methodologies will result in lidar datasets of differing resolutions and accuracies. Moreover, the data products themselves will determine the utility of

the data for different applications. It is essential for any biologist to understand the **strengths and limitations** of a lidar dataset before it is used as a predictor variable from which to draw inferences regarding animal–habitat relationships.

Lidar Technology

There are 3 general classes of lidar instruments that differ in mode and therefore the scale of data acquisition: **ground-based, spaceborne, and airborne lidar**. Ground-based lidar systems can be stationary (mounted on a tripod) or mobile (i.e., vehicle mounted), and collections of dense point clouds from multiple vantage points provide for detailed views of study areas at small spatial scales (meters). Satellite sensors currently in operation include the Geoscience Laser Altimeter System NASA 2009) and the Vegetation Canopy Lidar mission, both administered by NASA. Applications of satellite sensors are typically to answer questions at very large spatial scales, such as deforestation rates on a continental scale (e.g., Potter 1999, DeFries et al. 2006), and coarse measurements of forest structure (Dubayah et al. 1997, Lefsky et al. 2005). Although ground- and satellite-based sensors certainly can be applied to studying very fine or broad scale questions in wildlife biology, airborne sensors have been used to collect the majority of data at spatial scales that biologists are typically most interested in (from the watershed scale down to individual habitat parcels of relevance to wildlife). Among airborne lidar instruments, there are currently 3 primary sensor types with great potential for providing valuable terrain data to inform wildlife biology studies: discrete-return infrared (IR) lidar; full waveform IR lidar; and high-energy, full-waveform green lidar.

Discrete-return IR lidar instruments record the returning laser signal as one or more distinct returns and operate using a laser wavelength of 1,064 nm (the near infrared range of the spectrum) with laser pulses emitted at 10–200 kHz (Haugerud 2009). Discrete returns are simplifications of the continuous waveform into as many as 4 principal peaks corresponding to echos (returns) off of surfaces in the travel path of the laser pulse (Fig. 18.13). Quantity of discrete-return lidar data is measured as pulse density, which typically ranges between 1 and 12 points/m² (0.3–1.0-m spot spacing). Because **infrared light does not penetrate water**,

Fig. 18.13. Ten-meter deep cross-section of multistory canopy, showing laser returns (point cloud) of dense vegetation (right) and planar view of the surface derived from classified ground points (bare earth triangulated irregular networks; left). These data were acquired at a pulse rate of 70 kHz, Yamhill River Basin, Oregon. Lidar data acquired and imagery produced by Watershed Sciences.

discrete-return IR lidar instruments are principally used to map terrain that is above the water surface at the time of the survey. In contrast to discrete-return lidar instruments, **full waveform sensors** capture the entire return profile, providing highly detailed information and allowing biophysical features, such as canopy structure and aboveground biomass, to be estimated with unprecedented accuracy (e.g., Harding et al. 2001, Hyde et al. 2005).

High-energy, full waveform, green lidar instruments are used to provide bathymetric data at shallow (20 m) water depths. As such, their potential relevance to wildlife studies include characterizing habitat for aquatic wildlife (e.g., amphibians and riverine or coastal marine mammals). Green lidar sensors use information from the entire waveform and operate using a laser wavelength of 532 nm with laser pulses emitted at 0.8–4.0 kHz (Haugerud 2009). Typical pulse densities for full waveform green lidar vary from 0.05 to 0.25 points/m² (2–4-m spot spacing), much lower than can be achieved with near IR lidar, yielding data of lower resolution. Green lidar data may be advantageous by providing bathymetric data in shallow streams, where a hydroacoustic survey may not be possible. The prominent available green lidar systems include Compact Hydrographic Airborne Rapid Total Survey (CHARTS; Joint Airborne Lidar Bathymetry Technical Center of Expertise [JALBTCX 2009]; available commercially from Fugro Pelagos), Hawk-Eye (Airborne Hydrography AB 2009), and Experimental Advance Airborne Research Lidar (EAARL; U.S. Geological Survey 2009a). Although not available commercially, the EAARL system's short pulse width (5 kHz) and narrow field of view allows for simultaneous mapping of bare-earth topography and shallow submerged topography, enabling characterization of the littoral zone of coastal and riverine environments. The EAARL system is operated by the U.S. Geological Survey.

Lidar Data

Using rapid pulses of light photons, lidar systems detect and determine the **distance (range) of terrain features** to provide the location of objects in (x, y, z) space. When an emitted laser pulse hits a target surface, portions (most for full waveform) of that laser energy will be returned to the sensor. Given the speed of light, aircraft position and attitude, and time elapsed between laser pulse emission and reception of these returns, the spatial coordinates (latitude, longitude, and particularly, elevation) of reflected laser pulses can be calculated. Reflections off tall or high objects have faster return times than those off the ground surface. The pattern of this information allows discrimination of such features as trees or buildings from the ground surface. Current sensors can resolve laser information fired and returned at rates of up to 200,000 pulses of light per second and as many as 4 returns per pulse. Depending on the flight parameters, the lidar sensor is capable of essentially “painting” the study area

features using a multitude of laser pulses that are returned to the sensor.

A lidar system includes a scanning pulse laser scanner and receiver, a GPS device, and an inertial measurement unit (IMU). Throughout the survey, the collection of **real-time GPS** and IMU data enables calculating the (x, y, z) position and exact orientation and attitude (roll, pitch, and yaw) of the lidar sensor with a precise time reference. Combining this information with the time reference encoded for each laser pulse return yields the absolute position of each laser pulse return. Finally, concurrent operation of ground base stations strategically placed to provide geodetic survey support for the mission enables adjustment and correction of the laser positions to result in a dataset of high absolute accuracy.

The spatial data provided by current lidar technology enables the generation of **3-dimensional models** of the surface of **Earth and land cover** that are of amazingly high resolution (Fig. 18.14). Lidar data are far superior to the traditional topographic maps researchers have worked with in the past: current datasets are correct to within a few centimeters of their true absolute elevation in space and to within a few meters horizontally. In addition, compared to traditional survey techniques, lidar has revolutionized the speed with which surface terrain data can be collected over large survey areas, making it relatively inexpensive to collect per unit area.

Raw lidar data are collected as a cloud of (x, y, z) points. The **points** are associated with a myriad of features, including not only the ground, but also manmade structures (buildings, bridges, powerlines, vehicles, etc.) and vegetation. To extract a topographic surface, the data needs to be processed to generate clean **surface models**. Processing includes automated and manual techniques for modeling ground-level and aboveground points and filtering points erroneously classified as ground. A triangular mesh of the points is

Fig. 18.14. Detail of bare earth (top) and highest hit (bottom) lidar-derived digital elevation models (1-m resolution) in the Siskiyou National Forest, Oregon. Lidar data acquired and imagery produced by Watershed Sciences.

then output as a grid, or **digital elevation model (DEM)** at resolutions as high as 0.5 m, depending on resulting ground point density and terrain. Hill shading and coloring can be applied to display final maps. The DEM can be generated from only the ground-classified points (bare earth model), or from the first returns (highest hit model). From the data cloud, specialized remote sensing software packages, such as FUSION (McGaughey 2009), are helpful in further characterizing vegetation and generating canopy surface models.

Applications to Wildlife Biology

Two general classes of lidar data products have been useful and provide great promise for studies in wildlife ecology. These include the point cloud of data points, elucidating vegetation structure, and the digital elevation models generated from the ground-classified points, providing **detailed information on surface topography**. Naturally, these 2 classes relate to applications in wildlife ecology in 2 general ways: (1) use of point cloud data and lidar-derived canopy surface models in studies of terrestrial vegetation, primarily forests (Figs. 18.15, 18.16), and (2) use of digital terrain models in studies related to geomorphology and topography, in both terrestrial and aquatic environments (Fig. 18.17).

VEGETATION STRUCTURE

For a great majority of terrestrial wildlife (e.g., birds and mammals), the structure of vegetation (placement, quantity, shape, type, and connectivity) is of great interest for understanding species–habitat associations (Hansen and Rotella 2000; Fig. 18.2). For these studies, of the data provided by lidar instruments, it is the point returns from the vegetation that are of primary interest. Using lidar, **canopy structure** can most simply be measured and defined by canopy height and cover (Lefsky et al. 2002). High agreement between lidar-derived data and field measurements for canopy height, cover, and biomass have been observed in temperate, boreal, and tropical forests as well as desert scrub (e.g., Ritchie et al. 1995; Nelson et al. 1997; Magnussen et al. 1999; Hyde et al. 2005, 2006; Clawges et al. 2007). In addition, compared to other active sensors (e.g., radar) and passive optical sensors (e.g., Landsat and Quickbird 4-band imagery), lidar has

been found to be the best single sensor for estimating canopy height and biomass (e.g., Hyde et al. 2006). Additional descriptors of canopy structure, such as the height distribution of outer canopy surfaces quantifying light gaps, also have been made with lidar (Lefsky et al. 1999). The 3-dimensional vertical distribution of all material in the canopy, or foliage-height profiles, can be measured with full waveform IR lidar (Harding et al. 2001). Finally, combining lidar data with ancillary data can provide measurements for a variety of wildlife-relevant vegetation patch characteristics, including stand density, age, and volume; number of snags and downed trees; number of large trees; basal area; understory height and density; ground surface texture; and landscape metrics, such as patch/edge characteristics and the landscape matrix (Dubayah and Drake 2000, Lefsky et al. 2002, Turner et al. 2003, Corona and Fattorini 2008; Fig. 18.16). The Precision Forestry Cooperative of the University of Washington is an active group researching the many forestry applications of remote sensing, including lidar (Precision Forestry Cooperative 2009).

Lidar data has been used as an analytical tool to **predict species distributions** based on prior knowledge of species' habitat preferences. For example, Nelson et al. (2005) used lidar to identify potential habitat for the Delmarva fox squirrel (*Sciurus niger cinereus*; known to prefer tall, dense forests with an open understory) across extensive areas in Delaware to guide survey efforts for this endangered species. In addition, lidar data can be used as an exploratory tool to determine **habitat selection patterns**. Broughton et al. (2006) used lidar data to determine habitat preferences of marsh tits (*Poecile palustris*) by comparing lidar-derived vegetation structure in territories to that in surrounding locations that were not occupied by the species. As determined from the lidar data, birds occupied sites containing mature trees with a subcanopy shrub layer, and they avoided sites containing many small young trees. The relationship between lidar-derived woodland canopy height and structure and songbird (great tit [*Parus major*] and blue tit [*Cyanistes caeruleus*]) breeding success in local territories was investigated to develop a map depicting habitat quality for these species across an entire woodland study forest in England (Hinsley et al.

Fig. 18.15. Example of lidar-derived highest-hit digital elevation model of forest habitat (left) with a 5-m cross-section of the lidar point cloud (right). From this data, forest structure can be quantified, and patch characteristics can be inventoried and stratified using data from the multiple laser returns that paint the canopy vegetation. Lidar data and imagery acquired by Watershed Sciences.

Fig. 18.16. Examples of stem density measurements and forest stand delineations developed from lidar-derived vegetation heights. These can be used as valuable habitat attributes describing components of forest landscape structure of relevance to the habitat associations of wildlife. (A) The tops of individual trees (stems) >2 m in height (local maxima) are identified, enabling the generation of a 30-m resolution stem density grid. (B) In this example, with ancillary Ikonos-2 color infrared data, delineations are based on a number of lidar-derived data outputs, including elevation, terrain aspect, slope, stem number and density, canopy density, vegetation height, and percentage distributions of conifer, deciduous, and nonoverstory vegetation.

Lidar data and imagery acquired by Watershed Sciences.

2002, Hill et al. 2004). In addition to forested ecosystems, lidar-derived characteristics of vegetation structure have been made to examine wildlife–habitat relationships in low-lying shrubland (Streutker and Glenn 2006), farmed landscapes (e.g., sky lark [*Alauda arvensis*] and other grassland species in English's cropland; Davenport et al. 2000, Mason et al. 2003, Bradbury et al. 2005), and dune vegetation (feral horses on Assateague Island National Seashore, MD; Stoppelaire et al. 2004).

Lidar data also has been used to evaluate wildlife community structure. For example, relationships between lidar-derived measures of vegetation structural diversity and bird species diversity have been found in both deciduous forests

in Maryland (including forested wetlands; Goetz et al. 2007) and mixed conifer/aspen forests in South Dakota (Clawges et al. 2008). In particular, Goetz et al. (2007) found that vertical distribution of canopy elements as characterized by lidar was the strongest predictor of species richness; Clawges et al. (2008) found that lidar-derived foliage-height diversity indices were positively correlated with indices of bird species diversity, particularly near the forest floor (5 m from ground). Boelman et al. (2007) used lidar data to determine how an invasive plant species has affected avian species abundance and community composition across a range of Hawaiian submontane forests, finding that total avian abundance and the ratio of native to exotic avifauna were highest in stands with the highest canopy height and cover, but that among biophysically equivalent sites, stands dominated by

Fig. 18.17. Example of topographic parameters that can be derived from high resolution lidar data and applied to questions of interest to wildlife ecologists. In this example, terrain elevation, slope, and curvature (top) are used to delineate the detailed routing of streams and roads (bottom) for use in hydrologic flow modeling. *Lidar data and imagery acquired by Watershed Sciences.*

native tree species hosted larger native avian communities than did mixed stands of firetree (*Morella faya*), an invasive evergreen shrub.

TOPOGRAPHY

For characterizing topography, in certain situations, lidar provides a number of advantages over traditional photogrammetric mapping and field methods (e.g., to detect the ground under dense forests where the ground is not visible, and where the time and labor costs would preclude an equivalent volume of data collection). Given that **terrestrial and bathymetric topography** can affect components of landscape structure and ecological processes (e.g., erosion and hydrologic flow; e.g., Fig. 18.17) that impact wildlife, lidar-derived bare earth models (DEMs) also have been used in wildlife studies and hold great promise for further application development. For example, lidar ground models have been used to characterize wetland topography (Irish and Lillycrop 1999); the surface dynamics of beaches and dunes (Krabill et al. 2000); underlying forest topography (Harding and Berghoff 2000); and the structure and elevation of abandoned, paleo, and overflow stream channels (Jones 2006); they also have been used to map river corridors and riparian habitats (see Hilldale et al. 2009, McKean et al. 2009). All these features of terrestrial and aquatic wildlife habitats may be significant determinants of habitat selection, population distributions, and responses to restoration efforts for some species. There are few studies, however, that have directly related a detailed understanding of topography to questions of interest to wildlife biologists. Among these are an effort to understand the impacts of grazing by feral horses on vegetation and dune topography on an island national refuge in Maryland (Stoppelaire et al. 2004) and the use of elevation, among other lidar-derived metrics, as a predictor of bird species richness in temperate forests of Maryland (Goetz et al. 2007).

A number of studies have demonstrated the usefulness and applications of using accurate DEMs. Although many of these researchers used 10–30-m resolution DEMs, it is not difficult to see how their applications would be strengthened by ground surface models of a higher resolution, such as the 1-m DEMs derived from current lidar technology. For example, Jenness (2004) demonstrated a calculation of landscape surface area and topographic roughness relevant to characterizing wildlife habitat using digital elevation data. Goetz (2002) looked at how to use topographic information from DEMs to better resolve different riparian zones of critical importance to fish and wildlife in Idaho and Wyoming. Brandes and Ombalski (2004) modeled **raptor migration pathways** based on knowledge of terrain updrafts calculated using wind direction, terrain slope, and terrain aspect data determined from DEMs in a simulation experiment. The usefulness of DEMs in terrain representation models

for ungulates residing in mountainous environments has been repeatedly demonstrated: Wairimu (1997) evaluated the effectiveness of DEMs in locating and mapping wintering areas of white-tailed deer (*Odocoileus virginianus*), Divine et al. (2000) assessed the use of DEMs of varying resolutions to categorize desert bighorn sheep habitat in Mojave Desert mountain ranges, Locke et al. (2005) appraised escape terrain (slopes >60%) using DEMs for desert bighorn sheep to assess the probability of translocation success on public land in Texas, and Wallin and Wells (2006) used DEMs to evaluate predictors of seasonal variation in habitat selection for mountain goat (*Oreamnos americanus*) in the Washington Cascades.

Future Opportunities and Applications

The accuracy and spatial scale of lidar data have already brought it to the forefront of recognition in terms of its utility for certain applications in remote sensing. However, lidar data have only recently become a research tool for wildlife biologists, and we have far to go in terms of tapping into that tool's full research potential (Vierling et al. 2008). The one class of sensors that may truly elevate the utility of lidar, particularly for forest wildlife studies in the future, is full waveform IR. Lefsky et al. (2002) include further information on applications and utility of waveform lidar.

Research applications of lidar are most notably missing in terms of geographic scope, habitat types, and the species groups for which its use has been explored (the majority of studies have only thus far used lidar to characterize habitat and evaluate wildlife–habitat associations in forested systems, primarily for birds and to a lesser degree for mammals, and principally in the United States and England). Some studies have ventured into **evaluating the accuracy and source of errors** in characterizing wetland habitats using lidar (e.g., Hopkinson et al. 2005), and some researchers have evaluated the use of various lidar sensors to map stream channel characteristics for fisheries research (see Bayer and Schei 2009). But the use of lidar to examine the influence of features of aquatic habitats (e.g., rivers and wetlands) that are of relevance to wildlife species distributions, habitat use, movements, survival, and restoration response has yet to be developed. Moreover, applications of ground-based lidar to examine wildlife–habitat associations for **small organisms** (e.g., amphibians and insects) with finer spatial scale habitat requirements is another greatly **untapped area** for lidar applications in wildlife studies, although it has gained recent popularity for urban and corridor mapping.

With future advances in lidar technology and applications, lidar may make its greatest contribution yet to the field of landscape ecology. Many researchers recognize the need to study species–habitat relationships at multiple spatial scales relevant to individuals, populations, and metapopulations to effectively address the pressing global conserva-

tion issues of today. For a number of questions of interest to wildlife scientists, lidar data have the potential to revolutionize the scale and dimension of questions posed by landscape ecologists, as well as to refine the resolution and accuracy of detected patterns. In addition, advances made by the use of lidar, particularly when combined with other remote sensing data, are likely to impact large-scale conservation programs and have far-reaching policy and management implications. A prime example includes the Gap Analysis Program led by the U.S. Geological Survey (Scott et al. 1993), in which lidar data are being incorporated into GIS databases to map on a national scale the key habitat classes of importance to native species distributions, areas of high biodiversity, and areas of priority for conservation (Vierling et al. 2008).

Data Availability

At present, discrete-return IR lidar surveys **costs can range widely** (approx. US\$1.25–2.50/ha for areas >45,000 ha), depending on data quality, specifications, and size and shape of study area; ground-based lidar data are considerably more costly per unit area than IR lidar data (but is usually purchased only for small areas), and commercially available bathymetric data (e.g., CHARTS) are an order of magnitude more expensive. Although costs for lidar data can be high relative to other remote sensing data, the multi-utility nature of the data has encouraged collaborative partnerships for data sharing and acquisition. For instance, a growing number of states (Iowa, Louisiana, Ohio, Pennsylvania, North Carolina, Texas, and Florida) may soon have discrete-return IR lidar coverage, and others (Oregon and Washington) have formed consortiums of agencies devoted to collecting public lidar data at reduced cost for large, regularly shaped areas of interest (e.g., DOGAMI 2009, PSLC 2009). A visit to the Center for Lidar Information Coordination and Knowledge (CLICK) website (U.S. Geological Survey 2009b) will provide more information on collaborative cost sharing programs for large-scale public acquisition of lidar data.

Accuracy Assessment of Remotely Sensed Data

A variety of devices and techniques, such as **Landsat Imagery** and **Forward Looking Infrared** systems, can be used to record characteristics of Earth's surface from remote positions. However, interpretation of remotely sensed data can introduce error (Janssen and van der Wel 1994). Error in mapping can be generated in several ways: error in thematic classification, both by **omission** and by misclassification (**commission**; Story and Congalton 1986) and error in **cartographic delineation** (location error).

Accuracy assessment of landscape maps generated from remotely sensed data is generally accomplished through field verification of a select subset (samples) of thematic or areal map units. The investigator must identify accuracy as-

essment objectives as well as the level of error acceptable for accuracy estimates (based on planned uses of the map). To keep the sampling design simple, easy to analyze, and statistically robust, it is important to define the sampling unit and to use a basic probability sampling design (inclusion probabilities are equal and nonzero for all members of the population). Design-based statistical inference can be applied when sampling is of characteristics of a real, explicitly defined population (Stehman 2000). Probability sampling designs can be interpreted as accuracy estimates for the entire population via established statistical estimators that vary according to the particular sampling design (Stehman 1999). Limitations of resources for field verification or site access can constrain a sampling design. Sampling designs that meet the requirements of equal probability sampling are simple random sampling, systematic sampling, stratified systematic unaligned sampling, and one-stage cluster sampling (Stehman and Czaplewski 1998, Stehman 1999).

Investigators initially developed the confusion or error matrix, which permitted calculation of simple test sample ratios (the number of land use classes incorrectly depicted on the map divided by the number of correctly depicted land use classes confirmed by field verification; van Genderen et al. 1978, Fitzpatrick-Lins 1981). Since those efforts, a great variety of error matrix interpretations and new error metrics have been presented in the literature. The most important contributions of recent work for accuracy findings have been the increase in statistical rigor and decrease in confidence intervals (Richards 1996, Stehman 2001).

Variation in size and frequency of thematic cover types necessitates adjustments in sampling intensity that reflect their relative importance. Thus, a cover type with limited occurrence can be sampled with greater frequency, whereas those most common and abundant will be sampled according to statistical parameters. Stehman (2001) reported that sample size required to achieve a standard error of 0.05 for a population estimate reaches a maximum sample size of 100, when population size is $\geq 10,000$ (for populations 10,000, the sample size required to achieve $SE = 0.05$ is a function of $n = N/[0.01N + 1]$, where n is sample size, N is population size, and SE is standard error).

The **error matrix** is composed of orthogonal axis with cover types (Table 18.1) and allows analysis of accuracy and error rate for each cover type. Cover type accuracy is measured by dividing the number of correctly classified sample points for each cover type by total points sampled. **Map accuracy** also can be presented as **user's** (diagonal values divided by row totals for each matrix) and **producer's** (diagonal values divided by column totals for each matrix) values for each cover type, which are the converse of commission and omission error, respectively.

The assessment of map accuracy by field verification could benefit from methods that increase the accuracy of sample

Table 18.1. Error matrix for cover type

Cover class	Cover class					Total
	A	B	C	D	E	
A	2	0	1	0	0	3
B	7	10	3	0	2	22
C	1	0	6	1	0	8
D	0	0	0	9	0	9
E	0	0	0	0	8	8
Totals	10	10	10	10	10	Diagonal total: 35

point capture (Woodcock 1996). This improvement could be accomplished by tagging the sample points with location information (UTM coordinates, or latitude and longitude), which could be targets for the field verification. GPS units could help in quantifying variability encountered in accessing sample points. Further, proximity to each sample point could be quantified and used in the assessment of map accuracy.

The overall objective of performing an accuracy assessment of a map is to provide a quantified measure of how well the map represents reality. If proper procedures are followed in the design, performance, and analysis of sampling, the accuracy assessment results can be used as an integral part of the map.

DATA DOCUMENTATION

Data documentation represents a critical component in the creation of a spatial dataset for wildlife biology and helps complete the dataset. In an age of increased technological abilities and information sharing, a dataset created for a particular effort may be used in many other ways not perceived at the time of development. Thus, detailed documentation enables data users to better understand why the dataset was developed, the process steps taken, when the data was collected, what was collected, and where geographically the collection took place. In addition to assisting a wide variety of data users, a **metadata record** also provides useful information for the data creator, because it includes a detailed **account of how the dataset was developed** before the passage of time interferes with memory. Another use for metadata involves providing information to help the natural resources community avoid data duplication and thus decreasing the cost of data collection. Furthermore, the creation of metadata serves as an institutional memory for an organization (a history of datasets at a given institution). Metadata transcend people and time, allowing a new data manager to continue work with a dataset his/her predecessor may have left behind. Metadata creation retains valuable

information about data for internal organizational or external client use and provides a key component in sustaining a biological GIS program in the long term. Finally, delivering metadata records through **clearinghouses** allows users to discover and find data, determine their applicability, and possibly form new research collaborations.

History of Metadata

The metadata concept was formalized at the federal level in 1994 with release of Executive Order 12906 and the Office of Management and Budget's Circular A16 as part of a government-wide effort to reduce duplication of effort when collecting information and to provide a way for federal agencies and taxpayers to access data created with federal funding (Federal Register 1994). The Office of Management and Budget (2002) released a revised circular A16 to reflect technology changes, but kept the core component of establishing a coordinated approach to electronically develop the National Spatial Data Infrastructure (NSDI). As part of the NSDI, release of the Content Standard for Digital Geospatial Metadata (CSDGM) provided a **common set of terms and definitions** needed to document data. All types of **spatial and nonspatial data** can be documented using this standard. Additionally, several profiles of the standard provide users with additional elements for biological, shoreline, or remote sensing data. In 1998, the **Federal Geographic Data Committee (FGDC)** approved the Biological Data Profile, an effort led by the National Biological Information Infrastructure. Additional elements include taxonomy, methodology, and analytical tools allowing data managers for wildlife biology to provide more accurate documentation of their data. The Executive Order states that any dataset created with federal funding needs documentation using the CSDGM. Many state and local governments and other organizations that receive federal dollars have adopted the standard. Other standards exist, but many GIS professionals either use or work on data created with federal funds and need a working knowledge of it for their jobs. Crosswalks exist to share metadata among the major standards for non-federal organizations that choose to use other standards for documentation.

The **International Organization for Standardization (ISO)** has released an international geospatial metadata standard as part of an effort by a network of national standards institutes from 145 countries working in partnership with international organizations, governments, industry, business, and consumer representatives (Technical Committee ISO/TC 211 2003.). The CSDGM along with the several other major standards provided many content contributions to the development of ISO 19115. In December 2003, the American National Standards Institute (ANSI) adopted the international standard, ISO 19115, and the ANSI International Committee for Information Technology Standards—

L1 signed an agreement with Canadian General Standards Board Committee on Geomatics to co-develop the **North American Profile**, a regional profile of ISO 19115 Geographic Information—Metadata. Inquiries were made into Mexico's participation early in the profile development process; however, Mexico decided to pursue another option for developing its national profile. In developing the North American Profile, the United States and Canada join many other nations in furthering the Global Spatial Data Infrastructure that extends capabilities for documenting geospatial data to a global scale (Box 18.9). Compared to the CSDGM, the ISO NAP structure uses a Unified Modeling Language or object-oriented structure and supplies a few new elements, such as the addition of language and character sets. The **National Biological Information Infrastructure (NBII)** leads the effort to build a set of biological elements that will extend the ISO NAP standard, so that data managers can enter information pertinent to wildlife biology, such as taxonomy, methodology, and analytical tools. Similar efforts are on-going for topics of concern for other interest groups, such as shoreline information and remote sensing.

Précis of Content Standard for Geospatial Metadata

As the **FGDC** CSDGM standard transitions to ISO NAP, metadata creators and users should be aware of both standards. Many extensive systems of metadata repositories and tools for metadata creation in existence use the CSDGM, and it will take time for the implementation of ISO NAP.

The CSDGM metadata standard is organized into **10 sections** (7 main sections and 3 supporting sections) that

provide elements to **answer a series of questions** (Federal Geographic Data Committee 1998, 1999, 2000).

- Who collected and who distributes the data?
- What is the subject, processing, and projection of the data?
- When were the data collected?
- Why were the data collected? (What is the purpose?)
- How were the data collected? How should they be used?
- How much do the data cost?

Although the standard includes many elements, not all require data entry. Those that do are labeled mandatory, and metadata creators may make selections from a series of other elements that directly apply to their data (labeled as mandatory if applicable and optional). Definitions provide clear descriptions about the type of information to include in each field about the dataset.

Standardization of the NAP Content

Aside from the Unified Modeling Language structure of the ISO standard, the NAP is organized into sections, classes, elements/attributes, domains, and code lists (Box 18.10). The ISO NAP includes 16 sections. Classes are a secondary component of the organization of the ISO NAP; they can occur at multiple levels and can contain both subclasses and attributes. Attributes are an important part of the ISO NAP structure, as this is where information is entered by the metadata creator. Attributes can be found in sections, classes, or subclasses (Federal Geographic Data Committee 2009). High-level sections of the ISO NAP include:

- Identification Information,
- Constraint Information,
- Data Quality Information,
- Maintenance Information,
- Spatial Representation,
- Reference System Information,
- Content Information,
- Portrayal Catalog Information,
- Distribution Information,
- Application Schema Information,
- Extent Information,
- Citation Information,
- Date Information,
- Responsible Party Information, and
- Contact Information.

The ISO NAP includes an expanded list of attribute types, such as Boolean (true/false), date, distance, free text, generic name, integer, and URL. Additionally, NAP employs codesets that represent fixed domains. This new and beneficial addition to the metadata standard allows the development of standardized descriptors to enhance search capabil-

BOX 18.10. HIERARCHY OF THE INTERNATIONAL ORGANIZATION FOR STANDARDIZATION'S NORTH AMERICAN PROFILE

Identification Information (Section)

Content Information Online Resource (Class Name)

(Attributes): Data filled in here

+ linkage	+ name
+ protocol	+ description
+ application profile	+ function

ities. The NAP also introduces a structured hierarchy for the documentation of related levels of data, including dataset series, datasets, features, and data attributes. These categories allow metadata authors to detail metadata content to a certain level (Federal Geographic Data Committee 2009).

New elements contained in the ISO NAP incorporate needs of the international community. Added fields include Dataset Language, Dataset Character Set, Metadata Language, and Metadata Character Set. Other sections of the CSDGM have been expanded in the NAP, such as Data Quality. The ISO NAP adds an area to document geospatial data services, which include such resources as web-mapping, data models, online data catalogs, online data processing, ontologies, thesauri, data hierarchies, and classification systems. Elements related to documenting web services include service type (e.g., OCG Catalog), coupled data resources, and operations the service can perform (Federal Geographic Data Committee 2009).

The NAP deals with keywords in a slightly different way from the CSDGM. At a very high level, the NAP supports Topic Categories as a required element. In addition, an Online Linkage Function Code is built into the NAP to capture the type of link the metadata creator is providing. The NAP also includes a Portrayal Catalog section, in which a metadata creator can provide a citation to standardized (e.g., Anderson Land Use Cover Land Cover Mapping) or internally developed symbologies. An Application Schema provides a method for describing the use of standardized software applications that includes attributes to describe a schema, constraints of the application, software dependencies, and others (Federal Geographic Data Committee 2009).

Software Tools

Software tools provide a way to **create a metadata record** and, in many cases, tools can automatically enter values into elements as users create their data. When selecting a tool, note the pros and cons for your environment. As with any software tool, there are trade-offs. The FGDC provides a review of tools available for creating metadata at its website

(<http://www.fgdc.gov>). The NBII also hosts information about tools that contain the Biological Data Profile option at its website (<http://www.nbii.gov>). The FGDC website also reviews tools available for creating ISO NAP metadata at its website(<http://www.fgdc.gov/metadata/iso-metadata-editor-review>).

Distributing and Accessing Metadata

A completed metadata record should be posted on the **Federal Geographic Data Committee clearinghouse** website (<http://geodata.gov>) and on the NBII Clearinghouse website (<http://mercury.ornl.gov/nbii>). These clearinghouses provide a single point of entry for discovery of thousands of metadata records. Organizations that want to establish a node in the clearinghouses are provided directions on the websites. Additionally, individual records can be uploaded to the clearinghouse after completing a quality control process. In general, clearinghouses utilize a harvesting method to obtain records. The clearinghouse benefits, because it avoids a hassle with ports of entry, such as Z39.50, being mysteriously unavailable. The organization providing records benefits, because it maintains control of its original metadata records at all times and can easily serve records to multiple clearinghouses to distribute its information more broadly. Clearinghouses provide an opportunity for powerful collaborations to develop, as scientists and other users can discover many types of data.

The websites (<http://www.fgdc.gov> and <http://www.nbii.gov>) offer a wide range of tools, training, and information about creating and serving metadata and provide links to a variety of agencies and organizations that specialize in metadata. Visit geodata.gov (<http://gos2.geodata.gov/wps/portal/gos>) or the NBII Clearinghouse (<http://mercury.ornl.gov/nbii>) to search for metadata records on a wide variety of topics in geospatial activities or wildlife biology.

SUMMARY

All projects, whether habitat or animal related, occur spatially in wildlife biology and management. Thus, spatial technologies can be used to evaluate research and management efforts. This chapter provides a brief look into using 3 spatial technologies: GIS, GPS, and remotely sensed data (Landsat Imagery and lidar). It also highlights the need to understand data documentation, data accuracy, and Internet applications. Spatial technologies should be considered as tools to assist resource managers with mapping and as a way to merge or incorporate datasets from a variety of sources into one format. Maps can focus discussion by presenting what is known or thought to be known about an area or issue. Additionally, most people readily accept maps, because they are easier to understand at first glance than some tables or figures, and because many people use them to navigate across town or across a country. High resolution

data are increasingly becoming more widely available and hold high potential for contributing to questions in wildlife biology, conservation, and management. We have discussed several studies relating habitat use and distributions to vegetative and topographic features derived directly from these data. As the tools and methods for extracting information relevant to wildlife and inherent in these datasets continue to evolve, it is likely that we will see further development on the full potential of GIS, GPS, Landsat imagery, and lidar applications. Spatial technologies rely on computer technologies and currently are expensive to develop and maintain. However, their value outweighs their costs when information is incorporated into products that help managers make wise decisions about natural resources.

Animal Behavior

INTRODUCTION

SINCE THE DAWN of time, the study of animal behavior or **ethology** has been a key component of human ability to utilize and manage other species. The earliest hunter-gatherers had a keen insight into the subtle behavioral traits that both determined the differences in animal groups (now called species) as well as the traits of individuals that were to be their target or prey. Today, members of hunter-gatherer societies, such as the San Bushmen of southern Africa, can tell entire stories from the placement of an animal's single track in the sand. The most skilled hunter or conservationist can likely describe with incredible detail the behaviors of the individual being tracked. A founder of the field of wildlife biology, Aldo Leopold (1949), used animal behavior to illustrate the need for new management paradigms in *A Sand County Almanac*. A species' relationship to its environment and its subsequent management or conservation cannot be interpreted without understanding factors influencing its **social behavior**. Currently, wildlife biologists and managers struggle with understanding animal movements, site fidelity, and social transmission of information in an increasingly fragmented environment. Given the importance of comprehending animal behavior, it is remarkable how few studies combine the fields of wildlife management and animal behavior.

Perhaps one of the most compelling stories for why wildlife managers need to better understand animal behavior comes from comparing studies of red deer (*Cervus elaphus*) movements in Europe to Florida Key deer (*Odocoileus virginianus clavium*) movements in the United States. More than 20 years ago, the Berlin Wall, a fortified barrier of electric fences and barbwire separating Czechoslovakia, East Germany, and West Germany was removed after separating the nations for more than 25 years. The area that was once patrolled by men with machine guns is now one of Europe's largest natural preserves housing red deer. Game managers and biologists began to suspect in the 1990s that something odd was going on with the red deer. After 7 years of tracking deer during the 2000s, biologists on both sides of the border found that deer, all of which have been born since the wall came down, stopped at the border and turned back, creating 2 distinct populations separated by a few hundred meters of contiguous habitat. This amazing **group phenomenon** may be the result of red deer use of traditional trails being a learned trait. Although an occasional male may venture across the invisible line, he always returns to his natal side, and females have not been known to cross, likely a result of females staying with mothers even longer than males do and learning their mother's movement patterns.

Comparing the red deer to Florida Key deer provides an even more intriguing management quandary, as the Florida Key deer not only move across significant barriers, such as fenced highways, they quickly become **adapted** to wildlife underpass tunnels (Braden et al. 2008), and other species easily adapt to wildlife overpasses, which can provide connectivity and prevent genetic isolation in areas with roads (Corlatti et al. 2009).

Despite the importance of understanding animal behavior, its study has not been widely used in the field of conservation or management because of differences in training and study emphases. Sutherland (1998b), in a 1996 survey of the journal *Animal Behaviour*, reported that of 229 papers, none directly related to conservation or management. Martin (1998) reviewed 8 behavioral texts and found that only one had a chapter on the application of behavior studies to management and conservation, while Arcese et al. (1997) found only 2 of 17 animal behavior, ethology, or behavioral biology texts had such chapters. These authors and others have proposed hypotheses about reasons wildlife biology and animal behavior have not become more integrated. One of the major issues may be the unit of study used. **Animal behavioral biologists** tend to focus on an individual's physical or behavioral differences as they apply to survival and reproductive success. **Wildlife biologists** are generally more concerned with study of populations; consequently, as individuals become summarized as numbers in demographic or habitat use models, the importance of behavior of individual animals is often lost (Caro 1998, Martin 1998).

Traditional boundaries between different academic departments reinforce disconnection of animal behavior from management studies (Martin 1998). In the United States and Canada, practitioners in their respective fields are generally in different academic departments in colleges and universities. Although it is fairly common for a behavioral ecologist in a higher education program to include coursework in community and population ecology, wildlife biology programs rarely (5% in the United States; J. R. Young, unpublished data), include a required course in animal behavior or behavioral ecology. Many wildlife biologists continue to believe that most studies in animal behavior have little direct impact on species management. In contrast, conservation biologists are increasingly recognizing the importance of the field of animal behavior to wildlife conservation (Buchholz 2007).

There are notable examples in which wildlife studies and conservation biology studies have thoughtfully integrated behavior into management. Proceedings from wildlife management and conservation symposia (e.g., Weller 1988, Festa-Bianchet and Appollonio 2003), books (Gosling and Sutherland 2000), and book series (Chapman and Hall's [London] *Wildlife Ecology and Behaviour*) demonstrate an increasing awareness of the importance of studying animal behavior. Although more papers in management journals include aspects of animal behavior, studies generally are focused on

basic descriptions of foraging behaviors and habitat use and fail to integrate modern developments, such as game theory, optimal foraging, cultural evolution, and the importance of phenotypic plasticity (Sutherland 1998b). Wildlife studies are rarely conducted in a manner that encourages development of **predictive models** of population demography, dispersal, or habitat use based on changes in individual behaviors caused by **anthropogenic activities** or on factors that include variation in individual behavior. Two solutions are needed to correct the disconnect between wildlife biology and animal behavior: (1) researchers and students in each discipline need more exposure to the concepts and ideas of both disciplines, and (2) management teams should include behavioral biologists (Arcese et al. 1997) to incorporate behavioral studies relevant to management or conservation issues.

ANIMAL BEHAVIOR AND WILDLIFE BIOLOGY

Behavior of Whooping Cranes

Wildlife biologists have learned to include insights from animal behavior into management of wildlife populations. For example, the whooping crane (*Grus americana*) has become an international symbol of the challenges of managing and recovering populations of endangered species. This largest of North American cranes was once widely distributed across the north-central United States and southern Canada. During the late 1800s and early 1900s, **overharvesting** by settlers and homesteaders led to large-scale population declines (Allen 1952). By 1939, J. J. Lynch (Aransas National Wildlife Refuge, unpublished data) reported the large size and conspicuous plumage of the whooping crane had made it an easy mark for hunters, and there were only a few scattered pairs left breeding in the wild. By 1939, only 2 populations remained, a migratory population that nested in Canada and wintered in Texas, and a nonmigratory group nesting in Louisiana. Wildlife biologists faced a crisis when, by 1941, only 16 birds remained in the **migratory population** at the Aransas National Wildlife Refuge, Texas (Lewis 1995b) and fewer than a dozen in the nonmigratory population. Today, all whooping cranes are genetic descendants of those 16 individuals. The nonmigratory genetic heritage was lost with the death of Josephine in the New Orleans Zoo (R. C. Drewien, U.S. Fish and Wildlife Service, personal communication). A major challenge for wildlife biologists was to increase the size of the migratory population, because migration routes, nesting locations, and wintering sites were **learned** behaviors. Although in many species, migration appears to be an **innate** behavior (Box 19.1), in whooping cranes, social interactions appear to be key to the establishment of migration routes. In 1975, a field experiment was initiated to re-establish a migratory flock through cross-fostering whooping cranes by using sandhill cranes (*Grus canadensis*) as foster parents (Drewien and Bizeau 1978).

Box 19.1. LEARNED BEHAVIORS

These are behaviors that are modified by experience and the environment. For example, young whooping cranes learn which types of areas are suitable for foraging by following adults. In contrast, innate behaviors are those performed the same way each time after their initial expression. Innate behaviors are usually “hard-wired” in species’ nervous systems. An example of an innate behavior in cranes is performing highly ritualized mating displays, such as head bowing and leaping into the air.

Wildlife biologists cross-fostered whooping cranes by placing them with closely related sandhill crane parents. Whooping cranes generally produce 2 eggs, but raise only 1 chick. Wildlife biologists took advantage of this behavior by removing 1 of the eggs from nests of wild and captive birds and placing them in nests of selected pairs of sandhill cranes at Grays Lake National Wildlife Refuge, Idaho, in 1975 (Drewien and Bizeau 1978).

This experiment initially appeared to be successful, as the foster parents raised whooping crane chicks and successfully taught them feeding habits and the 1,350-km migratory pathway to Bosque Del Apache National Wildlife Refuge, New Mexico (Drewien and Bizeau 1978). However, it became apparent that lack of previous behavioral studies on one key aspect of the social behavior of whooping cranes was critical to understanding the underlying failures of the experiment. Although migratory behavior was a learned behavior, **sexual imprinting** influenced choice of mates. This is a special type of imprinting, in which choice of sexual partner is determined during early development. Exposure in the initial hours after hatching can permanently influence the choice of mates for many species of birds. Unfortunately, no one had studied the extent to which whooping cranes became sexually imprinted on their parents, as there was little opportunity to do so prior to the cross-fostering experiment. Although male whooping cranes raised by foster parents established breeding territories and nests, they did not pair with whooping crane females. However, at least 1 hybrid was produced by a male whooping crane and a female sandhill crane. The last known whooping crane in the experimental population disappeared in 2002.

Wildlife managers and conservation biologists learned from this experience and recently established a new migratory population of whooping cranes that migrate between Wisconsin and Florida following motorized ultralight aircraft. The first autumn migration occurred in 2001. In au-

tumn 2002, 16 young whooping cranes imprinted to ultralight aircraft migrated over 7 states in a 1,900-km journey lasting 49 days (www.operationmigration.org). In 2002, birds from the previous year migrated north without aid of the ultralight aircraft. The success of this experiment, as measured by successful reproduction with members of their own species, will not be known for several years.

The use of information from behavioral studies has been critical to the initial success of the Wisconsin–Florida experiment (Operation Migration) as well as to the releases of >200 fledged juveniles in the Florida nonmigratory population (R.C. Drewien, personal communication). Care has been taken in these experiments to prevent **imprinting** young whooping cranes on humans. In the Wisconsin–Florida experiment, cranes hatched from eggs incubated by captive mothers are taken to Necedah National Wildlife Refuge, Wisconsin, for acclimation to the wild. Human handlers dress in costumes and teach the young cranes critical survival skills, including foraging, predator avoidance, and avoidance of humans (Fig. 19.1). Eventually, these birds are taught to follow their costumed trainer as the trainer operates a motorized ultralight (Fig. 19.2) in an effort to reestablish a migratory population. Efforts for the nonmigratory flock in Florida include teaching young cranes to avoid predators by roosting in water as well as other survival skills. The challenge of teaching learned behaviors to long-lived species that depend on social transmission of behavior is difficult with experimental flocks. The lesson learned from whooping cranes is that prior studies of species’ behavior in their natural environment are critical for future management and conservation efforts.

Placement of Wood Duck Nest Boxes

Understanding the mechanisms of social interactions among female wood ducks (*Aix sponsa*) has led to recent manage-

Fig. 19.1. A costumed pilot works to train young whooping cranes by using a puppet head and a loudspeaker playing a soft purring sound that chicks would normally hear from their mothers. *Photo courtesy of Operation Migration.*

Fig. 19.2. Whooping cranes follow an ultralight craft from Wisconsin to Florida, possibly establishing a new migratory population. Photo courtesy of Operation Migration.

ment changes. Wood ducks are secondary cavity nesters and inhabit wetlands, including swamps and marshes during the breeding season, and they seek cavities created by other species, such as pileated woodpecker (*Dryocopus pileatus*; Bellrose and Holm 1994). In such cavities, wood ducks may lay a clutch of up to 14 eggs (Semel and Sherman 1992). In a natural setting, wood ducks typically nest solitarily in dispersed and cryptic cavities. Deforestation and wetland habitat loss led ornithologists to predict that wood ducks would be extinct around the turn of the 20th century (Hepp and Bellrose 1995). Several factors have contributed to the existence of the healthy populations observed today. The establishment of the Migratory Bird Act (<http://www.fws.gov/laws/lawsdigest/migtrea.html>), conservation and creation of wetlands, and use of nest boxes (Fig. 19.3) to replace cavities lost from old growth forest harvesting were major factors leading to wood duck recovery.

Fig. 19.3. Wood duck female emerging from nest box. Drawing courtesy of R. W. Henninger.

Undoubtedly, use of artificial nest boxes has led the overall **recovery** of wood duck populations since the turn of the 20th century (Hepp and Bellrose 1995). Ironically, the mechanism for recovery led to an overall reduction of clutch sizes when artificial boxes were compared to natural cavities. Although establishment of nest boxes helped provide nest cavities for wood ducks, it also increased intra-specific brood **parasitism** (Semel et al. 1990, Semel and Sherman 1993). The most common method of placing wood duck nesting boxes by wildlife managers was to cluster the boxes to make them visible. This clustering changed the solitary nesting practices of wood ducks to semicolonality. Thus, females had a much higher chance of being observed by conspecifics and, therefore, a higher probability of having their nest parasitized (Semel and Sherman 1986).

Intra-specific brood parasitism occurs when a female lays eggs into the nest of another female (egg dumping); egg dumping is triggered in wood ducks by females observing members of their own species entering or leaving nest sites (Semel et al. 1988). Waterfowl have relatively high rates of nest parasitism, and studies have shown that nest parasitism in wood ducks can exceed 50% (Semel et al. 1988, Roy-Nielson et al. 2006). A consequence of intra-specific nest parasitism in natural cavities and nest boxes can be unusually high clutch sizes. Although natural cavity nests of wood ducks have an average clutch size of 9–12 eggs, parasitized nests in nest boxes often contain ≥ 20 eggs and have lower hatching success (Semel et al. 1988). One possible reason could be that larger clutch sizes have a greater hatching asynchrony, or eggs that hatch at different times, causing fewer chicks to be produced per clutch. Hatching success also may be lower because of aggressive interactions between females when nest parasitism is attempted. At Nauvoo Slough, Illinois, 379 eggs of 76 nesting females were crushed due to female intra-specific aggression (Bellrose and Holm 1994). Recent genetic studies have suggested that rates of intra-specific nest parasitism in some populations using natural cavities are similar to those in populations using nest boxes, and that wildlife managers should focus on identifying other behavioral causes of larger clutch sizes in nest boxes (Roy-Nielson et al. 2006).

Animal behavior biologists continue to team with wildlife managers to find solutions to enhance wood duck populations (Semel and Sherman 2001). Understanding female intra-specific nest-parasitism behavior has led to placement of nest boxes in dispersed and concealed areas in habitats preferred by wood ducks. Although occupation rates may be lower, clutch success should be higher, and the dispersed nesting behavior of the species will be preserved.

IBEX REINTRODUCTIONS

Understanding natural **behavioral rhythms** is critical, as reintroductions and population augmentations often have a high failure rate initially. One reason for lack of success may

be lack of integration of animal behavior into study designs. Unfortunately, despite considerable effort to examine habitat suitability and food availability, rarely do wildlife managers seek to understand how the fundamental behavioral ecology of a species might differ among populations and subspecies or among individuals of different ages and genders.

A classic example of reintroduction efforts not succeeding due to a lack of behavioral knowledge occurred when ibex (*Capra ibex*; Fig. 19.4) from the Tatra Mountains in Czechoslovakia were extirpated during the first half of the 19th century. The Tatra Mountains rise in elevation to 2,600 m and are quite cold in spring, with frequent snowstorms and temperatures below 0° C. Local populations of ibex were adapted for the mountainous environment and bred in mid-winter, causing young to be born in late spring (Turcek 1951).

During the beginning of the 20th century, ibex from 3 different populations (from nearby Austria and warmer climates in Asia) and 3 different species (*Capra ibex*, *C. hircus*, and *C. nubiana*) were **translocated** to the mountains. The 3 species interbred, and their hybrids had different physical and behavioral characteristics than the ancestral stock. The breeding season for the hybrids occurred in late summer, and offspring were born in early spring. Young born in early spring were unable to survive the cold temperatures and storms, so generation after generation failed until they became locally extirpated (Turcek 1951). An understanding of the reproductive behavior of the 3 species would probably have helped provide better management solutions to re-establish ibex to the Tatra Mountains.

SENSORY PERCEPTION

The examples above demonstrate how understanding fundamental aspects of an animal's behavior can lead to better management and conservation decisions. A major challenge for wildlife biologists is to not allow their own sensory limitations to blind them to the importance of sources of infor-

Fig. 19.4. A lack of behavioral knowledge led to an initial failed reintroduction attempt of ibex in the Tatra Mountains in Czechoslovakia. Photo courtesy of C. Pourre.

mation for other species. This blindness could lead to **anthropomorphism** of the animal's behavior, or interpretation of the behavior in terms of human contexts, motivations, and biases. When wildlife managers are deciding which behavioral information is important, they should consider that one of the fundamental principles of animal behavior is to learn to comprehend the world through the senses of the animal being studied. Jakob von Uexkull (1864–1944) coined the term **Umwelt** to describe how an animal senses its universe (von Uexkull 1921). He recognized that preconceived ideas about how animals should behave often came from ignorance of how animal senses worked. He challenged us to imagine the world from an animal's perspective by learning what senses were available and active during different stages of their lives.

One example von Uexkull (1921) used that is useful to consider for all who have walked the woods is how a tick's perception of its universe changes depending on environmental stimulus. Ticks have simple sequential behaviors based on which sensory perceptions of their external environments are functioning. While adult ticks are waiting on the end of a piece of vegetation, they are in a form of almost suspended animation until their olfactory senses detect the unique shape of a butyric acid molecule (common in mammalian sweat). Their nervous system reacts by sending signals that allow them to let go of the vegetation. They then quit receiving signals from their butyric acid receptors and can only detect heat. When they detect heat, they burrow toward the sources of greatest heat. Imagine a world from a tick's perspective. One would not see, hear, or feel until one encountered butyric acid. The encounter would turn on a new sensory perspective of the world centered on heat. Other environmental signals would have little meaning.

Bubenik (2007) suggested that a key to understanding moose (*Alces alces*) behavior was to understand the concept of Umwelt. He stated that a basic requirement of understanding why and how moose reacted to different environmental cues was to understand the basic differences between humans and moose in their perception and response to environmental cues. He goes on to further explain that scientists often wonder why an excellent foraging area was not being used by moose or was visited more by one sex or social class than another. His explanation was that such behavior was determined by neurohormonal factors that may be specific to a population, gender, or social class.

Often our lack of understanding of other animals' **sensory perception** and its importance has led to poor management decisions or unintended consequences. Studies contrasting our sensory perception to that of other animals have shown how differently they view the world from us. Animal senses are the mechanisms through which animals find food, mates, and shelter, and they affect timing and processes of migration and hibernation. Most senses, such as hearing, sight, smell, taste, and touch, are familiar to us;

however, sensitivity to the stimuli activating the senses varies greatly. Radar, compasses, and infrared detectors are technologies that allow us to mimic other animals' senses that humans do not possess.

Understanding the importance of animals' sensory mechanisms has become increasingly important in understanding subtle impacts of human activities on the landscape. For example, some forest birds depend on certain light conditions before performing their mating displays (Endler 1997). Further, changes in stream turbidity due to forest management can affect the duration and location of fish mating behaviors (Endler 1997). The major point of understanding sensory perception is that researchers cannot begin to comprehend animal behavior until they let go of their human biases and place themselves in the animal's world.

Hearing

Hearing has a large role in how most mammals interpret their environments. It also has a critical role for many species in individual recognition, mate choice (Howard and Young 1998), prey location (Ryan et al. 1982), predator avoidance, and navigation (Roeder and Treat 1961). One can misunderstand animal behavior, because human hearing is often less acute. Because animals use sound for so many purposes, one often underestimates the extent to which sound pollution interferes with vital functions of wildlife, such as mating activities and foraging behavior (reviewed by Larkin 1996). Of particular concern is the degree to which the sounds produced by commercial, research, and military activities influence marine mammals' abilities to communicate and locate prey (Tyack 2008). There has been increased attention to understand the degree to which anthropogenic activities impact animal populations. For example, whereas Jepson et al. (2003) found that different species of whales (Cetacea) may have beached themselves due to brain hemorrhages caused by strong military sonar, Krausman et al. (2004) found that auditory effects of military activities had little impact on the behavior of an endangered population of Sonoran pronghorn (*Antilocapra americana sonoriensis*).

Mammals and birds hear sounds by detecting pressure waves with use of membranes and **hair cell sensory receptors** (Bradbury and Vehrencamp 1998). The tympanic membrane vibrates in tune to the frequencies of the pressure waves and stimulates sensory cells in the ear that send signals for processing in the brain. Sound waves have no inherent directionality, so one challenge for wildlife is to localize sounds. Most mammals have **pinnae** or external ears to aid in localizing the source of sounds (Bradbury and Vehrencamp 1998). Bats (Chiroptera) and many ungulates, such as mule deer (*O. hemionus*), can rotate their pinnae toward the source of the sound to aid in locating it. Barn owls (*Tyto alba*) have offset ear openings to allow them to localize small running rodents by sound in the complete absence of all light. Their offset ears and facial ruffs allow processing dif-

ferences in the intensity and timing of the arrival of sound waves of running rodents to help precisely locate them (Proctor and Konishi 1997).

There is significant variation in animal hearing. Elephants (Elephantidae) use low frequency sounds undetectable to humans (20 Hz) for communication across vast expanses of open savannah environments (Heffner and Heffner 1982, Langbauer et al. 1991). Many avian species can hear faint sounds at low frequencies that may warn them of approaching storms or may disrupt their flight when exposed to commercial jet shockwaves (Hagstrum 2000). Bats hear high frequency sounds above our detection abilities (>20,000 kHz) and use these sounds to detect prey as small as mosquitoes. Cave swiftlets (*Aerodramus linchi*) and oilbirds (*Steatornis caripensis*) use relatively high frequencies for **echolocation** to locate entrances to caves and relatively large (≥ 20 mm) items in their environment in the dark (Griffin and Suthers 1970).

Perhaps one of the most common reasons for animals to produce sounds is for communication. There is a rich body of research examining the different things animals communicate through sound. For example, Gunnison sage-grouse (*Centrocercus minimus*) perform elaborate mating displays (Fig. 19.5), in which their sounds can be heard for ≥ 1 km. Their vocalizations and mechanical sounds are used to communicate their willingness to mate, warn members of the same gender away from potential mates, and attract females to their mating site (Young 1994). Bull elk (*Cervus canadensis*) produce a variety of calls during rut that serves to defend their territories and attract cows to their location; the calls vary, depending on aggressive context (Feighny et al. 2006). Common ravens (*Corvus corax*) vocalize loudly when finding a large carcass. This behavior seems counterintuitive (why bring competitors for food to the scene?). Careful testing of alternative hypotheses led to the discovery that young ra-

Fig. 19.5. Gunnison sage-grouse perform ritualized displays on their mating grounds. Sounds are produced by both syringeal vocalizations and mechanical release of air from their yellow air sacs. Photo courtesy of J. D. Sartore.

vens intruding on territories of older pairs vocalized to draw large groups of conspecifics to the scene to avoid being forced from the food bonanza by the **territory** owners (Heinrich 1988). Begging by young birds is a signal to parents to increase food delivery. This communication between parents and their offspring has been used by such species as brown-headed cowbirds (*Molothrus ater*), in which the young brood parasites produce louder calls than those of their nest mates.

Vision

Although almost all organisms are sensitive to light, vertebrates have developed the ability to capture images from their environment and synthesize information about those images. We can misunderstand the impact of different levels of **visual acuity** unless we understand that humans have only moderate abilities for detecting electromagnetic energy or light. Most other animals have evolved different levels of light sensitivity for finding food, detecting threats, and orienting themselves in their environments (Bradbury and Vehrencamp 1998).

Light is captured in photoreceptor cells that contain **photopigments**. In vertebrates, the cells are called rods and cones and are packed densely in the eyes to form the retina. Rods allow for vision in low light conditions, and cones are responsible for color vision in high light intensity environments. The ability to resolve fine details in the environment depends on the number of receptor cells in a given area, the optical system, and the neurological mechanism for passing the signals to the brain (Bradbury and Vehrencamp 1998).

One of the most obvious ways humans alter visual habitats is the extent to which nights are illuminated. **Photopollution** is the detrimental addition of light into an animal's environment, with nocturnal animals being most at risk. For example, most species of sea turtles (Cheloniidae and Dermochelyidae) are listed as threatened or endangered and will not nest on preferred beaches if the beaches are lit (Witherington 1992). If they do nest on beaches with night lighting, their hatchlings are often at risk as they move toward the light rather than toward the relative safety of the sea. Behavioral research is providing wildlife managers with guidelines for safely lighting beaches without impacting sea turtle behavior (Witherington 1997). Another problem with light pollution occurs from **phototaxis** (light attraction) by birds toward lighted radio towers at night. When weather conditions bring low cloud ceilings or fog, lights on towers cause refraction, creating areas of illumination around the towers. Thousands of migrating birds that have lost their stellar cues are attracted to the lighted area and may die if they collide with the tower or its supports (Avery et al. 1976).

In general, most birds have better distance vision than do mammals and can see 2–3 times farther than humans can (Gill 1995). One of the greatest variations in vision among species is differing abilities to see color. Many mammals,

such as hamsters (Cricetinae), Virginia opossum (*Didelphis virginiana*), raccoons (*Procyon lotor*), some monkeys (Primates), and bats, have little to no color vision, whereas birds can sense portions of the color spectrum, such as **ultraviolet** light. For example, Eurasian kestrels (*Falco tinnunculus*) use ultraviolet trails left by small mammals marking their runs with urine to locate prey corridors (Koivula et al. 1999), and female European starlings (*Sturnus vulgaris*) use ultraviolet cues for mate choice (Bennett et al. 1997). Some snakes, such as rattlesnakes (*Crotalis* spp.) and other pit vipers (Viperidae), use wavelengths of light not visible to us at the other end of the visual spectrum and can detect **infrared waves** (Hartline et al. 1978). The ability to sense an infrared wavelength is critical for their success in hunting small mammals emitting such frequencies of light. The position of a tail may send subtle signals to subordinate members of a gray wolf (*Canis lupus*) pack. The same wolves may end a chase of white-tailed deer that wave their tails in a conspicuous flagging behavior, alerting the wolves they have been seen (Fig. 19.6). Such species as Thomson's gazelle (*Gazella thomsonii*) use vigorous "stotting" displays to warn approaching predators they have been seen by their prey (Caro 1986). Stotting occurs when gazelles bound up and down with all 4 legs held stiffly while displaying their white rump patch.

Fig. 19.6. Tail wagging by white-tailed deer provides visual signals to potential prey and predators. Such signals are probably adaptive evolutionary traits, as the prey signal the unprofitability of pursuit to the predator. Thus, both prey and predator can save energy by avoiding energetically expensive escape activities and chases. Photo courtesy of N. Paothong.

Olfaction

Smell is poorly understood, and the extent to which anthropogenic activities influence the “smellscape” is only beginning to be recognized. Such species as Pacific salmon (*Oncorhynchus* spp.), an important food item for bears (Ursidae), are significantly impacted by our olfactory pollution of their streams. One mechanism involved in the decline of salmon in the Pacific Northwest appears to be their dependence on olfactory cues for returning to their natal streams (Scholz et al. 1976, Nevitt et al. 1994, Dittman and Quinn 1996).

Olfaction is possible through reception of chemicals and was likely one of the first animal senses to evolve. Most, if not all, wildlife possess some sort of olfactory organ that allows them to detect airborne chemical messages. In general, there is some type of inlet (e.g., mouth or nose) that leads to a chamber carpeted in sensory cells that respond differentially to diverse olfactory chemicals (Bradbury and Vehrencamp 1998). Historically, scientists believed that birds had poor or no sense of smell, due to the relatively small olfactory bulbs in their brains. Currently, we know that most, if not all, birds possess a sense of smell and can detect odors as accurately as mammals can (Clark et al. 1993b). Nocturnal birds and carrion eaters, such as vultures, have better senses of smell than do other birds. Turkey vultures (*Cathartes aura*) can detect traces of the chemical ethyl mercaptan that is released from decaying meat (Smith and Paselk 1986). Engineers have taken advantage of the vultures' olfaction abilities by pumping small amounts of ethyl mercaptan into pipelines with breaks and watching where vultures gather (Gill 1995). Leach's storm-petrels (*Oceanodroma leucorhoa*) can detect odors up to 25 km away emitted by krill, small crustacea that occur in groups in the ocean (Clark and Shah 1992). Mammals also have a keen sense of smell, with nocturnal predators having abilities thought to be 10–100-fold as great as those of humans.

There are many advantages of using chemical communication over auditory cues. For example, pheromones in urine are likely to last days or weeks, whereas songs and howls last only until the singer is finished. **Allomones** are chemical signals passed between species, such as between predator and prey. **Pheromones** are chemical messages (organic compounds with a carbon skeleton) passed within the same species. Pheromones are likely used by mammals for mate identification and attraction, territory marking and defense, and as alarms of danger or stress (Bradbury and Vehrencamp 1998).

Sources for pheromones include excretory products, such as urine and feces, or specialized glands on the outside of the animal's body. Some mammals, such as ground squirrels (*Spermophilus* spp.) and goats (family Bovidae), produce pheromones from sebaceous glands associated with their skin and hair follicles. Other mammals, such as mustelids (Mustelidae), have anal glands that produce secretions. Some ungulates, such as pronghorn (*Antilocapra americana*), have pre-

orbital glands by their eyes. Most cervids, such as mule deer, produce pheromones from tarsal and metatarsal glands on their legs and tails. They often rub their leg against their head and then rub their forehead on stems and barks to transfer their scent.

Pheromones can be used for courtship, and cervids likely convey information about individual identification and reproductive status, as well as social status (Eisenberg and Kleiman 1972, Johnston 1998). Some birds may use pheromones to elicit sexual responses in males. The ability of mallards (*Anas platyrhynchos*) to mate may be influenced by males detecting pheromones produced by females. Balthazart and Schoffeniels (1979) found that male mallards with their olfactory nerves excised did not exhibit courtship behavior in the presence of females. Animals often also use pheromones for territorial marking. Pheromones in mammalian urine are a common method of territorial marking for large carnivores and other mammals.

Taste or Contact Reception

Although smell entails sensing airborne chemicals, taste depends on contact reception of chemical molecules. We know little about how changes in animals' environments interfere with their sense of taste. Currently, most management activities studying taste are taste aversion studies. **Conditioned taste aversion** is a learned behavior that occurs when negative consequences (getting ill, hurt, shocked, etc.) occur following the consumption of an item. Cowan et al. (2000) published an excellent review of the use of the behavior for reducing predation.

Chemical receptor cells in the mouth are specialized nerve cells that react on contact with different molecules. Taste is shaped by an initial molecule that binds tightly to a specific protein receptor and then undergoes a physical change, causing a neurological signal to be passed to the brain. The intensity of a taste is influenced by the number of cells binding to receptors, types of cells, and density of receptors being activated at a given moment. Chemical receptor cells are some of the shortest-lived cells in an animal's body, only functioning for a few days before they are replaced (Bradbury and Vehrencamp 1998).

The number and kinds of receptors present likely influence taste. Birds have relatively few taste receptors (usually 100), whereas mammals, such as humans, have >10,000 taste buds on their tongues (Gill 1995, Mason and Clark 2000). Both amount and types of receptors are important in the sense of taste.

One way that mammals communicate by taste is through use of a chemosensory organ called the **vomerolnasal organ** (Jacobson's organ), a single opening lying between the nasal cavity and the roof of the mouth (Bradbury and Vehrencamp 1998). Some ungulates perform a behavior called **flehmen** (Fig. 19.7) after they contact another individual's urine or secretions, in which they pull back their upper lip

Fig. 19.7. Elk performing flehmen behavior to expose its vomeronasal organ to “taste” the air. Drawing courtesy of R. W. Henninger (after Bradbury and Vehrencamp 1998).

to cover their nostrils and raise their head to close off airflow into their epiglottis (Doty 2001). This behavior enables them to draw air into their vomeronasal organ. The receptors in the organ are more structurally similar to taste receptors than those located in the nose for smell. This form of communication is probably important for assessing information about mating status and territoriality. For example, male mountain goats (*Oreamnos americanus*) spend about 4% of their time during rut performing a flehmen behavior after they scent the urine or genitalia of their tended female or nearby females (Mainguy et al. 2008), and scientists speculate that males may be selecting among females in estrus through this sensory mechanism.

Tactile

Tactile sensory systems are commonly used by all wildlife, but are poorly understood and studied. Although the importance of touch in mating rituals, agonistic encounters, social grooming, and other social behaviors is recognized, its role is not well investigated, compared to those of visual and vocal displays. In addition to using touch for communication, it can be a critical sense for navigation in the dark in forests or through subterranean or subnivean (below the snow) environments.

Touch occurs when **mechanoreceptors** are directly stimulated. Although tactile sensory systems are most developed in burrowing mammals, moles (*Talpidae*), and elephants have tactile sensors in their lips and snout, allowing them to sense their environment through touch. In birds, filoplumes and bristles are specialized feather mechanoreceptors used for sensory functions. Filoplumes associated with flight feathers in the joints of the wings help adjust to minute changes in wind pressures during flight; those associated with general body feathers may provide information about airspeed (Clark and De Cruz 1989, Gill 1995). Flightless birds, such as pen-

guins (*Spheniscidae*) and ostriches (*Struthionidae*), are devoid of filoplumes.

The types of mechanoreceptors can vary as well as their location and numbers. Specialized mechanoreceptors occur in the vibrissae (whiskers) of many mammals and in filoplumes and bristles on birds. Touch receptors in the bristles of birds can be seen on flying insectivores, such as common nighthawk (*Chordeiles minor*) and swallows (*Hirundinidae*), that have bristles around their mouths to sense the lightest touch of a mosquito (Gill 1995). In mammals, vibrissae often occur around the eyes, muzzle, ears, or tail and can provide detailed information to the animal about size, shape, and movement in its environment (Ahl 1986). **Pressure receptors** are often associated with hair in mammals. Social grooming in primates stimulates the receptors and is an important aspect of many primate's social systems. Many small mammals, such as kangaroo rats (*Dipodomys* spp.), use touch for seismic communication in their environment. Kangaroo rats communicate by foot-thumping species-specific and individually recognized patterns (Randall 1997). Blind mole-rats (*Spalax ehrenbergi*) thump their heads against their subterranean tunnel walls to defend territories (Hill 2001).

Several species of animals, including black bears (*Ursus americanus*), shift from using primary sensory modes (e.g., visual) for foraging to using tactile and auditory modes during twilight and night. For example, black bears can have increased foraging success when they cue in on the touch and sounds of salmon splashing as salmon become more active in increased darkness (Klinka and Reimchen 2009).

Other Senses

Barometric Pressure

Many species of birds apparently have some form of mechanical receptors to allow them to assess subtle changes in barometric pressure (Bagg et al. 1950). Many species of songbirds often engage in feeding frenzies prior to low-pressure systems that create winter storms. Birds of the same species are often found in the same altitudes during nocturnal migration, suggesting they can adjust their flights based on pressure differences (Gill 1995).

Magnetic Fields

Another important sense that birds and other species possess is the ability to sense magnetic fields. The exact mechanism behind this sense is still under debate (Walcott et al. 1979, Phillips and Borland 1992); however, there is strong evidence that many avian species can detect weak magnetic fields from Earth (Wiltschko and Wiltschko 2003). There is increasing evidence that some species of birds use a magnetic compass or map, whereas others use a polarity compass that distinguishes pole-ward from the equator rather than north from south; the evidence suggests these birds have receptors in their retinas. Such a system would be

quite effective for migration movements from the equator toward the poles and back again (Beason 2005).

Although use of magnetic fields for both orientation and mapping appears to be common in invertebrates (Boles and Lohmann 2003), bacteria (Blakemore 1975), and sea turtles (Lohmann et al. 2001; Fig. 19.8), the extent to which mammalian species can detect magnetic fields is just now being explored. Some evidence suggests that rats are influenced by magnetic fields (Reuss and Oclase 1986).

Sensory Perception Summary

As one learns to better understand the complex and divergent ways in which animals perceive their environments, one can escape from the limitations of one's own sensory perceptions and develop hypotheses relevant to other species' actions based on their perceptions of their environments. One can then better understand how the presence of other species, conspecifics, and changes in species auditory, olfactory, or visual environments might affect management and conservation actions. One also can develop behavioral hypothesis based on individual responses to the perceived environment.

FORMING BEHAVIORAL HYPOTHESES

Our activities and efforts can have unintended consequences on management of a species because of ignorance of how those actions will change the animals' social behavior and social organization (e.g., attempts to control animal populations believed to have an economic impact on our activities). Efforts to control the transmission of bovine tubercu-

Fig. 19.8. Lohmann et al. (2001) outfitted loggerhead sea turtle (*Caretta caretta*) hatchlings with harnesses tethered to an electronic tracking unit that recorded the turtles' positions as they responded to manipulated magnetic fields. The hatchlings processed magnetic information to follow innate migration routes, suggesting they possess a "magnetic map." Photo courtesy of K. J. Lohmann.

losis by killing European badgers (*Meles meles*), which are hosts of the disease, may actually cause higher transmission rates, as individuals encounter one another at increased rates because of the changing dynamics of their social organization (Swinton et al. 1997). Hunting can have significant effects on population parameters that initially seem unrelated, due to changes in individual behaviors, social systems, or mating systems. For example, killing male mallards after pair-bond initiation can result in lower population reproductive success for yearling female mallards (Lercel et al. 1999). Killing male black bears may result in changes in population sex ratios and an increase in infanticide, lowering reproductive success at the population level (Swenson 2003).

Once wildlife biologists have accepted that animals have different senses and different behavioral responses due to social structure and density, biologists can begin to understand the importance of developing hypotheses about how an animal's behavior can influence its response to efforts to manage or conserve its population. Garton et al. (Chapter 1, This Volume) present a review of critical features for hypothesis testing in wildlife biology and management. However, it is important to understand how formation of hypothesis for testing ideas about behavioral ecology may differ from traditional hypothesis testing for wildlife science.

Tinbergen (1963) recognized that all behavioral hypotheses could be examined using 4 categories: (1) evolution, (2) development/ontogeny, (3) function, and (4) causation. One way to develop hypotheses is to distinguish between **ultimate** (those involving evolution and development) and **proximate** (those involving function and causation) questions. Imagine behavioral biologists coming upon a male mule deer rubbing its antlers back and forth across a small aspen (*Populus tremuloides*) tree or a bush. When forming an evolutionary or ultimate hypothesis, they would ask such questions as: Does the rubbing of its antlers increase its survival or reproductive success? When did rubbing behavior evolve in this species? These questions can turn into testable ultimate hypotheses with specific predictions. Behavioral biologists may form mechanistic or proximate hypotheses about the physiological or neurological mechanisms leading to the rubbing behavior by asking such questions as: Do the male's hormones trigger the rubbing behavior? Are males more likely to rub their antlers during certain seasons? These questions can be turned into testable hypotheses regarding the mechanisms behind the expression of the behavior.

Both ultimate and proximate hypotheses can lead to important insight into the management and conservation of species. For example, if after careful study it was concluded that males who had more rubs on small diameter trees were more likely to mate, subsequent management of aspen tree age classes could influence the distribution and reproductive success of mule deer in that area. If it was found that males only rubbed their antlers during certain seasons, antler rubs would be an indication of population use of habitat on a

seasonal basis, promoting management decisions about access and physical disturbance activities during different times of the year. It is important to recognize that although there are 2 major types of behavioral hypotheses, examining one logically leads to examining the other.

DIRECT METHODS FOR OBSERVING BEHAVIOR

Direct observation is generally necessary to gather sufficient independent quantitative data for statistical testing of hypotheses about animal behavior. One of the most important and often overlooked methods for observing and recording behavior is keeping a daily **field journal**, which can lead to formation and testing of hypotheses about animal behavior. A good field journal should always include dates, times, places, weather conditions (wind, clouds, etc.), description of the habitat, description of activities, and distributions of animals in the habitat.

During direct observations, the researcher must consider and implement ways to minimize observer effect on animal behavior, yet still understand and acknowledge that observer presence may cause changes in their subject's behavior. While considering how to mask the observer's presence, one's sensory biases may lead one astray, so that only visual masking with blinds or platforms is considered. Olfactory presence is probably of even greater significance for mammals in general and is especially critical for carnivores.

Visual masking is important, but the observer should acknowledge that animals generally know the observer is present in blinds and towers. Often the observer will arrive well before the animal and leave after the study organism has left. While studying Gunnison sage-grouse in Colorado, Young (1994) often arrived by 0300 hours and spent long, cold hours in a blind until the last bird left the display ground after 0900 hours. Although the visual presence of the observer was somewhat masked, it is uncertain to what extent olfactory presence influenced the birds' breeding behavior. Even when the study organism appears to be habituated or accustomed to the observer's presence, it is difficult to ascertain the extent to which categories of individuals (genders, age classes, etc.) are differentially affected by other sensory indications that an observer is near. Bekoff (2000) provides a more complete review of **observer effects** on study animals.

There are a variety of ways to mark individuals to allow behavioral observation at a distance. The study design may require that marks are observable from a few to hundreds of meters. The common error of overestimating sample sizes in wildlife studies is exacerbated by a tendency for wildlife managers to mark study populations rather than individually mark captured animals, as is more common in behavioral studies. Behavioral ecologists should carefully consider their needs before embarking on individually marking their

study organism. One critical question that should be asked is the extent to which retention of the mark is needed. For example, amphibians may rapidly regrow clipped toes, and bands may discolor or be lost from birds. Other considerations should include minimizing stress or possibility of injury to the study animal. Finally, many **marking techniques** may have unintended consequences on the behavior of the study animal or the behavior of individuals interacting with the marked individual. For example, Burley (1988) found that color banding zebra finches (*Poephila guttata*) influenced mate choice. Silvy et al. (Chapter 9, This Volume) provide a more complete review of marking.

After animals are marked, researchers may assign a name for field recognition. Most researchers advocate use of letters or numbers that have no subjective bias associated with them and avoid using personal names. Bekoff (1997) offers a contrasting view that naming an animal increases researchers' respect for their study organism.

STRATEGIES FOR DEFINING BEHAVIORS

Observations

Observing animals leading to increased familiarity is a critical step in defining behaviors for a study organism. Martin and Bateson (1996) suggested that it was vital to get to know the organism and to review the literature before defining terms. There are 2 reasons for informal observations preceding quantitative studies. First, it is generally through informal observations that hypotheses are formed. Second, choosing the appropriate methods to address hypotheses is greatly assisted by a period of observation. Most animal behaviorists would suggest that young researchers or those studying an animal for the first time also should review published literature on how behavioral definitions have been formed and used. However, some researchers would recommend immersing yourself in the animal's environment with no preconceived notions, as was done by renown primate behaviorist, Jane Goodall.

Lehner (1996) distinguished between watching animals and rigorously observing them. Informal observers should understand the difference. A babysitter may watch children, whereas a psychologist observes them. Both are valuable activities, but the psychologist's observations are far more likely to lead to testable hypotheses. Although observations can initially be informal, they should still be able to provide intricate detail about individuals and their social behaviors.

Behavioral Definitions

Behavioral definitions should be sufficiently precise so they can be communicated clearly to other field personnel and researchers, and definitions should avoid **bias**. For example, defining types of movement, such as still, walking, running, or flying, is generally more objective than suggesting the cause of the movement (resting, boredom, fear, migration,

etc.). For each term, the researcher should apply a definition that makes the term mutually exclusive from other terms. Walking could be defined as taking 10 steps in a 5-second interval, whereas running could be defined as taking >10 steps in a 5-second interval. Behaviors can either describe structure (posture, movement, etc.), consequences (escape, compete, etc.), or relative position with inter- or intra-specifics (approach, flee). Two warnings are appropriate. Behavioral definitions based on consequences of the behavior and those based on inter- or intra-specific interactions are often larger categories of activities and can be associated with human bias. Definitions based on structure can often generate excessive detail that does not necessarily test general hypotheses well.

Indirect versus Direct Measures of Behavior

It is important to consider types of questions that can be addressed with indirect behavioral observations. For many animals, direct observations are challenging at best, and indirect observations may provide valuable insight into the social behavior of the species. **Indirect observations** of behavior include studying tracks, markings, foraging sites, bite marks, frequency of scars, feces, and even chewing of radio-tracking collars. One exciting method for using indirect behavior has been recording of nocturnal avian migration vocalizations to provide survey measurements (Evans and Mellinger 1999).

TYPES OF SAMPLING

Altmann (1974) provided an excellent paper on sampling methods for behavioral biologists. There are 4 basic sampling methods: (1) ad libitum sampling, (2) focal-animal sampling, (3) scan sampling, and (4) social structure sampling. Each type of sampling method has benefits and costs associated with its use (Table 19.1).

Ad libitum sampling occurs when the observer notes what they see that seems relevant or interesting. Major problems

with this type of sampling are that it lacks randomization for meeting the requirement of independence for statistical tests and is likely to bias observers to overestimate conspicuous behaviors. Consider the excitement of watching a coyote (*Canis latrans*) chase a ground squirrel. Although it may be interesting to note the sequence of action and the depredation event, it would not provide a researcher with information on the frequency or duration of predatory events for either species. Ad libitum sampling can be useful when the observer is first observing a species to gather preliminary information for hypotheses formation or to record rare events, but it is rarely useful for actually testing hypotheses.

Focal-animal sampling occurs when one individual or group (when several groups are present) is watched continuously for a set period of time, and all acts which the animal either initiates or has directed toward it are recorded. Generally, the investigator has formed an **ethogram** or a catalog of carefully defined, mutually exclusive behaviors to categorize the behavioral repertoire of the focal animal (Table 19.2). The choice of the focal animal is often randomized to prevent observer bias or is established for experimental design reasons prior to the initiation of the study. One major challenge of focal-animal sampling is the targeted individual may move from sight or leave before the period of time for their sampling is finished. Behavioral biologists form explicit rules about how to proceed with this common occurrence. Although each rule may differ among studies, the critical aspect is they are applied equally by different observers and across time in the same study. For example, while watching a herd of pronghorn, the targeted individual may disappear behind a hill. The observer can either record “time out” for the period it is out of sight or switch observations to a new focal animal. One caution about using this type of sampling occurs if the study animal generally does certain behaviors secretly or with great privacy (e.g., birthing or mating) that would lead to those behaviors being underrepresented. Focal-animal sampling provides good information about rates, durations, sequences, and interactions.

Table 19.1. Types of data obtained and behaviors measured with different sampling methods

Sampling method	State or event sampling	Behavioral measure	Weakness
Ad libitum	Either	Opportunistic measures suitable for field notes or for initial observations prior to hypotheses testing	Overestimates rare behaviors; cannot use statistics on observations, given nonrandomness of sampling
Focal-animal	Either	Provides good information about rates, durations, in animal sequences, and interactions	Difficult to gather data on sequence of interactions among individuals
Scan	State	Provides good estimates of time budgets or percentage of time individuals spend doing different activities in a group	Does not provide duration data and usually is limited to recording a few types of behavioral acts
Sociometric matrix	Event	May provide information about dominance structure and other group social structures	Obtaining random sequences is challenging and rarely done

Modified from Altmann (1974).

Table 19.2. An ethogram for bald eagles (*Haliaeetus leucocephalus*), providing mutually exclusive descriptions of behaviors. This ethogram identifies relative amount of time spent by male and female eagles in foraging, but it does not distinguish between relative frequencies of different types of aggressive behaviors.

Behavior	Description of behavior
Resting (RS)	The eagle is not performing any active behavior, remaining stationary for 10 seconds.
Self-preening (SP)	The eagle is manipulating its own feathers with its beak.
Allo-preening (AP)	The eagle is manipulating feathers of a conspecific.
Foraging (FG)	The eagle is actively attacking or consuming food items.
Nest building (NB)	The eagle is creating a nesting structure or carrying nesting material to a nesting structure.
Nest incubation (NI)	The eagle is sitting in a nest or manipulating an egg in a nest.
Courtship flight (CF)	The eagle is performing aerial flight displays with its mate.
Vocalizing (VC)	The eagle is vocalizing.
Flying (FY)	The eagle is in the air and is not courting a mate.
Walking (WK)	The eagle is hopping or walking on the ground.
Aggression (AG)	The eagle is demonstrating aggressive behaviors toward a conspecific (pecking, erecting feathers, etc.).

It is considered by most biologists to be the type of sampling that will have the highest dividends for testing the original hypothesis and providing information for subsequent studies.

Scan sampling uses a census (total count) of an entire group of animals for a single behavior or a small set of behaviors. For example, while watching a flock of geese (*Anatidae*), a researcher would scan the group for 15 seconds every 5 minutes to record how many geese in the group have their heads up in an alert manner. Although short sampling periods are important for this methodology, realistically the sampling period will be affected by group size and complexity of behaviors. The important factor is to keep sampling time short and constant across samples. The time it takes will be a function of group size, number of behaviors recorded, and general visibility. Scan sampling is a good method of measuring the distribution of behaviors in a group and also can be used to measure the extent to which behaviors are synchronized in a group. Scan sampling also can help the observer estimate **time budgets** (the percentage of time individuals spend doing different activities). For example, if the researcher wanted to know whether male green-winged teal (*A. carolinensis*) spent more time (and therefore energy) on vigilance behavior than did their mates prior to nesting season, scan samples could be quite useful. Problems with this type of sampling are that it does not provide the ability to estimate the duration of behaviors (unless

they are performed for long periods or the sampling is virtually instantaneous) and is generally limited in the number of behaviors that can be investigated.

Social structure sampling examines social structure rather than individual behavior. It is an important type of sampling that can be useful for examining social dynamics between pairs of individuals and among groups (McDonald et al. 2000). Social dynamics are the resultant interaction of an individual's ecology and behavior. Understanding the social dynamics of a species is critical to predicting the consequences of actions taken to manage wildlife.

Historical methods for studying social dynamics include sequence sampling, which allows the investigator to follow a chain of behavioral interactions between individuals or successive animals in a group. It can be challenging to identify the beginning or end of a sequence, and choosing sequences at random is rarely done.

Pairwise interactions between individuals or species that can be measured using sociometric matrix sampling can be useful for identifying social dominance (Lehner 1996) or other types of social behaviors. McDonald et al. (2000) provide an excellent review of current methodologies for examining and organizing questions about social structure.

Each sampling method has strengths and weaknesses. Most behavioral biologists combine more than one methodology to test their research hypotheses. The key to selecting the correct methodology is being certain the methods chosen are best to measure the behavior to be quantified for statistically testing the hypothesis and the methodology has been carefully defined to allow others to repeat the experiments.

TYPES OF BEHAVIORAL MEASUREMENT

Behaviors can be recorded as either events or states. **Events** are behaviors, such as mounting or vocalizing, that occur for a relatively short duration, whereas states are behaviors, such as rutting or foraging, that indicate prolonged activity.

Frequencies are measurements of how often specific behaviors occur during some unit of time (Fig. 19.9). Frequency of events, such as fighting, is often used to measure behaviors for social interactions. In general, frequencies are the most common type of behavior measurement. **Durations** are often used to measure states, such as rutting or migratory behavior. Durations are important measurements in time budget analyses. **Latency**, or the **initiation time**, measures the time interval between when a behavior begins and another behavior ends (Fig. 19.9). For example, a researcher may be interested in the latency to attack after a gray wolf raises the hair on the back of its neck. **Intensity** is an indication of how extreme the behavior expressed is or how loud a vocalization may be. Researchers can associate the presence of certain acts with either high or low intensity to provide more objective measurements. For example, a threat display from a gray wolf may be of higher intensity if it has hair raised, lips curled, and its tail is held in an upright pos-

Fig. 19.9. The black bars measure the occurrences of a behavior, such as foraging, by mountain sheep (*Ovis canadensis*) over time. The bars represent 3 occurrences of foraging in time (t), and frequency of foraging would be $3/t$. Latency is the measure of time until the behavior first occurred. The total duration of foraging during the observation period is $(a + b + c)$. The proportion of time spent foraging is $(a + b + c)/t$. After Risenhoover and Bailey (1985).

ture. **Bouts** are commonly used in post-field analyses. Bouts reduce behavioral observations into temporal clusters (court-ing bouts, foraging bouts, singing bouts, etc.) of behavior. A bout is generally recognized as a period of time in which a behavior occurs regularly, but not continuously (Bart et al. 1998). Occasionally, defining bouts is easy, because the behavioral activities occur in discrete clumps of time separated by a standard amount of time. When Gunnison sage-grouse perform mating displays, they have a fairly regular pattern of behaviors followed by a few seconds of rest (Young et al. 1994). However, sage-grouse can be quite variable in how long they perform the displays and how long they rest between bouts of mating displays. Because bouts of displays can vary by individual, absolute definitions of time defining a bout often mask individual variation in a species. There are several techniques that allow observers to define bouts mathematically (Slater and Lester 1982, Sibly et al. 1990, Martin and Bateson 1996).

USEFUL NEW CONCEPTS

Improved technology has made aspects of recording animal behavior easier and allowed us to view previously inaccessible types of behavior. Use of computers, specialized software, and improved camera technology has dramatically aided our ability to record and analyze behavioral data.

Software

Software has been developed for quantifying animal behaviors, social structure, movements, spatial data, and vocalizations. There are numerous programs available that allow a laptop computer or personal digital assistant (PDA) to record and analyze behavioral data. For example, Biobserve (<http://www.biobserve.com/>) provides software for generating ethograms, correlating ultrasound to behavioral observations, recording events and social interactions, and creating x/y coordinate systems from videos. The company also provides hardware for using infrared sensor and illumination to record observations of behaviors directly to computers. Many products allowing researchers to capture behavioral data and ethograms work on PDAs and smart phones (e.g., Spectator Go! Professional; <http://ptf.com/spectator/>), as well as on more traditional

hardware, such as laptops and desktops. Other commercial products include **Forager** (Amber Waves Software, Lancaster, PA), a program designed to simulate current foraging concepts, record data, and produce reports and maps. Many academic laboratories produce software for use on both Windows and Macintosh platforms. For example, JWatcher, developed by researchers at the University of California–Los Angeles and at Macquarie University, Sydney, is a powerful Java program designed to assist in recording focal animal data (<http://www.jwatcher.ucla.edu/>). The Animal Behavior Society has both a website with current software (<http://www.animalbehavior.org/Resources/software.htm>) and archives of software, as does an international site from the University of Saskatchewan, Saskatoon, Canada, focusing on applied ethology (<http://www.usask.ca/wcvm/herdmed/applied-ethology/links.html#software>). Colorado State University (Fort Collins) also has a large collection of software developed for examining mark–recapture data for population estimates and distributions (<http://www.cnr.colostate.edu/~gwhite/software.html>).

There are several challenges associated with using computers, cell phones, or hand-held PDAs to record observational data. Many researchers have been confronted with the unfortunate reality their electronic information has not been recorded or saved through a variety of failures. Another challenge, not unique to this platform, is that watching behavioral interactions while operating recording computers (or pencil and paper!) causes observers to take their eyes off of their subjects. The advent of voice recognition software will likely replace tape and digital recorders as a solution to this enduring problem (White et al. 2002).

Global Positioning System Telemetry Combined with Activity Sensors

Although Global Positioning System (GPS) collars have revolutionized telemetry (see Chapter 18, This Volume) and provided much more insight into individual use of habitat, their use simply provides an animal's position at a much more frequent rate than what traditional very high frequency (VHF) transmitters provided. A new generation of GPS transmitting collars are equipped with a dual-axis acceleration sensor (Vectronic Aerospace, Berlin, Germany), that can be highly correlated with simple individual behavior categories, such as feeding, resting, and locomotion in ungulates (Lötker et al. 2009) and to levels of activity in brown bears (*Ursus arctos*; Gervas et al. 2006).

Robotics

During the past decade, as technology improves and costs are reduced, some biologists are working with engineers to design robotic technology to address hypotheses about animal behavior. As robotic technology improves, it will provide an opportunity for doing experimentally based behavioral studies that can help explain individual responses to

specific visual cues in conspecifics. Robots have been used in the field of animal behavior to understand the evolution of learning and to test specific hypotheses about the mechanisms of behavior (Webb 2000).

Typically, a **robot** is an electromagnetic machine controlled by a computer program and is designed to mimic actions of humans or animals. Robots can either mimic the appearance of an individual in the species or, in research designed to look at the instinctive behaviors, they may look nothing like the animal itself, but accurately mimic a visual or tactile signal. The general concept of mimicking animal signals or behavioral cues has been applied in audio playback experiments and with mechanical models for decades; however, as robotic technology has become better and less expensive, researchers will increasingly be able to model more complex visual, tactile, and auditory behaviors for focal animal studies in the field.

Currently, a plethora of behavioral studies have used robots to mimic specific behaviors in focal animal studies both in the laboratory and in the field (Michelsen et al. 1992, Patricelli et al. 2002, Göth and Evans 2004b, Martins et al. 2005; Partan et al. 2009). One example of a current use of such technology is illustrated by Gail Patricelli's work (Patricelli and Krakauer 2010) with sage-grouse robots. Patricelli (University of California–Davis, personal communication) is using robotic technology to test hypotheses about male responses to female behavioral cues (Fig. 19.10). Another unique use of the technology that may assist in captive breeding programs is using female robots to collect sperm (T. L. Hicks, Western State College of Colorado, personal communication) from males of species in which traditional collection of sperm would involve invasive methods. Such use of behavioral signals and robotic technology also can lead to an examination of male fertility and inbreeding depression in field populations, in which habitat fragmentation may have led to low genetic variation and possible decline in individual fertility.

Perhaps one of the most promising areas of wildlife and conservation management currently being explored with

robotics is using robots to better understand social cueing. **Social cueing** is the mechanism by which individuals in a population make decisions about when to join groups (conspecific attraction) and exhibit social behaviors that can influence choice of habitats for foraging, predator avoidance, and mating interactions. Understanding how individual behaviors influence formation of social groups and habitat choices can be a strong tool for wildlife managers working to promote reintroductions of populations into underutilized habitats or habitats that may have been historically disconnected by fragmentation of core habitats. For example, Ackerman et al. (2006) found that social cueing was increased in some species of waterfowl when decoys were motorized to add wing movements.

Sound Recordings and Sound Arrays

An interesting combination of new technologies involving combining digital audio with video recordings has led to the creation of digital recording arrays, such as acoustic directionality measurement systems (Patricelli et al. 2007) and acoustic location systems (Mennill et al. 2006, Fitzsimmons et al. 2008). These **array systems** measure sounds in the field from animals inside an array of 8–16 microphones. Such technology can not only help explain the directionality and context of different types of vocalizations (alarm calls versus mating calls), but also may allow the possibility of spatially tracking and locating animals on larger spatial scales, helping to clarify their use of the landscape. The use of digital vocal arrays also is leading to current research on the effects of energy development on species dependent on acoustical signaling to attract mates, such as sage-grouse and songbirds in the shrubsteppe habitat in the West. Finally, such systems may become increasingly common for trying to ascertain the presence and location of increasingly rare species as habitat fragmentation and degradation leads to increased extirpation of species. Such information could lead to targeted protection efforts as well as to target population augmentation attempts to maintain small populations.

Cameras

Video can be useful for field studies, because observations can be viewed multiple times, and different sampling methodologies can be used on the same behavioral sample. Video images of field observations also can be used as important training tools to increase interobserver reliability. Video cameras can help observers see details of rapidly performed behaviors and understand the mechanisms of those behaviors. Longer battery life (up to 12 hr) and the advent of compact digital video cameras have made these devices increasingly useful and portable for field studies. Along with changes in size and weight have come improvements in technology. Today, even a relatively inexpensive digital video camera has superior light-gathering ability compared to those commercially available during the past decade, allowing high quality

Fig. 19.10. A female greater sage-grouse robot used to study male responses to females on the lek. Photo courtesy of A. H. Krakauer.

records during dusk and dawn. There also are video cameras and optical devices sensitive to infrared light that have infrared light emitters in them for night viewing. Another technology change has been the advent of **fiber optic** cameras that can be placed into nests, dens, and burrows to allow glimpses of behaviors previously unavailable for observation. Inexpensive wireless tilt cameras are increasingly being used to record data as well.

Digital cameras can be used to take pictures of feathers, pelage, skin, or scar patterns on animals, allowing them to be individually identified. Although traditional cameras also can perform this task, the resolution and ability to immediately access and manipulate digital images make them much more useful in the field. Both video and digital cameras can be set to automatically record events in the absence of the investigator (see Chapter 10, This Volume). Although there is some risk of technology failure with such endeavors, the ability to capture rare events of particularly secretive animals or to record depredation events makes automatic recordings a welcome additional field tool.

Internet Access

The advent of increased access to the Internet has enormous potential for allowing exchange of raw data and observations that can enhance research efforts and collaborations. Most peer-reviewed journals no longer publish general observations or common and rare events that can provide insight into behavioral events. The inability to examine other researchers' data in a form that leads to new analyses increases wasteful efforts of repeating studies and hinders population comparisons. Posting of such data on personal websites would be helpful. A second opportunity provided by the Internet is the ability for researchers to share video examples of tools, such as digital ethograms. Stewart et al. (1997) created a multimedia vocal ethogram of European badgers based on digital video. These types of contributions, although not publishable in the traditional sense, enhance communication among scientists and help alleviate disagreements in the published literature based on misunderstandings of basic methodology. Sharing of Internet databases and methodologies led to major advances in DNA research and could do the same in the field of behavioral ecology.

MANAGING HUMAN (ANIMAL) BEHAVIOR

Managing human behavior will be one of the most important wildlife management priorities in the 21st century. Historically, managing human exploitation of resources was the most common form of behavioral management. Currently, human behavior associated with nonconsumptive uses of wildlife is of growing interest and concern. Many states and provinces receive greater economic benefits and associated human impacts from recreational activities, such as wildlife watching, than they do from hunting. In 2006,

the 71 million American wildlife watchers (Fig. 19.11) who visited, photographed, and fed wildlife had a reported economic value of US\$122.6 billion, including paying US\$18.2 billion in state and federal taxes (Leonard 2008). Although federal land-management agencies are beginning to grasp the implications of changing uses of wildlife and their ecosystems, most state and provincial agencies are still focused on hunting and other consumptive uses.

As habitat and wildlife viewing becomes increasingly restricted due to reduced areas of suitable habitat and growing conservation concerns, the impact of human disturbance on animal behavior and fitness will increase (Hockin et al. 1992, Knight and Gutzwiller 1995, Gill and Sutherland 2000, Fernández-Juricic et al. 2005). Animals may avoid areas with high human traffic, noise, or light pollution, or structures (e.g., blinds), resulting in habitat sinks or areas unsuitable for their reproduction and habitation. For example, bald eagles are less likely to use areas with heavy foot and fishing boat traffic, may experience disturbances up to 500 m away, and will delay foraging by several hours if disturbed (Stalmaster and Kaiser 1998). Several studies have demonstrated that at least some species will avoid roads (Mattson et al. 1987, Gill 1996), causing the effects of roads to be greater than the actual area of habitat loss. Sutherland (1998a) developed mathematical models to examine the effects of human disturbance at the species level. Despite the documentation of recreational impacts, recreationists do not perceive their activities as impacting wildlife (Taylor and Knight 2003). A critical role for behavioral biologists and ecologists is to provide information to wildlife managers about the consequences of human disturbance on population parameters, such as density-dependent breeding and mortality.

Increasingly, wildlife managers will need to take proactive steps toward managing the impacts of human behavior on wildlife. Although the formation of "Watchable Wildlife"

Fig. 19.11. The increase in wildlife viewing requires new approaches to managing human behavior to prevent impacts on wildlife. The dancing greater prairie-chicken (*Tympanuchus cupido pinnatus*) on the photography blind was performing a breeding display at a watchable wildlife area at the Nature Conservancy's Dunn Ranch, Eagleville, Missouri.

(<http://www.watchablewildlife.org/>) sites may help consolidate impacts, it is important that such sites are monitored and evaluated as to their population-level impacts. In the Gunnison Basin, Colorado, the designation of Gunnison sage-grouse as a new species (Young et al. 2000) led to enormous increases in visitation at a designated viewing area. As visitor numbers increased, attendance of males and females at that mating ground declined at a rate greater than at mating grounds not designated for public viewing (J. R. Young, unpublished data). Clear criteria for managing human impacts are needed as well as studies providing wildlife managers with data to make informed decisions. Such incidents as bear attacks and other negative interactions with wildlife are increasing at refuges and national parks. Research, management, and education will be important undertakings as increasing numbers of people seek visitation to such sites with concomitant effects on wildlife and human behaviors.

FUTURE DIRECTIONS

The challenge for future biologists in wildlife management and animal behavior is to examine how studies can better integrate these fields. A study by Huwer et al. (2008) demonstrated the importance of integrating the fields of wildlife biology and animal behavior. They used human imprinted sage-grouse chicks (Fig. 19.12) to test ideas about effects of habitat quality on chick development. Their study was helping resolve important management and conservation questions in sage-grouse management that could not be resolved with traditional radiotracking or observational studies. This study is an excellent example of understanding the concept of Umwelt and using the species instinctive behavior to learn about the foraging ecology of a species. Such insights are leading to further imprinting studies to better understand the effects of grazing on Gunnison sage-grouse. Other areas of investigation for which behavioral studies can pro-

Fig. 19.12. Sherri Huwer uses a field incubator to collect her human-imprinted Gunnison sage-grouse chicks at the end of the field day. Photo courtesy of J. R. Young.

Table 19.3. Examples of animal behavior studies that could enhance current efforts to manage and conserve species

Behavior study	Description of study
Allee Effect	The Allee Effect is a decline in individual fitness due to low population density. Recent behavioral studies suggest that mechanisms for reduced fitness at low population densities may be behavioral. An important tool for conservation will be to understand the role of individual behavior in increasing risk of extirpation or extinction in populations of different sizes.
Communication	Detecting sources of communication among conspecifics can enhance understanding of social structure and increase wildlife managers' ability to census populations. Increasingly important is understanding how anthropogenic sources of environmental "noise" in smells, visual disturbance, and sounds influence populations.
Dispersal	Knowing which gender and at what age animals disperse from family groups, distances they travel, as well as the conditions leading to survival success, will be critical for habitat designation in multiple use areas and for reserve design.
Diversity	Research quantifying behavioral diversity among individuals and populations is an important tool for wildlife management. Although many wildlife managers are sensitive to the concept of maintaining morphological and genetic diversity, few consider the importance of managing to maintain variation in behavior. Behavioral flexibility in a population is critical for allowing adaptation to different ecological conditions and changing landscapes.
Foraging behavior	Studies showing the effects of habitat quality on distribution of animals and subsequent changes in behavior in suboptimal habitat patches will be important as increasing human populations intrude into traditional foraging sites of animals. Foraging behavior often tells us much about how to design or conserve species' habitats, as studies of foraging behavior can elucidate how an individual weighs the risks of predation, the quality of food supply, and interactions in and among species.
Learning and cultural	One of the major causes of failure of reintroductions has been that newly released animals fail to know transmission of behavior where to forage, find mates, and hide from predators. Field studies of species investigating the importance of conspecific's roles in the transmission of behavior could be invaluable.
Life history traits	Traits, such as fecundity, age class, and survival, can change due to behavioral responses to exploitation of species. Understanding population responses to exploitation will require an understanding of individual behavior.
Mating systems	A fundamental understanding of how changes in densities of populations and of their preferred habitats affect mating system and facultative sex ratios in species could help managers understand population-level responses of species of concern as well as hunted species. Understanding mating social structure in a population can aid in reducing the myriad of assumptions used to estimate parameters in population viability models.
Migration	Understanding the mechanisms and evolutionary causes of migration will be critical during the next century as human population growth leads to greater habitat degradation, fragmentation, and loss. Knowing why an area is critical for migratory success will allow either preservation or replacement to facilitate traditional movements.
Sensory studies	We are only beginning to understand the unintended consequences of how odor and light pollution impact migrating species. Basic research into animal senses could provide answers to some of the more intractable wildlife management and conservation challenges. A second area requiring more research is learning how to manipulate the distribution of animals through aversion conditioning based on an understanding of their sensory system. Such studies could lead to nonlethal animal control.
Sexual imprinting	Studying the mechanisms behind sexual choice are important steps to successful captive breeding programs, releases, and reintroductions.
Sexual selection	Studies examining the relationship between mating preferences and trait variation among populations could allow predictions of success for population augmentations.
Stress	Changes due to atypical weather, pollution, disturbance, and population density can change hormonal secretions, leading to adaptable changes in behavior. Understanding which factors cause a physiological and behavioral change due to an animal's stress level will be critical for managing human presence and activity in important wildlife habitats.

From Sutherland (1998b), Gosling and Sutherland (2000).

vide new insights into wildlife management include communication, dispersal, diversity, the Allee Effect, and foraging behavior (Table 19.3).

SUMMARY

This chapter introduces methods for studying behavior by wildlife biologists and suggests important future areas of study. Given the global biodiversity crisis, large-scale changes in global weather patterns, and the continued loss of habitat, integrating knowledge of animal behavior with wildlife management and conservation is critical. A fundamental understanding of animal behavior will be necessary to develop robust

metapopulation models, understand true effective population sizes, and elucidate consequences of anthropomorphic changes on landscapes. Although conservation often is directed at the ecosystem level, and wildlife management generally deals with populations, all levels of biological inquiry (from genes to communities) are necessary for successful management and recovery of species and their ecosystems. Important first steps to fostering cross-disciplinary approaches include adding classes on animal behavior in wildlife curriculums, holding joint regional and national meetings of disciplinary societies, developing chapters and units on applied animal behavior for courses and programs, and being willing to embrace collaboration across traditional disciplinary boundaries.

Analysis of Radiotelemetry Data

INTRODUCTION

THE USE OF RADIOTELEMETRY and other methods of remote sensing provide investigators with data about locations of animals and their fates. These data are used to estimate several individual and population parameters, including resource selection, home ranges, dispersal, migration, and survival; because animals are marked and then resighted with nonmarked cohorts, population estimates can be obtained. Radiotelemetry affords us the ability to investigate features of wild animal populations that would otherwise be impossible (see Chapter 10, This Volume). This chapter provides an overview of the techniques available to analyze radiotelemetry data. The increased use of radiotelemetry in the past 2 decades, ever-growing array of analytical methods, and developments in technology have been accompanied by many publications and books about the technique (Kenward 2001, Millspaugh and Marzluff 2001). However, rapid developments continue on all fronts, making it essential that biologists stay aware of recent advances by investigating the latest literature and corresponding with colleagues and those developing analytical methods and computer software.

GENERAL CONSIDERATIONS

Radiotelemetry is used to address a wide variety of objectives, each with corresponding analytical issues and methods. However, with any radiotelemetry analysis, several general issues are relevant, regardless of the methods being considered. First, choice among analytical methods should be determined by the question of interest and the ecology of the species being investigated. Radiotelemetry is a means to an end, and analyses need to be tailored accordingly. There is no universal best technique for the analysis of radiotelemetry data. Although some analytical approaches need to be avoided, there are often better and worse options. Second, proper sampling design and sufficient sample sizes are vital to determining the strength of study conclusions. No data analysis approach can save a study that was not designed to ensure representative sampling and adequacy of sample sizes. Third, increased sophistication in analytical methods is often a way to make more effective use of data and increase the depth of ecological inference in radiotelemetry studies. Methods that make use of all aspects of telemetry data, particularly the temporal component, often allow more powerful insights than do traditional approaches. Explanatory power will be increased with approaches that directly integrate biology into the analytical model(s). These approaches are clearly the wave of the fu-

ture in the analysis of radiotelemetry data. Fourth, more than with perhaps any other analytical topic in wildlife ecology, one must be very careful when assessing recommendations in the literature about radiotelemetry data analyses. These recommendations are often based on limited comparison of methods with new techniques. Simulations are valuable for comparing methods, but beware of broad advice based on very limited case studies or simulations, particularly chosen to show a technique at its worst. Additionally, in terms of comparing techniques, real data provide a case study, not a broad perspective, and such case studies do not offer adequate support for sweeping conclusions about the utility of techniques. Fifth, biologists should beware of software variations, because seemingly similar methods can produce remarkably dissimilar results stemming from differences in software. The analysis of radiotelemetry data is often done using standalone computer packages developed for specific analytical techniques, and the utility of these packages is dependent on the programmers' knowledge and skill (Appendix 20.1). Programmers should offer transparency in the coding and assumptions made in their software. Sixth, greater transparency is needed when reporting results from radiotelemetry investigations. We strongly urge biologists to make raw data available (e.g., www.movebank.org or other archive) and report sampling design, sample sizes, user-defined options in analysis, and assumptions in their analysis and interpretation of telemetry data. Not only is this practice essential to meeting basic scientific standards regarding repeatability, but also the quality of inference from radiotelemetry results may depend heavily on methodological details often not reported.

SPACE USE AND MOVEMENTS

There are many motivations for studying animal movement. Nathan et al. (2009) identified 4 fundamental questions about organismal movement: (1) Why does an animal move? (2) How does it move? (3) When and where does it move? (4) What are the ecological and evolutionary consequences of movement? White and Garrott (1990) offered questions of "which," "why," "when," and "where" as motivations for studying movements of wildlife. Building on these basic questions, Nathan et al. (2009) proposed a **Movement Ecology Paradigm** that attempts to unify movement studies of all organisms around a conceptual framework that comprehensively considers the interplay between the organism and the environment. Understanding the proximate causes, mechanisms, and spatiotemporal patterns of movement is critical for understanding the evolutionary causes and consequences of movements, as well as the role of these movements in broader ecological processes (Nathan et al. 2009).

Radiotelemetry is a powerful tool for collecting information about animal locations, rates of movement, and in some cases, general behaviors associated with individual locations.

As a result, radiotelemetry often is essential for addressing the specific scientific and applied motivations of any study or research program examining movements. In this section, we focus on 3 commonly used groups of analyses: (1) estimating general summaries of **space use**, such as home-range or territory size and intensity of use of areas in the home range over a relatively long period (weeks or months); (2) drawing inferences about intra- or inter-specific interactions, such as the amount of overlap between 2 individuals of the same species, and (3) examining more detailed aspects of movement rates and trajectories, including movements in the home range and larger-scale migratory or dispersal movements. Another primary goal of many studies is to relate the intensity of space use to habitat characteristics, a topic that is briefly addressed in the following section on resource selection and more intensively in Chapter 17 (This Volume). Although we focus on these categories individually, one of the most exciting analytical developments over the past decade is mechanistic models that integrate across these artificial categories.

The Utilization Distribution and Home Range Analysis

A major objective of many radiotelemetry studies is to estimate the spatial extent of the area used by an animal and the intensity of use of different portions of this area during a finite period of time. Commonly, studies estimate the size of the **home range**, generally defined as the 2-dimensional area in which the animal conducts its "normal" activities (Burt 1943). Given the ambiguity of "normal," numerous more precise definitions have been proposed, and investigators need to carefully define what "home range" means in the context of their species of interest. For example, a biologist might choose to include paths of excursions to and from outlying locations as part of the home range, but exclude dispersal movements (Kenward 2001). The terms territory and home range are not interchangeable; some territorial species maintain only portions of their home range for "exclusive" or "priority use" (Powell 2000:70). Furthermore, biologists need to carefully consider whether standard definitions of home range make sense for their study situation. Despite some views to the contrary (Gautestad and Mysterud 1993), the home range concept has broad utility: in a defined period of time (White and Garrott 1990) and at a spatial scale of ecological or management interest, there is a finite area in which an animal conducts its activities (Powell 2000), and individuals of many species repeatedly traverse their general area of use. The home range concept may be less useful for species that wander irregularly at large spatial scales or spend large amounts of time at a few discrete locations, perhaps with occasional large scale dispersal or migratory movements. However, estimators discussed below still may be useful for assessing some aspects of space use, such as location and extent of migration corridors.

Kernohan et al. (2001:126) defined home range as “the extent of area with a defined probability of occurrence of an animal during a specified time period.” The probabilistic component of this definition clearly identifies the home range as summarizing one aspect of an animal’s **utilization distribution** (UD), which estimates the relative intensity or probability of use of areas by an animal (i.e., the relative frequency distribution of locations used by the animal; Jenrich and Turner 1969, Van Winkle 1975). Seen as a probability density function, the UD is the basis for summarizing numerous aspects of space use, such as home range size evaluated at specified probability contours as well as the location and number of **core areas** (portions of the home range with disproportionately high probability of use). The UD also can form the basis for probabilistic estimates of space use overlap between animals (Seidel 1992; see below) and use of different resources (e.g., vegetation types) in the home range (Marzluff et al. 2004). Therefore, methods that estimate a probabilistic UD rather than simply home-range polygon boundaries have broad utility (Kernohan et al. 2001).

Outliers, Home Range Contours, and Core Areas

In studies of space use, investigators need to consider how to handle **outliers**: locations that are comparatively far from most other observations, but that accurately represent forays or excursions outside the area “normally” used by each animal. How outliers are handled depends on the aspect of space use being examined and the analytical technique being used. For the commonly used **minimum convex polygon** (MCP) approach, such observations can cause severe overestimation of home range size. For other approaches, these excursions may not dramatically affect the estimated UD, but the biologist may not be interested in spatial extremes of the UD that have low probability of use. However, the potential for disproportionately high importance of unique resources at these used locations also must be considered (e.g., Powell et al. 2000:75, Fuller et al. 2005). Kenward (2001) and Kenward et al. (2001) summarized methods for statistical identification of individual outliers. The percentage of locations that have disproportionately high effects on the home range size estimate can be evaluated through visual inspection of utilization plots, showing the incremental decrease in estimated size as locations are omitted.

Commonly, investigators focus on inner subsets of the home range, either the minimum area containing a specified percentage of observed locations or the minimum area with the corresponding estimated probability of use (i.e., the minimum area over which the UD probability density function integrates to the specified probability). The latter approach is recommended, because it makes full use of the estimated UD, focusing on probability contours rather than being tied only to a (usually limited) sample of locations (Kernohan et al. 2001:136). The choice of which probability

contour to select can be somewhat arbitrary. The 95% contour is a standard summary (White and Garrott 1990, Laver and Kelly 2008). However, this choice should be made not simply based on what other studies have done, but on the biological questions of interest, the underlying biology and patterns of space use by the species of interest, and the management context of the study.

Some authors refer to a core home range as the subset of the home range excluding occasional outlier excursions (Kenward et al. 2001). More frequently, core areas are defined as much smaller subsets of the UD with disproportionately high use compared to the rest of the home range beyond what would be expected from a random distribution. Similar to approaches used for eliminating outlying locations, core areas may be defined based on arbitrary contour levels (e.g., 50%) or graphical tests (see Powell 2000). We encourage biologists to consider whether some arbitrary contour level adequately identifies an area of intense use. In many cases, we argue that such arbitrary designation of core area does not adequately capture the metric of interest. Rather than justifying selection of the 50% contour because others have used it, consider methods that actually directly identify and estimate the area of intense use. For example, Samuel et al. (1985), Samuel and Green (1988) and Seaman and Powell (1996) have examined differential intensity of use in a range to help delineate the core area, regardless of associated probability contours.

Criteria for Comparing Home Range Methods

Before providing an overview of common estimators, we describe important criteria for comparing alternative methods, similar to the framework provided by previous reviews (Kenward 2001, Kernohan et al. 2001). Our criteria partly overlap those of previous reviews, but we emphasize some additional issues that are relevant to current trends in ecological data analysis (Table 20.1).

1. Calculation of a UD. As discussed above, methods that estimate a probabilistic UD allow estimation of home range size based on probability contours and facilitate other UD-based space-use analyses. The use of UDs also is useful in complementary analyses of space use overlap and resource selection.
2. Sample size requirements. Acceptable bias and precision at moderately low sample sizes is a desirable property of home range estimators (e.g., Seaman et al. 1999, Kenward 2001, Kernohan et al. 2001). Although our focus is on minimum sample sizes needed by each method, such technologies such as satellite telemetry now allow automatic collection of hundreds or thousands of locations on some species. The performance of estimators needs to be compared more thoroughly across a broad range of sample sizes, from datasets containing a few dozen observations, as is characteristic

Table 20.1. Comparison of home-range estimators based on selected evaluation criteria^a

Comparison of estimators	Home range			Explanatory/mechanistic		
	MCP	Cluster	KDE	Model entire set of locations	Sequential movements modeled	Sequential movements as a function of covariates
Calculates utilization distribution	No	No	Yes	Yes	Yes	Yes
Sample-size requirements ^b	No	Yes	Yes	N/A	N/A	N/A
Incorporates temporal dimension	No	No	Yes ^c	No	Yes	Yes
Information theoretic comparison of alternative models	No	No	Yes ^c	Yes	Yes	Yes
Integrates ecological hypotheses into model structure	No	No	No	Yes	No	Yes
Thoroughly evaluated?	Yes	No	Yes	No	No	No

^a KDE = kernel density estimation; MCP = minimum convex polygon estimation; N/A = not applicable.

^b Estimated home range extent often stabilizes with 50 data points.

^c The standard kernel approach does not incorporate the temporal dimension or allow direct statistical ranking of alternative models, but the method has been extended to incorporate the temporal component of locations by using a multivariate kernel estimator and to allow direct ranking of alternative models if bandwidths are selected with likelihood cross-validation (Horne and Garton 2006a, b).

of ground-based very high frequency (VHF) telemetry, to much larger datasets typical of satellite telemetry studies.

3. Use of temporal component or other dimensions of space use. As modern telemetry data analysis progresses, estimators that can make use of the temporal dimension of location data will allow greater insight into animal space-use dynamics (Laver and Kelly 2008, Keating and Cherry 2009). Such estimators also can incorporate other dimensions of space use, such as elevation (Keating and Cherry 2009). Ranking methods higher if they incorporate the temporal dimension is based on the idea the temporal dimension of radiotelemetry data provides important information, rather than being a nuisance element. Past discussion of the temporal component of telemetry studies generally treated autocorrelation as a significant problem, because sequential observations collected too close together in time provide less information about space use than would a set of independent locations (White and Garrott 1990). In some cases, concern about **autocorrelation** leads researchers to discard some hard-earned data (e.g., by removing observations that may have some degree of autocorrelation) or to collect locations too infrequently to define space use by the animal. However, if the study design produces an adequate sample of locations for each animal throughout the temporal frame of interest, autocorrelation is of little concern (e.g., De Solla et al. 1999; Fieberg 2007a, b). As discussed previously in this chapter, an adequate sample generally will be based on a systematic and/or stratified design that ensures samples are collected throughout the daily and seasonal period of interest.

4. Feasibility. Although wildlife ecologists continue to develop and apply increasingly sophisticated statistical tools,

for many biologists, the ability to run analyses in standard statistical or Geographic Information System (GIS) software packages still will be an important factor in the choice of an analytical technique. Ideally, the availability of user friendly software would not drive selection of analytical options; in reality, it does. We encourage those developing analytical techniques to also consider the end user.

5. Facilitation of modern explanatory model-based inference. In traditional space use analyses, biologists used a single descriptive statistical model to estimate some property of space use (e.g., home range size) and then treated the resulting estimates as the raw data for subsequent analysis to assess ecological patterns. Modern ecological data analysis attempts to integrate such multistaged inference using models that incorporate alternative hypotheses about both the ecological process of interest and the observation process, along with variability in the data contributed by each process (e.g., Royle and Dorazio 2008). Uncertainty about the best statistical model for a dataset is not ignored, but rather multimodel inference incorporates this model-selection uncertainty. Home range estimators that can fit into this framework may be more powerful than purely descriptive estimators.

6. Extent of evaluation. Frequently, new UD estimators are introduced and promoted based on very limited comparisons with existing estimators and without good understanding of how these estimators compare across a range of distribution types and sample sizes. Estimators that have been evaluated thoroughly support a more informed choice about which method is most appropriate for a particular study.

OVERVIEW OF CURRENT METHODS

In this section, we provide a brief overview of current methods for estimating the UD and home range size. Several formerly commonly discussed estimators, including the bivariate normal and other ellipse approaches, the harmonic mean, Fourier transform, and grid-cell methods, are not discussed here, because we see them as superseded by other available methods. Additionally, currently available forms of these methods and their limitations have been extensively reviewed (White and Garrott 1990, Powell 2000, Kenward 2001, Kernohan et al. 2001, and Fuller et al. 2005). Instead, we discuss methods that currently are widely used or that have been recently developed, including the MCP approach, other recently developed polygon or linkage methods that may be of broader utility than the MCP method, kernel density estimation, and nonmechanistic and mechanistic models. The latter 2 approaches share the important advantage of being able to estimate a true probability density function corresponding to the UD.

MCP

The MCP method produces a convex polygon around (1) the least number of locations that will enclose all other locations (Silvy et al. 1979), (2) all estimated animal locations by minimizing the sum of the distances of segments linking the outer locations (Kenward 2001), or (3) the smallest polygon encompassing a specified proportion of estimated animal locations (White and Garrott 1990; Fig. 20.1). The area

of this polygon is the MCP estimate of home range size. Although this technique is the oldest home-range estimation approach (Mohr 1947, Hayne 1949b, Powell 2000), it has been and continues to be the most frequently used method (Seaman et al. 1999, Laver and Kelly 2008). Moreover, it still is sometimes recommended over modern methods, such as kernel density estimation (Wauters et al. 2007). However, the continued use and recommendation of MCP as a default method is bizarre, given its severe limitations. For example, Börger et al. (2006:1402) argued the method “should not be used at all for estimating home range size” (see also reviews by White and Garrott [1990], Kernohan et al. [2001], and Fuller et al. [2005]).

Although the MCP method is simple and assumes no underlying statistical distribution, it, “more than any other method, emphasizes only the unstable, boundary properties of a home range and ignores the internal structures” (Powell 2000:80). It is highly dependent on sample size, both because it requires a large sample size to provide adequate estimates (e.g., >100; Harris et al. 1990) and because as the number of samples increases, so does the probability of obtaining an outlying location that has a large effect on the MCP estimate (e.g., Anderson 1982, White and Garrott 1990) that would not heavily influence other methods. Although interior polygons can be formed that eliminate outliers (e.g., by delineating the polygon around the subset of 95% of locations that produces the smallest such polygon), defining such a polygon requires an even larger sample size to be collected, so that a sufficient subsample remains to cal-

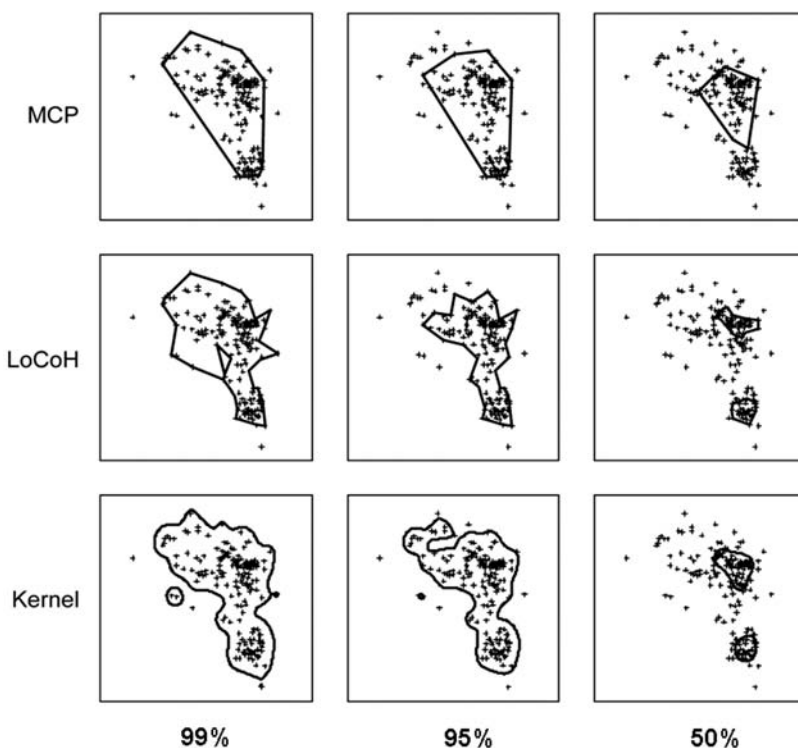

Fig. 20.1. Estimated 99%, 95%, and 50% home-range contours based on 187 radiotelemetry locations of a bull elk in Custer State Park, South Dakota. Results of 3 methods are shown: MCP = minimum convex polygon method; LoCoH = local convex hull method (adaptive form, with parameter a set as the maximum distance between observed locations; Getz et al. 2007); Kernel = fixed kernel estimates (normal kernel, plug-in estimation of bandwidth matrix with differential smoothing along x - and y -axes). Produced with program R (R Development Core Team 2008) using package *adehabitat* (Calenge 2006) for MCP and *LocoH* and package *ks* (Duong 2008) for fixed kernel.

culate this interior polygon. The MCP method ignores information provided by points within this outer boundary, and there may be large areas within this boundary that were never used by the animal (Powell 2000, Kenward 2001).

The simplicity of the MCP approach has led to it being recommended as an appropriate estimator for comparisons across studies (Harris et al. 1990). However, its sensitivity to sample sizes, insensitivity to internal use of the home range, and inconsistency in performance depending on the underlying point pattern (Downs and Horner 2008) make this comparability an illusion (Kernohan et al. 2001). In most cases, other modern methods discussed below better address the problems used by some authors as justification for recommending continued use of the MCP method. Problems with comparability among estimates from different studies are not limited to the MCP approach. In home range estimation in general, it is difficult to compare home range estimates from one study to another because of differences in sample sizes used to construct the estimate, choice of techniques (e.g., method of analysis and user defined options), and variations in software. All these factors should be reported and considered when comparing home range estimates across studies, and they argue for the importance of archiving raw data (<http://www.movebank.org> or other archives) to facilitate robust comparisons.

Other Linkage and Cluster-Based Methods

The MCP approach fits into the general category of methods that use alternative strategies for linking observations based on distance (e.g., between nearest neighbors or from a central point) and forming or merging polygons and/or clusters into one or multiple home-range components (Kenward 2001). More recently, applied approaches in this category can overcome some problems with the MCP method and currently may be the best approaches when there are unusable areas within the home-range outer boundary or other sharp boundaries between used and unused areas, if delineating these sharp boundaries is a priority (Kenward et al. 2001, Getz et al. 2007). One such approach, **incremental cluster analysis**, links locations into clusters that minimize the sum of nearest neighbor distances (Kenward 1987). In contrast to the MCP approach, this method allows multinuclear home ranges with multiple components making up the home range encompassing a specified percentage of locations. Kenward et al. (2001) also incorporate a test for identifying outlier locations that deviate from the distribution of nearest neighbor distances for the location set.

Similarly, local **convex hull** approaches first form local convex polygons for each location, where each polygon encompasses the focal point and either its k nearest neighbors or all neighbors within a specified distance of the point (Getz and Wilmers 2004, Getz et al. 2007; Fig. 20.1). Hulls are sorted based on their size or the number of locations they contain; the union of polygons is formed incrementally, starting with

the smallest polygons or those with fewest points, until a specified percentage of the locations are contained in the resulting polygon. This polygon is then taken as the $x\%$ contour of the estimated UD (Fig. 20.2). An adaptive form of this approach uses variable distances to determine which neighbors to include in each point's convex hull, with shorter distances used for locations in heavily used areas. With local convex hull approaches, the number of neighbors, the distances used, or sum of local distances in the adaptive approach to form local polygons must be specified. Getz et al. (2007) recommends choosing the minimum values for these parameters needed to form polygons that exclude known holes in the UD (e.g., unusable areas, such as lakes for a terrestrial species that does not swim).

These linkage or convex hull methods form clusters and polygons based on linking observed locations (Fig. 20.1). The resulting home ranges therefore will be delimited by observed locations. This is true for both the individual polygons associated with each point or cluster and the resulting overall polygons formed from merging polygons or clusters. As a result, the home range isopleths can follow rigid boundaries and exclude known unusable areas in the home range. However, the property the estimated home range will not contain areas outside the observed set of external locations is not always an advantage: with limited sample sizes, there may be a high probability that nontrivial use occurs outside the outer periphery of locations, particularly if there is clustering of high use at the inner edge of this periphery.

Although the nearest neighbor approach of Kenward et al. (2001) has been evaluated using numerous real datasets, evaluation of local convex hull estimators has mostly focused on a limited set of point patterns with sharp boundar-

Fixed kernel utilization distributions for these locations based on 3 bandwidth values (h). (B) $h = 500$. (C) $h = 150$. (D) $h = 1,500$. UTM = Universal Transverse Mercator coordinates. (A) From Millsbaugh (1999); kernel plotting routines from Bowman and Azzalini (1997).

ies and on a location data from a few animals. These estimators need much more extensive examination across a broader range of point patterns and sample sizes. Although with the MCP and these approaches, a series of isopleths can be formed that approximates probability contours of the UD, none of these approaches form a formal probability density function as an estimate of the UD. Resulting isopleths could still be used to modify estimates of space use overlap or resource selection to account for nonrandom space use in the home range, but their use would depend on binning areas into discrete isopleth slices rather than using a continuously defined UD.

Kernel-Based Methods

Kernel density estimation (Silverman 1986; Worton 1987, 1989, 1995) has been widely recommended as the default home-range/UD estimation method (Seaman and Powell 1996, Powell 2000, Kernohan et al. 2001, Gitzen et al. 2006), although this recommendation is challenged frequently (Getz and Wilmers 2004, Hemson et al. 2005, Row and Blouin-Demers 2006b, Downs and Horner 2008). Like other approaches discussed above, the standard kernel method is nonparametric, in that it assumes no specific probability distribution for the underlying UD. Like convex hull methods, the kernel approach is formed by the union of individual components (i.e., kernels) formed for each location; in this case, the overall estimated UD is the sum of individual kernel functions centered at each location (Silverman 1986, Kernohan et al. 2001). This overall probability density function typically is evaluated across a fine mesh grid of points encompassing the observed locations and extending beyond them to allow for nonzero probability of use exterior to the outer periphery of locations. The density value at an evaluation point x (usually a grid point) is given by

$$\hat{f}(x) = \frac{1}{nh^2} \sum_{i=1}^n K\left[\frac{\bar{x} - X_i}{h}\right],$$

where X_i contains the coordinates of the i th observed location, n is the number of observed locations, h is the **bandwidth or smoothing parameter** (or vector of (h_x, h_y) to allow differential smoothing along the x - and y -axes), and $K(\cdot)$ is a kernel function. Usually $K(\cdot)$ is a probability density function; most frequently the Gaussian (bivariate normal) kernel has been used, but this choice has the slight disadvantage of allowing locations far from the evaluation point to have a finite if very small contribution to the estimated density. Other kernel functions ensure that points beyond some distance (in relation to the bandwidth) have exactly zero contribution.

The choice of a suitable bandwidth is the most critical, and controversial, factor involved in applying the kernel method (Table 20.2). The bandwidth affects the amount of smoothing applied to the observed locations by controlling how the effect of each location on the estimated density at an evaluation point scales with the distance from the loca-

tion (Fig. 20.2). Relatively large bandwidths allow locations far from the evaluation point to significantly influence the estimated density function at that point, producing unimodal, smooth estimated UD and large estimates of home range size (Fig. 20.2D). Overly small bandwidths cause the estimated UD to fragment into numerous individual components (Fig. 20.2C). Thus, estimates of home-range size necessarily increase as bandwidth values increase; this phenomenon is not a weakness of the kernel method (Row and Blouin-Demers 2006), but is simply an inherent property. Separate bandwidths for the x - and y -coordinates, or a **bandwidth matrix** that allows smoothing to be oriented along axes rotated from the x - and y -coordinates, are recommended (Wand and Jones 1995, Amstrup et al. 2004), but many home-range software packages do not allow automatic incorporation of such differential smoothing. The optimal bandwidth for a set of locations (i.e., the bandwidth minimizing discrepancy between the estimated and true UD) is affected by the spatial spread of the data and the overall spatial pattern (e.g., degree of clustering) of observed locations.

In addition to the choice of a general bandwidth selection method, there are options of using either **fixed kernels**, in which the bandwidth stays constant for all locations, or an **adaptive or variable kernel** approach, in which different amounts of smoothing are applied locally, depending on the number of nearby locations. Generally the fixed kernel approach may perform better than the adaptive kernel approach implemented in ecological studies, primarily because the latter produces relatively greater smoothing at the edges of the estimated UD (Seaman and Powell 1996, Seaman et al. 1999). When there are sharp boundaries between used and unused areas, the standard kernel method may overestimate home range size and estimate significant use of unusable areas, regardless of which bandwidth method is used (Getz and Wilmers 2004, Downs and Horner 2008). Thus, territories that have rigid boundaries may be problematic for current kernel estimators. However, the imprecise and ambiguous nature of territorial boundaries (Powell 2000) may mitigate this problem, especially for species with larger ranges (Jetz et al. 2004). Bounded kernels that allow a sharp discontinuity between heavily used and unused areas are possible (e.g., Hazelton and Marshall 2009), but have not been implemented in ecological studies

Nonmechanistic Models

Many noninferential statistical models have been used to analyze movement paths of wildlife. These include random walks, first passage time, multibehavioral models, fractals, and Lévy flights (Hagen et al. 2001). These statistical approaches have been widely reviewed (Turchin 1998, Schick et al. 2008) and applied in the ecological literature. For example, the **fractal index** (D) is a scale-free measure of the tortuosity of the movement path (With 1994). The value of D typically ranges from 1 to 2; a value of 1 implies straight line move-

Table 20.2. Overview of bandwidth selection methods used for kernel density estimation in space-use studies^a

Method	Description	Strengths	Weaknesses	Selected references
Reference (optimal)	Would minimize discrepancy between true and estimated UD's if the distribution was bivariate normal	Easily calculated; performance has been evaluated thoroughly	Oversmooths greatly, leading to high over-estimates of home range size; not optimal except for unimodal UD's	Silverman 1986, Seaman and Powell 1996
Scaled-reference	Reference bandwidth multiplied by a fixed proportion	Easily calculated; can reduce oversmoothing and out-perform unscaled reference bandwidth	Optimal scaling proportion depends on UD shape and must be picked subjectively	Worton 1995
LSCV	Numerical minimization of objective function based on mean integrated squared error of estimated distribution	Bias is low compared to reference method; if it does not fail, it can perform well for UD's consisting mainly of tight clusters of locations	Often fails or identifies inappropriately small bandwidth if there are identical observations or large sample sizes; high sampling variability	Silverman 1986, Seaman et al. 1999, Gitzen and Millspaugh 2003
Likelihood cross-validation	Minimize score function corresponding to the K-L distance between the true and estimated UD's	Outperforms LSCV in terms of integrated squared error at sample sizes 40–60 in terms of K-L distance and sampling variability at all sample sizes and enables multimodel comparisons	Performance versus plug-in or solve-the-equation approaches unknown; size estimates compared to positive bias in home-range size estimates compared to LSCV	Silverman 1986, Horne and Garton 2006a
Plug-in or solve-the-equation	Error function is minimized theoretically, then numerical estimate is iteratively calculated	Always produces a meaningful estimate (unlike LSCV); oversmooths much less than reference bandwidth	Oversmooths significantly and may be outperformed by LSCV if the UD has sharp boundaries between used and unused areas or consists mainly of tight clusters of locations	Wand and Jones 1995, Gitzen et al. 2006

^aK-L = Kullback–Leibler; LSCV = least-squares cross-validation; UD = utilization distribution.

ment and of 2 denotes a random movement path (but see Turchin [1998] for cautions about the use of this index). The primary attraction of these descriptive methods is for linking these movement patterns to patterns of the landscape to determine how species respond to and perceive their environment (With 1994, Nams 2005). For example, With (1994) evaluated how D for 3 species of acridid grasshoppers (Orthoptera) was affected by landscape structure in a grassland mosaic.

However, the linkage between these statistical descriptors and the underlying landscapes has historically been weak and “none of these models has an ability to test for how landscape features actually influence the movement process” (Schick et al. 2008:1344). Instead, new inferential models, such as state-space modeling (Morales et al. 2004, Forester et al. 2007, Eckert et al. 2008, Patterson et al. 2008) and other mechanistic models provide powerful new tools for modeling the movement steps and relating the species' movement patterns to its environment.

MECHANISTIC MODELS

Most home range estimators discussed to this point are models of animal movement based on a statistical description of point-location patterns. Modern approaches to modeling

space use and movements include both statistical and conceptual advances over traditional estimators. Traditional home-range analyses have not included the time of locations as an important variable, but only used them to be sure locations were statistically or biologically independent (Swihart and Slade 1985, Doncaster and Macdonald 1997). However, the exact sequence of points in an animal's path contains additional information not exploited by approaches that ignore the temporal aspect, and many models explicitly consider the links between successive locations. Temporal autocorrelation thus is not an issue of concern, but it is directly integrated into the model structure (Patterson et al. 2008, Schick et al. 2008). As discussed earlier in the chapter, location error is present and often significant in all radiotelemetry studies. Furthermore, unless location estimates are made every few seconds, trajectories connecting consecutive locations also will include additional error by presuming a straight line path between points. Modern analytical approaches explicitly incorporate uncertainty in estimated locations and movement paths, with separate components modeling the observational process (to account for location uncertainty) and the biological processes (Schick et al. 2008). The best of these models directly incorporate biological mechanisms relating space use and movement to the underlying landscape, separate biotic and abiotic forcing (e.g.,

wind or water currents), and recognize that multiple behavioral patterns may be represented in movement data. Rather than basing inference on a single descriptive model, investigators increasingly are using multiple models tied to alternative biological explanations for patterns of space use, using a likelihood framework that allows direct comparison of these alternative models (Burnham and Anderson 2002, Royle and Dorazio 2008).

Thus, there is rapidly increasing focus, both in home-range/UD analyses and in broader analyses of locations and movements, on multimodel inference based on models that directly incorporate both observational and biological uncertainty and that make use of the temporal and behavioral dimensions of radiotelemetry data. Compared to traditional descriptive methods, this approach is well suited for predicting how space use may change under alternative ecological or management scenarios (Moorcroft and Lewis 2006). We use this section to briefly review these approaches and encourage readers to review Lima and Zollner (1996), Morales et al. (2004), Armsworth and Roughgarden (2005), Jonsen et al. (2005), and Schick et al. (2008) for additional background and specific examples.

The key process that most movement models are trying to elucidate is the relationship between a moving animal and its environment. Explanatory and mechanistic models directly incorporate ecological factors hypothesized to affect space use into the UD estimation process, incorporate rules governing movements between sequential locations, or combine both of these approaches to model sequential movements as a function of hypothesized explanatory factors. The first approach does not assess movements per se, but fits explanatory models to observed locations without incorporating the temporal link between sequential observations. For example, Matthiopoulos (2003) used a descriptive kernel of space use, with supplemental information about ecological factors and other factors affecting space use, and therefore can be seen as a link among descriptive and explanatory approaches. Additionally, Horne et al. (2007) estimated a probability density function with a maximum likelihood approach as a function of spatially explicit covariates, such as habitat variables and proximity of potential mates. In both studies, alternative models were compared with an information theoretic approach (Burnham and Anderson 2002); both the probabilistic UD and coefficients for the effects of covariates are estimated simultaneously, thus unifying home range estimation and resource selection analysis into an integrated approach (Horne et al. 2007).

Another category of methods explicitly considers the links between successive locations (Kernohan et al. 2001). Temporal autocorrelation thus is not an issue of concern, but is directly integrated into the model structure. However, these movements are not typically modeled as a function of explanatory variables. This family of approaches is not new. The estimator of Dunn and Gipson (1977) assumes that a

stochastic diffusion process determines movements between successive locations, with an underlying UD that is a bivariate normal distribution (White and Garrott 1990). Horne et al. (2007) demonstrate the potential utility of **Brownian bridges** for estimating home range size and other movement characteristics. The Brownian bridge approach models a stochastic movement process (random walk) conditioned on the locations of each pair of sequential location; Horne et al. (2007) build on the Brownian bridge to develop a probability density function for overall space use (i.e., the UD) that also incorporates telemetry uncertainty associated with each recorded location. No assumptions are made about the shape of the UD. Like standard nonmechanistic approaches, the estimation of the UD does not integrate habitat or other ecological factors directly into the estimator.

The final, and most sophisticated, approach to relating animal movement to environment also builds on simple rules determining movements and then scales from individual movements to produce an estimate of the overall probabilistic UD. However, in contrast to the previous approach, here ecological factors are directly incorporated. These methods start with simple statistical descriptions of movement (e.g., diffusion or random walk processes), but then add movement rules as functions of covariates hypothesized to affect movements. Movement rules might include moving toward or away, or changing the movement rate or turning propensity, in response to certain habitat characteristics or social factors (Moorcroft and Lewis 2006). This mechanistic approach allows direct modeling of the primary ecological factors and processes hypothesized to affect space use as well as a prediction of how space use may be affected with changes in these primary factors. Models are fit with maximum likelihood techniques, allowing information theoretic comparison of alternative models and multimodel inference. For example, Moorcroft et al. (1999, 2006) used local landscape data on topography and prey availability to build a model of coyote (*Canis latrans*) movement based on random diffusive movement. They found the prey-driven model was a better fit with telemetry data from the same area. By making sequential movement direction a function of habitat features, Moorcroft and Barnett (2008) demonstrate how a mechanistic model can integrate estimation of the UD and resource selection analyses into a single framework. Christ et al. (2008) perform a similar integration by making the likelihood of a relocation, given the previous location, a function of habitat covariates. Moorcroft and Barnett (2008) essentially used a resource selection function (RSF) embedded in a mechanistic home-range model, but they did not explicitly consider the time series nature of the telemetry data. Models that consider temporal autocorrelation in data, as well as connections with the underlying landscape, are essentially deducing a RSF from movement paths.

The final conceptual advance we review here regarding animal movement modeling is the integration of movement

patterns with animal behavior. Movement patterns can be used to infer the behavior of an animal (also known as its state) and then used to better predict its subsequent movement and habitat use. The effect of factors on subsequent movements depends partly on an animal's perceptual range (Mech and Zollner 2002), and this relationship can be directly incorporated into behavioral movement models. When integrated with the other statistical and conceptual advances discussed above, these integrated **movement ecology models** offer the most sophisticated view of animal movement. These models offer the potential for predicting the realistic response of individual animals to changing conditions, be they dynamic environments or management scenarios. Such models will allow us to infer behavior from movement patterns, find relationships between behavior and habitat, and use these relationships to better predict movements.

Although we expect rapid expansion of the models described in this section, several issues must be considered if a biologist is considering using these approaches. First, the ability to develop models that target specific hypotheses about the species of interest is a major advantage, but this specificity also means that models need to be tailored to each species and study situation, if not to every individual animal. Although this approach more accurately reflects the complex reality of animal movement, it also produces a new challenge to make the results of one study more generally relevant, particularly for conservation and management. Second, the mathematical complexity of these approaches is beyond the quantitative skills of many biologists. The examples we describe above include models developed as partial differential equations, hierarchical Bayesian statistics, and state space models, to name a few. The hierarchical aspect of many of these models is functionally useful, because it allows them to factor higher dimensional problems into lower dimensional, conditionally dependent ones (Berliner 1996, Wikle et al. 1998, Clark 2005). However, even quantitatively inclined ecologists may have difficulty implementing such complex models. Finally, their bias and precision, compared to previous estimators, in estimating home range size and parameters related to factors affecting space use have not been evaluated thoroughly. Sample size requirements and evaluation of how frequently data need to be recorded have not been examined in detail (Horne et al. 2007).

SITE FIDELITY, ANIMAL INTERACTIONS, AND SPACE USE OVERLAP

We discuss site fidelity and animal interactions together, because to some extent they both fall under the general umbrella of space use overlap. **Fidelity** is "the tendency of an animal either to return to an area previously occupied or to remain within the same area for an extended period of time" (White and Garrott 1990:133). Fidelity measures components of overlap over time for the same individuals or

group, whereas interaction analyses looks at overlap among different animals at the same time or over time. Therefore, some analytical methods used to assess fidelity also are useful for looking at spatiotemporal overlap among individuals of the same or different species.

Analyses of animal interactions frequently are classified as either **static** or **dynamic** (MacDonald et al. 1980, Doncaster 1990). Static analyses consider spatial interaction and overlap over a long time period, whereas dynamic analyses consider the temporal dimension to look at extent to which animals are in close proximity simultaneously. Techniques used for assessing static animal interactions are equally useful for comparing site fidelity over time. These approaches include comparing changes in one aspect of the UD (e.g., home range centroid) over time, or examining to what degree the overall UD has changed. Distances among centroids or average locations can easily be calculated and compared over time and across different groups of animals; a null hypothesis of no shift in centroids or no differences in the magnitude of shifts for different groups can be compared with multivariate tests (Hotelling's T^2 or a Mann-Whitney method). However, this approach is not sensitive to changes in space use, such as expansions of the area used, that do not change the mean location (White and Garrott 1990).

Broader changes in space use over time or among groups can be assessed by examining whether the sets of locations from different periods or animals come from the same underlying distribution, by assessing overlap among the 2-dimensional home range estimates, or by comparing overall overlap in UDs calculated for different times or animals. A flexible test of whether 2 sets of locations come from the same or different UDs is the multiresponse permutation procedure proposed by Mielke and Berry (1982). This method examines whether the average pairwise distance between locations in a group or time period are similar to the average distances among locations calculated independently of time period. It does not require an estimated UD from a statistical model, but simply uses the observed locations, which may be seen as an advantage of this approach (White and Garrott 1990). However, model-based quantification of overlap allows estimation of the amount of overlap rather than just a test of whether overlap occurred (Fieberg and Kochanny 2005).

Estimates of 2-dimensional overlap are based on the percentage of each home range polygon that overlaps the other polygon in the comparison. If $A_{i,j}$ is the area of animal i 's home range that overlaps animal j 's home range (with area A_i), then $HR_{i,j} = A_{i,j}/A_i$ is the proportion of animal i 's home range that overlaps animal j 's home range. For example, $HR_{1,2} = A_{1,2}/A_1$, and $HR_{2,1} = A_{2,1}/A_2$; these 2 indices are not equal unless both animals have the same home range size ($A_1 = A_2$). Although intuitively simple, these indices are appropriate only if use is uniformly random in each home

range. If home range use is not uniform, 2-dimensional overlap is a biased estimate of joint space use, because it does not consider each animal's probability of using the overlapping areas (i.e., outer contours of the home range may overlap significantly, even though this overlap occurs where probability of use by each animal is relatively low; Kernohan et al. 2001). Such problems are avoided by overlap indices that consider differential use intensity in each UD, based on joint probabilities of use of the same area. Use of estimated UDs allows direct estimation of the probability that 2 animals have used the same area over the time period for which data were collected. Such UD-based estimates should replace overlap analyses based on 2-dimensional overlap (Millspaugh et al. 2004, Fieberg and Kochanny 2005).

Fieberg and Kochanny (2005) reviewed and compared 3 alternative measures of overlap that consider the complete probability density function for each UD: the **volume of intersection** index, introduced by Seidel (1992); Bhattacharyya's affinity (Bhattacharyya 1943), and an alternative UD overlap index. The volume of intersection index estimates the integrated overlap in density among 2 UDs; Bhattacharyya's affinity index and UD overlap index measure the joint distribution based on the product of 2 UDs. Although these indices correctly rank pairs of UDs based on the true amount of overlap and should be used in preference to 2-dimensional estimators, they are biased. The amount of bias depends on the true amount of overlap. Simulations indicate these indices underestimate overlap when it is high and overestimate overlap when it is moderately low. Bias also is affected by sample size, making comparisons in overlap estimates among studies problematic (Seidel 1992, Fieberg and Kochanny 2005).

Dynamic interaction analyses consider whether 2 animals are using an area at the same time, and thus require near-simultaneous locations for each animal (Minta 1992, Fuller et al. 2005). Traditional dynamic interaction analyses compute indices of co-occurrence. Cole's (1949) coefficient of association compares the proportion of total observations for 2 animals in which the animals occurred in the same location simultaneously. A distance-based index (Kenward 2001) computes whether the average distance between simultaneously taken observations for 2 animals is different than the average pairwise difference among all locations regardless of time; it can indicate avoidance, positive association, or no relationship in simultaneous space use. The utility of dynamic interaction analysis has been facilitated greatly by technology (e.g., Prange et al. 2006), and continued sensor development will help us understand these interactions.

GENERAL MOVEMENT CHARACTERISTICS

In addition to broad properties of space use, investigators often focus on detailed aspects of discrete movements and

movement paths between observed locations. As with analyses of UDs, traditional analyses of individual movements have focused on nonmechanistic statistical descriptions of selected movement characteristics. The distance, direction, and rate of movement may be relevant to basic understanding of a species' natural history, may have direct management relevance (e.g., understanding the timing of migration in relation to harvest regulations), or may be compared among groups or habitats to test hypotheses about factors affecting movements. Distance between successive locations at times i and $i + 1$ can be calculated as $d_{i,i+1} = \sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2}$. White and Garrott (1990), Kernohan et al. (2001), and other sources provide formulas for calculating the direction of travel. Summaries and statistical analyses of movement direction must use methods designed for circular distributions. A summary of such methods is provided by Zar (1996), and comprehensive monographs also are available (e.g., Mardia and Jupp 1999).

Biologists are often interested in quantifying movement characteristics for migratory and dispersal movements, and in comparing these characteristics before and after onset of such larger scale movements. For land managers, understanding where animals go involves both determining the final destination as well as the path or corridor used to get to this destination. Understanding the "which," "what," and "where" aspects usually requires telemetry techniques that enable animals to be located far from their original location as well as a large sample of animals. For example, if the objective is to compare proportions of males versus females that migrate with real—but unknown—proportions of 0.3 and 0.6, respectively, basic power calculations (Zar 1996) indicate that one would need to monitor 33 animals of each sex to have high power (0.8) to detect such a difference at a significance level of 0.10. Any study of long-distance movements, such as migration, needs to develop objective criteria for determining the onset of these movements (i.e., separating these movements from the more normal movements that occur before and after migration or dispersal events). Ideally, these criteria are defined a priori, but in practice, they may have to be defined after exploratory analyses of the data, unless the investigator has a good understanding of what constitutes normal nonmigratory movements in the study population.

As with home range or space use analyses, analysis of specific movement attributes increasingly is done using a multimodel, often hierarchical approach in a likelihood-based framework (Schick et al. 2008). Moreover, the line between analyses of space use versus individual movements is increasingly blurred, as models scale up from properties of individual movements to estimates of an overall UD. Thus, the summary of mechanistic home range or space use models earlier in this chapter provides a starting point for understanding more recently developed approaches to analyzing movement data.

USE OF RADIOTELEMETRY DATA TO STUDY RESOURCE SELECTION

The study of wildlife–habitat relationships has been greatly enriched by use of radiotelemetry. **Resource selection** is a popular and active area of research that addresses the resource choices made by wildlife. Here, we consider resources to be vegetation, objects (e.g., a cavity), or environmental conditions (e.g., wind). In the study of wild animals, resources are tied to spatial features of the environment, making resource selection a spatially explicit issue. Managers often use the results of resource selection studies to guide vegetation management directed at improving conditions for a species, evaluate how species might overlap and compete for resources, or assess how human disturbances affect a species' distribution. There is an implied assumption in resource selection studies of wildlife that when a resource is selected, it promotes fitness of the animal. Radiotelemetry is uniquely able to provide unbiased estimates of resources used by wildlife, provided the important sampling issues discussed above are considered and appropriate analytical procedures are used and interpreted properly. In this section, we provide an overview of the concepts and methods of analyzing wildlife resource selection with radiotelemetry data. McDonald et al. (Chapter 17, This Volume) offer an in-depth, broader discussion of the analytical techniques that assess resource selection and food use and availability using a broad range of techniques.

The study of resource selection comes with its own jargon, and biologists should be aware of basic terms and concepts. Foremost among terminology is **use, availability, selection, and preference**. Use is the quantity of a resource utilized by the consumer in a fixed period (Johnson 1980) and is by default a subset of available ones (Buskirk and Millspaugh 2006). In telemetry studies, use is often defined by telemetry locations, but it also can be defined by a collection of points, such as a UD (Marzluff et al. 2004, Millspaugh et al. 2006) or other metrics (e.g., time, distance traveled, or energy expended; Buskirk and Millspaugh 2006). If resources are selected, they are used disproportionately more than would be expected based on their availability (Johnson 1980). **Availability** is one of the more difficult components to define in resource selection studies, because it is strongly affected by semantics and scale (Buskirk and Millspaugh 2006). Definitions of availability (Johnson 1980, Manly et al. 2002, Fuller et al. 2005) all consider accessibility and the amount of resources. However, such factors as accessibility are nearly impossible to determine in field studies. Instead, biologists consider only the occurrence of a resource in a study area or some finer scale when defining availability. Some recent evaluations and analytical options consider animal movement rates and simultaneous modeling of movements and resources, but most simply consider the maximum area that

could have been used as a means of defining resource availability. Preference for a resource reflects the likelihood of that resource being chosen if offered on an equal basis with others (Johnson 1980). Therefore, it is nearly impossible to determine resource preference for free-ranging animals, because resources are not available in equal units and in a random distribution (Marzluff et al. 2001). Thus, resource selection of free-ranging animals is restricted to use and selection, unless resources meet these criteria. **Avoided** refers to use that is disproportionately less than would be expected based on the availability of that resource (Johnson 1980). Based on this standard definition, the animal still may use resources that are “avoided,” so the intuitive connotation of the term does not match its definition in this context. “Unused” resources received no use during the study period.

The hierarchical nature of resource selection studies inherently requires those using telemetry to consider the order of selection (Johnson 1980). The selection of areas and resources by animals can be seen as a hierarchical process (Johnson 1980). The importance of **hierarchical selection** should be explicitly considered as part of the research design, because the selection order implicitly identifies the population of interest, the experimental units, and the level of management interpretation (Thomas and Taylor 1990). **First-order selection** considers the selection of the physical or geographic ranges of a species (Johnson 1980). **Second-order selection** evaluates the selection of a home range in the study area or geographic range of the species (i.e., it emphasizes resource selection in the overall study area; Johnson 1980, Thomas and Taylor 1990). **Third-order selection** evaluates the importance of resource components in the animal's home range, emphasizing resource selection patterns in the home range (Thomas and Taylor 1990). Most studies involving radiotelemetry will focus on second- or third-order resource selection.

A second critical element of the study design is the determination of how use and availability data will be collected, which determines which analytical methods are appropriate. The variety of available approaches primarily reflects data reliability, quantity of data recorded at each animal location, and the assumption about data independence among animals and animal locations. Thomas and Taylor (1990) described the 3 study designs for resource selection studies, depending on whether use or availability information is collected for the individual or for the population as whole. Study design I assumes that both use and availability data are collected and summarized at the population level. Study design II records use per animal, but defines availability for the entire population. In contrast, study design III estimates use and availability for each animal. Erickson et al. (2001) added a fourth design that considers recent developments in resource selection studies (Arthur et al. 1996; Cooper and

Millspaugh 1999, 2001). As with the 2 previous designs, design IV summarizes use per animal, but it defines availability for each location rather than assuming that availability is constant throughout the study area or home range. Alldredge et al. (1998) provide a useful discussion of the assumptions of each technique across different designs.

Resource selection analyses most often compare resources used by the animal to resources considered available to the animal or population. Resource availability represents the amount of area of each vegetation type (e.g., meadow or ponderosa pine forest) that is available for use by the population or individual animal. Unfortunately, it is one of the most troubling aspects of resource selection studies that compare use to availability (Cooper and Millspaugh 1999). The biologist's definition of availability might not correspond to what the animal perceives to be available (Marzluff et al. 2001). For example, various factors that may be immeasurable to the biologist might influence what is actually available to an animal (e.g., social hierarchies or predation; Otis 1997, 1998; Myrsetrud and Ims 1998). Thus, the determination of the area for each vegetation type may not provide an adequate means to measure habitat availability (Johnson 1980, White and Garrott 1990). In addition, definition of the appropriate study area can be problematic and can influence availability (Porter and Church 1987). A common problem in defining availability is the occurrence of widespread vegetation types that are rarely used, possibly indicating this vegetation type is not biologically suitable for the species. Inclusion or exclusion of this vegetation type may have a substantial influence on habitat selection analyses (Johnson 1980), and alternative analyses including and excluding these vegetation types should be presented (Thomas and Taylor 1990). There is limited general guidance on dealing with other problems related to defining availability (Johnson 1980, Porter and Church 1987, Cooper and Millspaugh 1999); appropriate strategies for addressing these problems depend on the species studied.

Resource selection studies may focus on selection of discrete sites or of general habitats. The spatial extent of availability commonly may be based on the entire study area or the area within some specified distance of the focal site, on composite population-wide "home range" in the study area, on individual home ranges, or on multistage approaches combining multiple scales (Buskirk and Millspaugh 2006). Ultimately, the decision of which boundary to use is dependent on what order of selection is being considered, the animal under investigation, and objectives of the study; each potential definition of spatial extent of availability has potential problems. The boundary of a study area may have no biological meaning from the standpoint of the animals being studied, but using the investigator-defined study area boundary may be appropriate in coarse scale evaluations (e.g., Erickson et al. 1998). Porter and Church (1987) demonstrated that when vegetation types are aggregated, the study area measure of

availability may provide spurious results. Using composite or individual animal home ranges is problematic, in that a researcher must select an appropriate home range estimator, and previously discussed issues, such as sample size, choice of contour, and the technique used, all affect home range estimates. Placing a buffer around individual locations to define availability helps refine what is considered available to an animal, but it requires the investigator define a biologically meaningful buffer size (Cooper and Millspaugh 1999, 2001). At any of these scales, defining availability may require or be facilitated by GIS layers for resources of interest. However, GIS data layers have limitations that should be carefully considered in resource selection analyses. For example, difficulties in assigning use locations to habitat features and a miscalculation of vegetation type areas or other landscape metrics are possible when map accuracy is low.

Use is usually quantified based on the telemetry points directly or on some summary of those observations via a home range analysis. Although many other measures have been proposed (see Buskirk and Millspaugh 2006), use of these methods is most dominant in the literature. Most studies use time as the currency of use, followed by event sites. However, as technology makes other options more readily available, we expect changes to the interpretation of use and frequency metrics, such as distance traveled.

One important and often overlooked aspect of resource selection relates to the animal's behavior at relocation points. Marzluff et al. (2001) argued that knowing what an animal is doing in a particular resource increases our understanding of why the animal is there. Marzluff et al. (2001:315) developed behavior-specific UD's based on kernel density estimates to evaluate whether resources were used differently for 4 behaviors (foraging, locomotion, perching, and parental care). Using nested discrete-choice models, Cooper and Millspaugh (2001) illustrated how to account for variation in animal behavior in resource selection studies. By comparing RSFs with and without behavior included as a component, they demonstrated potential problems with ignoring the behavioral element.

POPULATION ESTIMATION

Radiomarked animals provide considerable advantages for estimating wildlife population size and density, because information about the locations of animals can be incorporated into the estimates. Initially, especially for territorial pack animals (e.g., gray wolf [*Canis lupus*]; Burch et al. 2005), home range or territory size and percentage overlap of home ranges of radiomarked animals was scaled up to estimate population size based on the number of territories or home ranges the study area likely supported. However, this approach generally underestimates the actual population.

Many wildlife population studies now use data from radio-marked individuals as auxiliary information to refine esti-

mates based on other, independent techniques. There are 4 primary ways that radiomarked animals can be used to augment or improve population estimates (White and Shenk 2001). The first is direct **mark-resighting**, in which animals are marked and later recaptured or observed. The second uses **sightability** models developed from radiomarked animals that serve as correction factors applied to each individual or group of animals observed. The third employs radiomarked animals in conjunction with trapping or **capture grids** that are used to assess demographic closure. The fourth uses radiomarked animals as an auxiliary likelihood with age-at-harvest data in a statistical population reconstruction analysis (Skalski et al. 2005, Broms et al. 2010).

Mark-Resight Estimation

In mark-resight estimation, a sample of animals is initially captured (marked); however, resightings are rarely based on recaptures, but on observations, including direct observations or camera surveys. A major advantage of this technique is that costs of resightings are generally minimal relative to initial capture costs. A disadvantage is that standard mark-recapture closed population estimation models are not appropriate (e.g., Otis et al. 1978), because unmarked animals cannot be marked during resighting occasions. Mark-resighting techniques have been used frequently with ungulates, such as white-tailed deer (*Odocoileus virginianus*; Rice and Harder 1977), mule deer (*O. hemionus*; Bartmann et al. 1987), and bighorn sheep (*Ovis canadensis*; Bartmann et al. 1987, Neal et al. 1993), as well as with carnivores, including black bears (*Ursus americanus*) and grizzly bears (*U. arctos*; Miller et al. 1987, 1997), coyotes (Hein and Andelt 1995), and harbor seals (*Phoca vitulina*; Ries et al. 1998). The technique has broad utility for other species that can be marked and feasibly resighted (e.g., Magle et al. 2007).

There are 2 critical assumptions in mark-resight studies. The first assumption is that radiomarked animals must have the same sightability as unmarked animals. Thus, behavior of marked individuals is comparable to unmarked individuals, and marked animals adequately represent variability in the sightability of unmarked animals. For example, a study area having 3 markedly different understory vegetation types would require marked animals in each of these 3 types. The second assumption is the population is closed, with 2 forms of closure assumed. One form assumes the population has a fixed size with no births, deaths, immigration, or emigration during the study. The second form is geographic closure. Geographic closure is required for most mark-resight models, a notable exception being the joint hypergeometric estimator (White and Shenk 2001). The closure assumption needs to be carefully considered during study design. For example, surveys should be conducted during periods of minimal immigration or emigration. As discussed below, one analytical method allows the closure assumption to be relaxed by modeling immigration and/or emigration (Neal

et al. 1993). Statistical tests are available to assess geographic closure of populations (Stanley and Burnham 1999, Stanley and Richards 2003). In studies extending over longer periods, sampling needs to be scheduled in discrete sessions of concentrated surveys (e.g., 1 week/yr), with closure in each session (i.e., secondary occasions, such as 5 days of surveys in a 2-week period), but not necessarily between sessions (primary occasions, such as the survey week each year). However, data from all sessions can be integrated into a single analysis to support more efficient sightability parameters (McClintock et al. 2006). This framework also has been extended to allow estimation of apparent survival and transitions between observable and unobservable states (McClintock and White 2009).

Additional assumptions may be necessary to obtain unbiased population estimates, regarding whether the population is sampled with replacement and regarding heterogeneity in detection probabilities. Individual capture heterogeneity (e.g., heterogeneity in capture probability during the marking phase and in sightability during the resight phase) simply quantifies variation in detection among individuals in a population and has been demonstrated for numerous wildlife species, including black bear (Belant et al. 2005). Furthermore, capture heterogeneity can occur even with individuals and is influenced by behavior, as demonstrated in moose (*Alces alces*; Gasaway et al. 1985). The effect of violating assumptions of closure, sampling with replacement, and capture heterogeneity are dependent on the mark-resight population estimator used (White and Shenk 2001).

Commonly used models in mark-resight population estimation include the joint hypergeometric estimator (JHE; White and Garrott 1990; Neal et al. 1993), an extension of the JHE to accommodate immigration and emigration (Neal et al. 1993), Bowden's estimator (Bowden and Kufeld 1995), and the Minta-Mangel estimator (Minta and Mangel 1989). The JHE is a maximum likelihood estimator that estimates population size using an iterative numerical approach. It assumes the number of individuals in the population and number of marked animals is constant across sampling occasions. However, the probability of observing marked animals is not assumed to be constant across sampling occasions. The extension of the JHE accommodating immigration and emigration incorporates a binomial process (Neal et al. 1993). The likelihood function incorporating immigration and emigration is the product of the probability of an animal in the study area during the sampling occasion (calculated using the binomial distribution) and the joint hypergeometric likelihood (White and Shenk 2001).

Bowden's estimator is grounded in a sampling survey and based on the frequency of observations of marked individuals along with the sum of observations of unmarked individuals (Bowden and Kufeld 1995). This estimator calculates confidence intervals based on the variance of resighting frequencies of marked individuals. An unbiased estimate us-

ing this procedure requires identification of $\geq 90\%$ of marked individuals sighted (White 1996). The Minta–Mangel estimator employs a bootstrap of the population size based on the frequency of marked animal observations (Minta and Mangel 1989). Sighting frequencies of unmarked animals are randomly drawn from the observed sighting frequencies of marked animals, until the total number of captures equals the total number of sightings of unmarked individuals. The number of unmarked animals drawn represents an estimate of the number of unmarked individuals. The population size is then estimated as the number of marked individuals plus the number of unmarked animals sampled. Although this estimator is generally unbiased, confidence interval coverage is not at the expected 95% level, because the number of marked animals observed is fixed as opposed to being a random effect (White 1993). Recently developed estimators using mixed-effects models have expanded analytical options by incorporating random effects into the model heterogeneity when sightability varies among individuals (McClintock et al. 2009a, b).

Choice of model to use for mark–resight population estimation will be determined largely on the validity of model assumptions. Except for the most recently developed estimators, all other estimators described require equal sightability of marked and unmarked animals. All except the Neal et al. (1993) extension to the JHE assume demographic closure (White and Shenk 2001) during each primary sampling occasion. However, remaining assumptions necessary to obtain unbiased estimates vary among the models described. For example, all but the JHE model with immigration and emigration require geographic closure. Neither form of JHE accommodates sampling with replacement or individual capture heterogeneity. In contrast, Bowden's and the Minta–Mangel estimators allow sampling with replacement and individual heterogeneity. Estimators developed by McClintock et al. (2009a, b) are highly flexible in allowing individual heterogeneity, sampling with or without replacement, and estimation without exact knowledge of the number of marked animals currently in the population.

Sightability Models

Sightability models are used frequently in wildlife population estimates, particularly those derived from aerial surveys. Surveys typically involve dividing the study area into sampling units that generally are then selected using a random or stratified random design. Those sampling units selected are then surveyed with the goal of counting every animal in each unit. However, sightability can be influenced by vegetation, topography, group size, animal behavior, and observer (e.g., Floyd et al. 1979, Gasaway et al. 1985, Samuel et al. 1987, Cogan and Diefenbach 1998, Bleich et al. 2001, Walsh et al. 2009). Consequently, detection of animals is imperfect, and radiomarked animals are used to develop sight-

ability models that reduce visibility bias stemming from imperfect detection. Sightability models using radiomarked animals have been developed and applied to elk (*Cervus canadensis*; Unsworth et al. 1990, Otten et al. 1993, Walsh et al. 2009), moose (Gasaway et al. 1985, Anderson and Lindzey 1996), mule deer (Ackerman 1988), bighorn sheep (Bodie et al. 1995), mountain goats (*Oreamnos americanus*; Rice et al. 2009), Arabian oryx (*Oryx leucoryx*), and waterfowl (Smith et al. 1995b). Samuel et al. (1992) developed sightability models to correct age and sex bias in surveys of wildlife populations.

To develop sightability models, radiomarked animals are initially located, and a search area is delineated around the locations. An independent observer(s) without knowledge of the locations of marked animals then searches the area. Covariates (e.g., group size or vegetation) considered important are recorded for each marked animal sighted. Animals not sighted are located via telemetry after the search to record the same covariates. A logistic regression model is generally developed to predict the probability of sighting an animal based on the values of covariates in the model. The model is then used to correct sightability bias in the observed counts of animals. Thus, radiotelemetry is used only during the model development phase.

There are 2 important assumptions when using sightability models. The first is that conditions observed during operational surveys must be in the range of conditions that were observed during development of the sightability model. For example, it is inappropriate to use a sightability model that incorporated group sizes up to only 3 individuals for a survey where group sizes of up to 10 individuals were recorded. Also, sightability can be influenced by the type of aircraft, altitude, flight speed, and search pattern or effort; therefore, these factors must be constant between the model development and operational survey phases. The second assumption is there is no measurement error for covariates used to predict sighting probability. For example, undercounting group size during model development will result in a negatively biased population estimate when applied to survey data (Cogan and Diefenbach 1998).

Correction for Density Estimation

In traditional mark–recapture population surveys using a grid of sampling locations (i.e., trapping grids), the naïve density estimate (estimated population size/area of trap grid) is biased. Animals on the periphery of the trapping area spend only a portion of their time in the area, resulting in difficulty in estimating effective trapping area and naïve density estimates that overestimate true density. In a multisite study (e.g., comparison of abundance among different habitat types), comparisons based on absolute abundance estimates will be biased if effective trapping area systematically differs among the site types being compared. Heuristic approaches to estimating the effective trapping area (e.g., nested

trapping grids) are ad hoc approaches (Otis et al. 1978, Wilson and Anderson 1985) and are inferior to approaches based on distance sampling (e.g., trapping webs; Anderson et al. 1983).

Radiomarked animals have been used to refine estimates from trapping grids in 3 primary ways. The first is establishing a buffer around the trapping grid, generally one equal to the radius of a circle the size of the average home range during the period or season of inference (Kenward 1987, 2001; Soisalo and Cavalcanti 2006). The second means of correcting bias is to use the proportion of radiomarked animals that spend $\geq 50\%$ of their time in the trapping grid (White and Shenk 2001). However, this approach would result in a density of zero if no animals spent $\geq 50\%$ of their time in the area. To account for this problem, the third bias-correction approach is to estimate the proportion of time each radiomarked animal spends in the area trapped. From this estimate, a mean and variance can be calculated that can be applied to the population estimate and variance derived from the trapping. If tissue samples are collected from captured animals or if radiomarked animals are individually identifiable visually, this approach can be similarly applied to camera trap or hair snare grids (Garshelis 1992, Matthews et al. 2008). Populations estimated using the third approach may be biased if animals spending little time in the trapping grid are proportionately less likely to be initially captured and radiocollared.

Use of Radiotelemetry Data in Statistical Population Reconstruction

Statistical population reconstruction is a recent approach used to model age-at-harvest data for many wildlife species (Gove et al. 2002, Skalski et al. 2005, Broms et al. 2010). For many management agencies, age-at-harvest and hunter effort data are commonly used for population estimation, because they are easy to collect, applicable across large spatial extents, and do not require intensive or expensive sampling (Skalski et al. 2005, Millsbaugh et al. 2009).

Statistical population reconstruction uses an age-at-harvest likelihood, a reporting likelihood (e.g., incomplete harvest reporting or sampling for sex and/or age composition), and an auxiliary likelihood, such as radiotelemetry, but it could take several forms (Skalski et al. 2005). Auxiliary likelihoods are independent datasets that are used to estimate one or more demographic parameters. For example, use of radiotelemetry data to estimate natural survival could be used as an auxiliary likelihood to refine population estimates (Broms et al. 2010). Alternatively, population estimates obtained from mark-recapture efforts or aerial surveys using radiomarked animals can be used to calibrate estimates obtained using statistical population reconstruction (Skalski et al. 2005). This modeling technique has considerable potential; a thorough description of its development and applications is provided by Skalski et al. (2005).

SURVIVAL

Estimating **survival** of animal populations is an integral part of wildlife ecology and management. Monitoring radio-marked animals provides us knowledge of when animals were marked, the time and position of each consecutive location, and status (e.g., alive, dead, or missing); thus, radiotelemetry is the basis for many survival studies. Use of radiotelemetry allows us to understand cause-specific mortality, rates of survival, and what factors influence rates of survival (e.g., Haines et al. 2005, Bender et al. 2007). For example, radiotelemetry has been used to estimate the effects of humans on survival (Belant 2007, Adams et al. 2008) and predation rates (Vreeland et al. 2004, Knopff et al. 2009), and to compare survival among sex or age cohorts (Chamberlain and Leopold 2001, DelGiudice et al. 2006).

Numerous models have been adapted or developed to estimate survival of radiomarked individuals. The appropriate strategy to use depends on numerous factors, including study objectives, variability in survival rates, occurrence of **immigration** or **emigration**, and whether the fate of all study animals is known. Animals that are missing or animals at the end of a study are considered right-censored, because the death of the animal was either unknown or did not occur during the study; right censoring may occur because of migration from the study area, transmitter failure, or termination of the study. Left-censored individuals entered the study after it started and after some mortality may have already occurred. We provide a brief overview of those techniques most commonly used. More comprehensive treatments are provided by White and Garrott (1990), Kenward (2001), Winterstein et al. (2001), and Murray (2006).

The analysis of survival data from radiomarked animals can be divided into 2 general categories: one that considers estimating a survival rate for a discrete time interval and the other that estimates a continuous survival curve. Interval survival rates assume a constant mortality rate across the study period, so the timing of mortalities does not matter. Instead, the number of days each animal survives in the time interval is important. These interval-based methods are appropriate when the fate of all animals is known, the survival rate is constant throughout the time period, and all animals are radiomarked at the beginning of the interval. However, in many cases, biologists often add new radiomarked animals into the study, animals do not have constant mortality rates throughout an interval, and the fate of some animals may be censored. In such situations, continuous survival models are appropriate.

Heisey–Fuller Method

Originally developed for estimating avian nesting success (Mayfield 1961, 1975), this approach was later adapted for estimating survival of radiomarked wildlife (Trent and Rongstad 1974, Heisey and Fuller 1985) and used extensively to

estimate cause-specific mortality. Survival is assumed to be constant in each interval (e.g., day or week). Survival for each time step (e.g., daily survival) is derived from the number of deaths and number of exposure days during each time step (i.e., number of deaths per total radiodays), and the interval survival rate is calculated exponentially using daily survival and the number of time steps during the interval. This method is appropriate when survival is constant for short intervals, but may vary over longer time periods; that is, a study may consist of consecutive intervals with constant survival assumed within, but not among, intervals (Williams et al. 2004). Formulas for variance estimates of survival rates for time steps, as well as confidence intervals for animals located at irregular intervals, have been developed (Bart and Robson 1982).

Kaplan–Meier Estimator

The Kaplan–Meier (product limit) estimator (Kaplan and Meier 1958) was adapted for survival analyses in wildlife radiotelemetry studies during the 1980s (e.g., Krauss et al. 1987, Conroy et al. 1989, Pollock et al. 1989). It differs from the Heisey–Fuller method in the assumption of constant survival is relaxed in time intervals, because mortality events are used to define the time intervals (Murray 2006). For this estimator, the survival function is the probability of an animal in the population surviving for a specified number of time intervals since the study began. The Kaplan–Meier estimator will produce a survival curve showing the probability of survival as a function of time. At the start of the time step, survival is assumed to be 1.0; each mortality in the pool of radiomarked animals is demonstrated graphically by a decrease in survival (Fig. 20.3). The method is attractive, because it can incorporate the addition of radiomarked animals after the beginning of the study and is robust to right censoring.

The generalized form of the Kaplan–Meier estimator is recommended, because it adjusts the conditional probability based on individuals radiomarked after study initiation; however, this form is sensitive to small sample sizes (Pollock et al. 1989). Nelson (1972) and Aalen (1978) developed an alternative estimator that is better in dealing with small sample sizes. White and Garrott (1990) and Skalski et al. (2005) provide details on calculations used by this model. Important attributes of each Kaplan–Meier estimator are that it does not assume constant survival and it allows staggered entry of radiomarked animals (e.g., addition of new radiomarked animals after the initiation of the study). Limitations to the Kaplan–Meier and Heisey–Fuller estimators have been described (Rotella et al. 2004), but these approaches continue to be used and developed. For example, Heisey and Patterson (2006) recently described use of the cumulative incidence function to estimate cause-specific mortality with the Kaplan–Meier estimator.

Hazard Functions

Several multivariate approaches have been developed to address simultaneously the relative contributions and interactions of the multiple factors that can influence survival. Hazard functions estimate the probability of death at a specified point in time conditional on the survival to that time; parameter coefficients are generally estimated using regression techniques. Hazard functions are fit to survival data initially by calculating the cumulative hazard function for the dataset (Klein and Moeschberger 2003, Murray 2006). The Cox proportion hazard model is widely applied in wildlife telemetry studies and uses an exponential regression model containing parameters with constant hazards that are proportional through time. The Cox proportional hazard model does not assume a specific hazard function and is consequently robust, allowing detailed assessment of param-

Fig. 20.3. Survival distributions for radiomarked hatching-year (HY) mourning doves (*Zenaida macroura*), calculated using the Kaplan–Meier product limit estimator with staggered entry, during summer and autumn 2006 on the James A. Reed Memorial Wildlife Area, Lee's Summit, Missouri.

eter effects (Hosmer and Lemeshow 1999). Advantages of the Cox proportional hazard model are that variables can be discrete (categorical) or continuous, and the model can be extended to include time-dependent variables (Hosmer and Lemeshow 1999), such as behavior, age, and season. If hazards become discontinuous due to periods when animals are not monitored (e.g., temporary movement from the study area), the Anderson–Gill model can be applied (Anderson and Gill 1982, DelGiudice et al. 2002). Discrete time models also have been applied to radiotelemetry studies to model survival as a nonlinear function of model parameters (White and Burnham 1999, Williams et al. 2002a).

Staggered-Entry and Time Origin

Wildlife studies rarely capture all individuals at or near the same time. In addition, investigators frequently desire to augment the number of radiomarked animals when mortality or other factors (e.g., radiotransmitter failure) reduces samples below desired levels. Situations in which animals are introduced into the marked population over longer time periods are known as staggered entry (Pollock et al. 1989). Using Kaplan–Meier, the addition of animals is accounted for by adjusting the number at risk during respective time intervals (Pollock et al. 1989). The Mayfield method incorporates new animals using the sum of individual exposure days. Regardless of the analytical technique, a critical assumption is that recently marked animals have had the same survival rate since the beginning of the study as animals that were marked at the start.

An important aspect for estimating survival is using the appropriate time origin at which to begin measuring survival. This choice has relevancy at both the individual and population levels. At the individual level, an adjustment period following capture and marking may be necessary to allow the animal to return to what we consider normal behavior. At the population level, the investigator needs to ensure there is an adequate sample size of marked individuals before measuring survival. Measuring survival prematurely using either scenario has considerable potential to bias estimates.

Important Assumptions of All Radiotelemetry Survival Models

Irrespective of the model used for estimating survival from radiomarked animals, the following conditions should be met to minimize error (Bunck 1987, Tsai et al. 1999, Winterstein et al. 2001, Fuller et al. 2005):

1. The sample of radiomarked individuals must be representative of the population being studied. Generally, it is a random sample of individuals in each classification being investigated (e.g., sex or age class).
2. Radiomarked individuals represent independent samples. Animals that are closely associated (e.g., nestlings or pack

members) may be subjected to similar mortality factors and thus, provide biased information about mortality rates compared to data obtained from truly independent individuals. In the latter case, the nestlings or pack would serve as the independent sample.

3. Transmitters or tracking equipment should not influence survival. Animals with transmitters should provide an unbiased estimate of the rate of survival for the population of inference; however, this assumption may be violated (e.g., Guthery and Lusk 2004, Steenhof et al. 2006). These first 3 conditions also are required of survival estimates from band recovery and mark–recapture studies (Jolly 1965, Seber 1965, Pollock 1981, Brownie et al. 1985).

4. When the fate of an animal is unknown (i.e., censored), the known survival time is often assumed to be independent of the animal's actual fate. Censored individuals are assumed to be random in the marked population; however, biases likely exist in many wildlife studies (DelGiudice et al. 2002). Appropriate transmitter design, periodically monitoring outside the study area to search for marked animals, and extending study duration to obtain an appropriate number of mortalities have been suggested as means to reduce censoring rates (Garton et al. 2001, Bender et al. 2004).

5. The exact time of death is known. This assumption can be relaxed, however, without substantially affecting survival estimates (Johnson 1979a, Bart and Robson 1982, Heisey and Fuller 1985).

6. Newly marked animals must have the same survival function as previously marked animals.

Additionally, independence of consecutive radio locations is an assumption of the most survival estimators (Winterstein et al. 2001). However, consistency in timing of consecutive locations within and among radiomarked animals is likely of greater importance.

SUMMARY

As with technology, the analysis and application of telemetry data have developed greatly in sophistication and inferential power. Recent methods incorporate modern statistical tools and philosophies, such as hierarchical models and information theoretic approaches, and are increasingly based on mechanistic or process-based models that directly incorporate hypothesized relationships determining animal movements and space use. Although we outlined many general advantages and disadvantages of various analytical procedures, the biological and methodological assumptions appropriate for each analytical technique must be considered and tested prior to collection, analysis, and interpretation of

radiotracking data. There are numerous options for all aspects of a radiotelemetry study, from equipment to study design to analyses, and decisions about these aspects must be tailored to the specific study objectives.

APPENDIX 20.1. SOFTWARE TO ANALYZE RADIOTELEMETRY DATA

Home Range Programs

ArcGIS/ArcView extensions

<http://www.esri.com/software/arcgis/>

ABODE extension for ArcGIS

<http://filebox.vt.edu/users/plaver/abode/home.html>

Animal Movements extension for ArcView (future plans for ArcGIS tool)

<http://www.absc.usgs.gov/glb/gistools/>
Requires Spatial Analyst extension for full functionality:

Reproduction and Hormones

INTRODUCTION

MEASURES OF REPRODUCTIVE RATE and natality are central to understanding the biology of populations, and in many cases, they are more readily obtained than other components, such as population size. Estimates of diverse parameters from ovulation rate to neonatal survival provide a basis for calculation of natality and recruitment for a variety of wildlife species. Moreover, during the past 3 decades, hormonal regulation of reproductive cycles of a substantial number of wild species has been clarified, so that it is now possible to assess reproductive status and performance from blood levels of certain hormones. Promising new developments in contraceptive technology provide methods that are safe, effective, and sufficiently practical to offer an alternative, under some conditions, to traditional methods of population control.

This chapter is organized to meet 3 objectives: (1) review reproductive cycles of amphibians, reptiles, birds, and mammals and describe procedures to assess reproductive rates in each of these groups; (2) review basic endocrinology relative to measures of reproduction and stress, and (3) review recent developments in reproductive technology, particularly as they relate to contraception and control of recruitment in wild mammals.

The precipitous worldwide decline in amphibians (Semlitsch 2000, Whitfield et al. 2007, Hayes et al. 2010) and reptiles (Fitzgerald and Painter 2000) increasingly demands the attention of wildlife biologists, and background information and techniques relevant to these groups are highlighted in this chapter. Detailed instructions for some of the most commonly used methods are provided; for others, the reader is referred to primary sources and authoritative reviews (e.g., Zug et al. 2001). Stress is an important issue in wildlife research, first, as a potential factor in natural regulation of populations and second, as a consideration in the welfare of animals held captive for research and conservation. An expanding knowledge of the biology and endocrinology of stress provides measures and standards for meaningful evaluation of this factor in both wild and captive animals. The goal of this chapter is to increase awareness of and appreciation for a full spectrum of reproductive techniques and their potential application to the study and conservation of wild terrestrial vertebrates.

REPRODUCTIVE CYCLES AND MEASURES OF REPRODUCTION

Estimation of **natality** (i.e., number of young produced per unit of population per unit of time) is a fundamental requirement for understanding dynamics of a wild

population. In some instances, this information can be obtained indirectly through mark–recapture procedures. However, this approach is difficult; mortality of newborn young is high, and younger age groups may be difficult to trap for marking. Consequently, it is necessary to obtain some measure of **reproductive rate**, such as clutch size in birds or the number of **corpora lutea** (CL) in ovaries (for ovulation rate) or fetuses per female collected during the breeding season. Such estimates of reproductive rate can then be used with information on the sex and age structure of the population to calculate gross natality.

Reproductive rates can be estimated at several points in the reproductive cycle, beginning with courtship and ending with fledging or weaning and dispersal of offspring. The value of estimates made at different points varies with the species or taxon and with the goals of the investigation. For example, observations of singing males or nests in a given area will establish density of reproductive pairs, whereas counts of placental scars in mammals at necropsy provide only a size estimate of previous litters.

Knowledge of the variety of measurements of reproductive performance that can be made throughout the reproductive cycle of a given species provides the investigator with more options for meeting specific study objectives. This knowledge also allows the investigator to consider techniques that might be used at different times of the year to achieve more efficient use of fiscal resources and biological material. Accordingly, the sequential events in the reproductive cycle, from **gametogenesis** and breeding to **fledging** or **wean-**

ing, form an outline for this review of techniques and measurements used in the study of reproduction.

Reproductive Modes and Performance in Females

Amphibians and reptiles exhibit a fascinating array of reproductive patterns compared to the relatively uniform condition among birds and in mammals, and although similar protocols can be used with these taxa to study male reproduction (spermatogenesis), females are more challenging. Fertilization is external in amphibians (Fig. 21.1), but internal in **amniotes** (i.e., reptiles, birds, and mammals). Moreover, all birds and nearly all amphibians are **oviparous** (i.e., eggs are laid and hatch outside the mother), whereas all mammals, except monotremes, are **viviparous** (i.e., embryos develop to term in utero, sustained on nutrients transferred through a placenta). Most reptiles are oviparous, but about one-fifth of all lizards and snakes are viviparous (Blackburn 1993). Even in some oviparous species, shelled eggs are retained and hatch in the uterus. Awareness of these diverse modes and patterns of reproduction is important, because they pose constraints as well as opportunities in planning research. For example, in field studies of frogs, should investigators search for egg masses or sample for tadpoles? With viviparous snakes, can ovulation rate be estimated from counts of CL on the ovary and can pregnancy be diagnosed from plasma progesterone levels, as in mammals? These and similar questions often can be studied effectively through comparative biology, in which knowledge of a process in a well studied taxon (e.g., gestation in mammals) is applied to

Fig. 21.1. Modes of reproduction in amphibians and reptiles. Fertilization is internal in reptiles and external in amphibians. Postovulatory follicles develop into corpora lutea in most reptiles, but remain empty in most amphibians. In viviparous reptiles, embryos are retained in the uterus without a shell and are nourished via a placenta. From Zug et al. (2001) with permission from Elsevier.

the same process in a closely related taxon (e.g., viviparous reptiles).

Three major stages of reproduction in females provide a framework for comparative methodology of reproduction in terrestrial vertebrates: (1) ovarian activation and mating, including seasonal and social activation, follicular development, yolking of eggs, and courtship behavior; (2) ovulation, fertilization, and embryonic development (incubation and gestation); and (3) hatching or birth and parental care of neonates and young.

Ovarian Activation and Mating Follicular Development

Onset of the breeding season in vertebrates is indicated by an increase in size of the ovary, stemming from an increase in number and size of **tertiary follicles** (i.e., large, yolk-filled [except in mammals] preovulatory follicles). For example in toads (*Bufo* spp.), a small subset of the 30,000–40,000 oocytes in the ovary is responsive to gonadotropin in any given cycle and begins to accumulate yolk. **Vitellogenesis** (i.e., yolking of eggs) is rapid just prior to ovulation, when mature ova reach 10–100 times their original size (Jorgensen 1992). In most oviparous species, the ovary, nearly undetectable in the nonbreeding season, increases to nearly fill the body cavity with yolked eggs, a process wherein ovarian mass increases to represent up to 30% of the total body mass in some taxa. In such species, a **gonadosomatic index** (i.e., ovarian mass divided by body mass) provides a convenient indication of the onset of the breeding season (Licht et al. 1983, Itoh et al. 1990) and, by extrapolation, the proportion of breeding females in a population, whereas body

mass alone provides information on the energetic status of individuals (Leary et al. 2008).

Tertiary ovarian follicle counts have been used as measures of reproductive activity in band-tailed pigeons (*Patagioenas fasciata*; March and Sadlier 1970) and mourning doves (*Zenaidura macroura*; Guynn and Scanlon 1973). Ankney and MacInnes (1978) were able to distinguish a group of large >20-mm diameter, highly vascularized preovulatory follicles from smaller (10 mm) ones (Fig. 21.2) and thereby estimate potential clutch size in a sample of snow geese (*Chen caerulescens*) shot as they arrived in nesting areas. Because these estimates of ovulation rate are collected at necropsy, they can be analyzed with reference to other data, such as carcass weight, nutrient reserves, and blood hormone concentrations.

Courtship and Estrus

Follicular development and yolking of eggs is accompanied by increased secretion of **estrogen** from large ovarian follicles. **Estrus** is the behavioral state of sexual receptivity associated with elevated estrogen immediately preceding or coincident with ovulation. Elaborate courtship behaviors, which ultimately bring male and female together to fertilize eggs, are obvious and well known in many species of vertebrates. These include calling of male frogs, toads, and passerine birds and visual displays, such as the head-bob and dewlap extension of the male green anole (*Anolis carolinensis*; Crews 1980). In other groups, including salamanders, reptiles, and mammals, social status and readiness to breed may not be communicated in obvious vocal or visual displays, but through **pheromones** (Johnston 2003, Vanden-

Fig. 21.2. Avian ovary showing a presumptive clutch (group of preovulatory follicles) in a hierarchy of follicles. Also shown is a postovulatory (collapsed) follicle with a ruptured stigma and an ovum entering the infundibulum of the oviduct. From Nelson (1953) with permission.

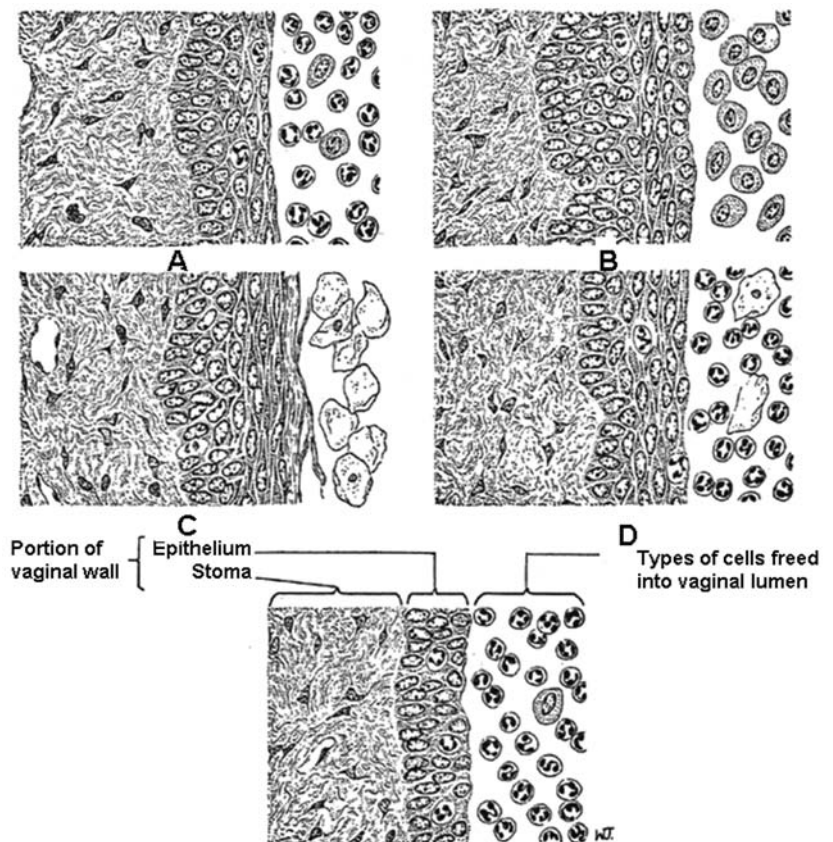

bergh 2006, Harder et al. 2008), which are chemicals released by one individual that elicit a behavioral or physiological response in conspecifics. Pheromones, which may be released in scent marks of urine or feces, or secreted by specialized glands (e.g., cloacal glands in salamanders and skin glands in many snakes; Norris 2007), attract and activate reproductive behavior in the opposite sex and may also signal the loss of attractivity and receptivity in females after mating (Mendonca and Crews 2001). Pheromones are widely recognized in sexual signaling (e.g., estrus in females), but in some species, **priming pheromones** also regulate physiological processes. For example, male urine accelerates puberty in female mice (*Mus musculus*), with potential demographic effects (Drickamer 1990), and female opossums (*Monodelphis domestica*) remain reproductively inactive when isolated from males and their scent marks, which contain a nonvolatile estrus-inducing pheromone (Harder et al. 2008).

Wildlife biologists have found that captive breeding programs may be required when prospects for natural reproduction are diminished, as with endangered species, such as the California condor (*Gymnogyps californianus*) and black-footed ferret (*Mustela nigripes*). Zoos holding threatened or endangered species have begun to use more advanced techniques, such as cryopreservation (freezing) of sperm and in **vitro fertilization** in wild species (*Felis nigripes* and *F. margar-*

ita; Herrick et al. 2010) and **embryo transfer** with multiple laparoscopic oocyte retrievals in fishing cats (*Prionailurus viverrinus*), caracals (*Caracal caracal*), and domestic cats (Pope et al. 2006).

Detection of the time of estrus relative to the time of impending ovulation is essential to success of nearly all captive breeding programs. **Artificial insemination** requires placement of sperm into the vagina in a relatively narrow time period within 6–24 hours of ovulation. Proper timing can be accomplished in large species by monitoring follicular development near the time of estrus by laparoscopy or ultrasonography (Ginther 1990) and, in some cases, with predictive hormone profiles (see below; Brown et al. 2004). Hormonal changes that occur throughout the estrous cycle induce changes in the relative proportion of leukocytes and types of epithelial cells in the vaginae of rodents and certain other mammals (Fig. 21.3). A rise in circulating **estradiol** (a type of estrogen) that occurs just prior to estrus stimulates a rapid proliferation and sloughing of keratinized epithelial cells into the lumen of the vagina, a condition indicative of estrus. Because each stage of the cycle is characterized by a particular vaginal cytology, estrous cycles can be monitored, and time of estrus can be predicted (Fig. 21.3, Box 21.1). The technique, first described for domestic rodents (guinea pigs, rats, and mice, [Zarrow et al. 1964]), has been applied

Fig. 21.3. Sections through the vaginal wall of the rat, illustrating changes in the proportions of two types of epithelial cells and leukocytes that are released into the lumen of the vagina during each stage of the estrous cycle. (A) diestrus: a predominance of leukocytes; (B) proestrus: primarily nucleated (basal) epithelial cells; (C) estrus: an abundance of keratinized epithelial cells; (D) metestrus; (E) a female that had been ovariectomized for 6 months (i.e., diestrus). From Turner and Bagnara (1976) with permission.

BOX 21.1. CHARACTERISTIC VAGINAL CYTOLOGY FOR EACH STAGE OF THE ESTROUS CYCLE AND PROCEDURES FOR COLLECTION AND STAINING OF CELLS FROM THE VAGINA

Estrous Cycle

The estrous cycle is a sequence of changes in ovarian activity and physiology of the reproductive tract, punctuated with recurring periods of sexual receptivity (estrus) and ovulation. Although estrous cycles of different species vary considerably in length (from a few days to several weeks) and in the timing of cytological changes around estrus, the following description of the 4–5-day estrous cycle of the laboratory rat (adapted from Turner and Bagnara 1976) is reasonably representative of the 4 stages in other species that exhibit cyclic vaginal cytology.

Diestrus is a relatively long stage (60–70 hours) that extends into pregnancy if fertilization occurs or into anestrus during the nonbreeding season of many wild mammals. Corpora lutea (CL) begin to regress, and progesterone levels decline late in this stage. Leukocytes migrate through the thin vaginal mucosa and appear as the predominant cell type in vaginal smears (Fig. 21.3A).

Proestrus precedes estrus and lasts for 17–21 hours; it also is known as the follicular phase in species with longer estrous cycles. It is characterized by growth of preovulatory follicles, elevated estrogen levels, and swelling of the uteri. Nucleated epithelial cells dominate the vaginal smears collected at this time (Fig. 21.3B).

Estrus is the period of heat, peak estrogen levels, and ovulation; sexual receptivity is high and limited to this period, which lasts for 9–15 hours. The vaginal epithelium proliferates rapidly, causing the upper layers to exfoliate into the vaginal lumen. Vaginal smears taken at this time are dominated by keratinized (wrinkled) epithelial cells with low numbers of nucleated epithelial cells and leukocytes (Fig. 21.3C).

Metestrus lasts for 10–14 hours in the rat, begins with formation of CL following ovulation, and is characterized by elevated progesterone levels. Metestrus and diestrus are generally known as the luteal phase in species with longer estrous cycles. Large numbers of leukocytes invade the vaginal lumen and often appear clumped around a few keratinized epithelial cells in the vaginal smear.

Vaginal Smear Procedure

1. Appropriate restraint for collection of the smear varies with size and behavior of the animal under study, but many species, ranging from mice to opossums in size, can be handled by grasping the tail. The animal is allowed to stand on the top of a bench or a cage while the tail is raised to expose the vaginal orifice. With this approach, the animal's struggling is reduced and focused on escape, which directs the head (and teeth) away from the handler.
2. To collect cells from the vaginal lumen, a cotton swab is moistened with physiological saline and inserted into the vagina, rotated, and removed. Cells are transferred by rolling the tip of the swab over the surface of a microscope slide. Alternatively, cells can be collected by vaginal lavage, which is the recommended approach for mouse-sized animals. With this procedure, the tip of a fire-polished Pasteur pipet or disposable pipet tip containing a drop of physiological saline is inserted a few millimeters into the vagina. The saline solution is aspirated several times to rinse the vaginal lumen and collect cells. A drop of the aspirated cell suspension is then placed on a microscope slide to dry.
3. The dried vaginal smear may be fixed by gently rinsing with or immersing the slide in 100% ethanol and allowing the smear to dry.
4. The smear is then stained by immersion in a methylene blue solution for 10–15 minutes. After the smear is rinsed gently with distilled water and dried, it is ready for microscopic examination. Reliable monitoring of estrous cycles by vaginal cytology requires that observers be able to recognize 3 types of cells found in the smears (Fig. 21.3A–C).

Polymorphonuclear leukocyte is a small cell (less than half the size of epithelial cells) with a large, lobed nucleus and little visible cytoplasm. This cell is represented by small, dark-staining, C-shaped nuclei in vaginal smears (Fig. 21.3A).

Nucleated epithelial cell is a large, rounded cell with a prominent nucleus (basal cell) that appears in greatest numbers during proestrus, but it can be found in smears collected during all stages of the cycle (Fig. 21.3B).

Keratinized epithelial cell is a large, squamous cell with a wrinkled, “potato chip” appearance. The nucleus is degenerate and is often not visible, even in stained preparations. These cells are present in such large numbers at estrus that a vaginal lavage takes on a milky appearance (Fig. 21.3C).

to diverse species, including pine voles (*Microtus pinetorum*; Kirkpatrick and Valentine 1970), American beaver (*Castor canadensis*; Doboszyńska 1976), domestic dogs and cats (Stabenfeldt and Shille 1977), coyotes (*Canis latrans*; Kennelly and Johns 1976), and Virginia opossums (*Didelphis virginiana*; Jurgelski and Porter 1974).

Ovulation and Embryonic Development

Perhaps the one reproductive parameter of greatest importance to natality and recruitment in all vertebrates is **ovulation rate**. Fortunately, it can be measured directly, or indirectly, with accuracy in most species.

Postovulatory Follicles

After ovulation and release of mature eggs into the oviduct, the collapsed wall of the ovarian follicle in most vertebrates does not form a **corpus luteum** (CL; the acronym is used for both singular and plural [corpora lutea]), as it does in viviparous reptiles and mammals. Instead, **postovulatory follicles** (POF) regress, the process being completed in many avian species within a month after ovulation (Payne 1973). However, in some species, such as the ring-necked pheasant (*Phasianus colchicus*), POF persist for months as small (1–2 mm) pigmented (reddish brown) structures that can be viewed macroscopically (Fig. 21.2). Kabat et al. (1948) reported a high correlation between number of eggs laid and number of POF counted in captive pheasants killed up to 100 days after ovulation, thus providing a potential method for estimating clutch sizes in summer from hens harvested the following autumn. However, Hannon (1981) found that POF in blue grouse (*Dendragapus obscurus*) could not be counted macroscopically beyond approximately 25 days of age, although they could be used to distinguish laying from nonlaying hens shot during the hunting season. Similarly, POF allowed independent observers to correctly distinguish breeding from nonbreeding mallard (*Anas platyrhynchos*) hens 60–90 days after laying and thereby estimate breeding propensity in free-ranging mallard populations (Lindstrom et al. 2006).

Observation of the avian ovary need not be limited to necropsies. **Laparotomy** has been widely used for identifying the sex of monomorphic birds that are captured live in mist nets and other types of traps (Risser 1971). An incision is made on the left side to expose the left testis or ovary, the latter being distinguished by the presence of follicles. The incision is small, and the procedure can be accomplished in the field, providing that appropriate surgical procedures are used (Wingfield and Farner 1976). Although an accurate classification or count of POF is not feasible under such conditions, laparotomy can provide useful information on the stage of follicular development and proportion of birds nearing the egg laying stage.

Clutch Size

Estimation of **clutch size** (number of eggs in a nest) is by far the most popular and practical method of estimating

ovulation rate in oviparous vertebrates. However, locating the nest is a challenge, particularly with many species of frogs and salamanders. Even when nests or egg masses are obvious, difficulty may be encountered in developing unbiased sampling procedures that permit projection of estimates to the population level or unit area of habitat. In species whose nests and egg masses can be reliably located, number of nests, their distribution, and survival to time of hatching are recorded, but seldom is the number of eggs per egg mass noted. Enumeration of the tadpole and larval stage is more commonly recorded and used as an index of reproductive rate and hatching.

Clutch size has been most extensively studied and applied to avian population ecology. Most birds lay at most one egg per day immediately prior to incubation. Ovulation precedes laying or deposition of the egg by approximately 26 hours. Thus, close observation of a laying hen provides immediate, real-time data on ovulation rate and an opportunity to study the temporal relationships among courtship behavior, copulation, ovulation, and associated hormone changes.

Avian nests found early in the incubation period provide not only a good estimate of number of eggs laid, but also a basis for estimating egg loss and hatching success. Furthermore, sampling procedures normally provide estimates of nest density that in turn can be used to calculate size of the breeding population of females in monogamous species. In such cases, estimates of reproductive rate and population structure are available, and thus, **gross natality** may be calculated.

Clutch size has been estimated in relatively few amphibians. More often, numbers of nests or egg masses per area or habitat type are recorded. Crouch and Paton (2000) found these data more useful than estimates of the number of calling males as an index to abundance of wood frogs (*Rana sylvatica*). However, even with frogs that lay obvious egg masses, the number of eggs is most often expressed in 10s or 100s and seldom with estimates of mean and variance.

Follicular development (Leyton and Valencia 1992) and clutch size have been estimated for a large number of reptiles. It is possible to visualize even partially calcified eggs in the oviduct with X-ray photography and thereby estimate time of ovulation and future clutch size (Gibbons and Green 1979). However, the short- and long-term effects of radiation exposure on the young remain largely unknown. Vitt (1992) summarized studies of 26 species of squamate reptiles in the Caatinga of Brazil; clutch sizes across species were primarily in the range of 2–15 (maximum of 31) and were positively correlated with body size in some species (Abell 1999, King 2000). Many reptiles, including turtles, lay >1 clutch per season. Congdon and Gibbons (1996) reported clutch size data on nests (>2,500) of 3 species of turtle as part of a long-term multifaceted study of community structure and dynamics in southern Michigan.

Nesting behavior and clutch size have been studied extensively in several species of sea turtles (Cheloniidae). Their

nests are concentrated in traditional nesting beaches and thus can be located with relative ease. Nests are the focus of sea turtle biology, because all other phases of the life cycle occur in the open ocean and are largely unavailable for study. Most species of sea turtles require >20 years to reach maturity and have complex multiyear reproductive cycles with evidence of delayed fertilization. Females lay from 2 to 5 clutches during a season. Owens (1995) recommended establishment of colonies of adult turtles held captive in large natural ponds with beaches to study these events in greater detail. This effort could be particularly valuable in clarifying details of male reproductive biology and temporal relationships between insemination and fertilization in a number of sea turtle species. Clutch size in sea turtles usually exceeds 100 (Miller 1997) and shows a positive correlation with body size of the female, at least in green (*Chelonia mydas*) and loggerhead turtles (*Caretta caretta*; Ehrhart 1995). Although largely peripheral to the scope of this chapter, it should be noted that Cheloniidae is one of 19 families of reptiles with species in which sex determination is temperature dependent (Zug et al. 2001). For example, if the average incubation temperature in the nest of many species of turtles exceeds approximately 30° C, nearly all young will be female, whereas the opposite effect is seen in some lizards and alligators (Nelson 2000).

Because the avian egg contains all nutrients and energy required by young from conception through the immediate post-hatching period, egg size and quality are major factors affecting hatching success and survival of avian young. This was demonstrated in studies of yolk and albumen content of eggs of snow geese (Ankney 1980) and the positive relationship between egg size, motor ability, and postnatal weight gain in Australian brush-turkey (*Alectura lathami*) chicks (Göth and Evans 2004a). Vangilder and Peterle (1981) observed a reduction in eggshell thickness and proportion of yolk contained in eggs laid by mallards fed either crude oil or DDE (1,1-dichloro-2,2-bis[*p*-dichlorodiphenyl]ethylene), and Beckerton and Middleton (1982) demonstrated that increasing protein content (from 7.6% to 20.1%) in isocaloric diets of ruffed grouse (*Bonasa umbellus*) was associated with linear increases ($P < 0.025$) in a series of 9 reproductive parameters, ranging from clutch size and egg weight to chick survival. However, Arnold and Green (2004) cautioned against using allometric regression to characterize the relationship between proportional egg composition and egg size.

Ovarian Function and Ovulation in Mammals

Mammalian eggs are microscopic (10–30 μm), retained in the female reproductive tract, and therefore, cannot be easily counted. Direct enumeration of the number of eggs released in a given estrous cycle requires flushing eggs from the oviduct and/or uterus with isotonic medium and examining the resulting fluid microscopically. This approach is impractical for most wildlife investigations and is seldom

used except for embryological studies or intensive studies of reproductive physiology, such as those involving embryo transfer. Instead, ovaries are examined for follicular development or evidence of ovulation, such as the presence of CL and related scar structures.

Ovarian analysis requires a basic understanding of anatomy and physiology with respect to the events preceding and following ovulation. The mammalian ovary contains a life-long supply of **primary oocytes** (in prophase of meiosis) at birth, contained in small primary follicles (Fig. 21.4). During each estrous cycle, a small fraction of these follicles begin growing more rapidly and develop a fluid-filled cavity or antrum. These growing follicles secrete increasing amounts of estrogen, which stimulates estrus and, indirectly, ovulation in spontaneous ovulators. Some of these **antral (Graafian) follicles** reach precisely the appropriate stage of preovulatory development to respond to a surge in **luteinizing hormone (LH)** secretion at estrus and ovulate. Most follicles, however, do not reach the preovulatory state, but instead undergo atresia, a degenerative process leading to disassociation of the granulosa layers of the follicle and death

Fig. 21.4. Drawing of the mammalian ovary, illustrating (in clockwise progression) follicular development (from primordial to Graafian follicle), ovulation, development of a corpus luteum (CL), and regression of the CL. The ovum is released with follicular fluid from the ruptured follicle. From Turner and Bagnara (1976) with permission.

of the oocyte. Thus, a dynamic balance of follicular development and atresia affects the ovulation rate in any given estrous cycle.

Ovulation results in rupture of the follicle that leaves a **corpus hemorrhagicum** (the ovulation point or blood spot) and initiates immediate luteinization of thecal and granulosa cells of the follicle wall (i.e., they enlarge and sequester lipids). This process results in filling of the cavity and the formation of the CL (Fig. 21.4), a transient endocrine gland that secretes progesterone, a hormone essential for support of pregnancy.

If fertilization or pregnancy fails, CL regresses, and a new estrous cycle begins with growth of preovulatory follicles. However, if conception occurs and embryos implant in the uterus, CL persist and secrete large amounts of **progesterone** throughout a substantial portion of the gestation period. CL of pregnancy become large, often occupying much of the volume of the enlarged ovary (Fig. 21.4). Prior to or coincident with parturition, CL begin to regress, and progesterone secretion declines sharply.

LAPAROSCOPY AND ULTRASONOGRAPHY

Ovarian analysis of wild mammals is usually conducted on material collected during necropsy of carcasses obtained at hunter check stations or other sources, such as traffic accidents. However, with application of fiber optics to surgical instruments, internal examination of live animals has become safer and more convenient through a technique known as **laparoscopy**. The abdominal wall is punctured with a large needle cannula, through which a fiber optic scope (2–10-mm diameter) is inserted. Organs can be manipulated with a probe inserted through a second canula. With this technique, it is possible to observe ovarian follicles and CL as well as uterine swellings. The animal must be anesthetized, but incisions per se are not made, which minimizes surgical trauma and risk of infection. An extensive review of laparoscope methodology is presented in Harrison and Wildt (1980). Although laparoscopy is widely used in medicine and animal science, applications in wildlife research have been limited. However, Nelson and Woolf (1983) observed no complications or mortalities in 20 radiocollared white-tailed deer (*Odocoileus virginianus*) monitored after laparoscopy of ovaries in the field. Laparotomy and laparoscopy both require special equipment and training and are recommended only in situations where (1) multiple observations on the same animals are required, as in pen-based experiments; (2) the animal under study is rare or endangered; or (3) the animals are valuable, and little is known of their basic physiology (e.g., zoo animals).

Echoes of high frequency sound (3–8 megahertz [mHz]), processed by real-time computerized video displays, also can be used to reveal internal morphology. This technique, known as **ultrasound** or **ultrasonography** and widely used in human medicine, is recognized as a practical and reliable ap-

proach to monitoring estrous cycles and gestation in live-stock and several wild species, including bottlenose dolphins (*Tursiops truncatus*; Williamson et al. 1990), red deer (*Cervus elaphus*), black rhinoceros (*Diceros bicornis*), giraffe (*Giraffa camelopardalis*), gaur (*Bos gaurus*; Adams et al. 1991), and several species of rhinos and elephants (Hildebrandt et al. 2006). The procedure is particularly effective in visualizing antral follicles, because the liquid phase absorbs ultrasound and appears black in contrast to surrounding tissue, which emits strong ultrasound echoes. Ultrasonography has been used successfully to count and measure follicles >2 mm in diameter (Fig. 21.5) and to monitor the growth of larger (5–15 mm) individual follicles in cows (Sirois and Fortune 1988). Ultrasonography with this level of resolution has the potential for monitoring ovarian activity in larger carnivores, ungulates, and gravid sea turtles (Kuchling 1999) without use of invasive surgical procedures. More recently, advances in ultrahigh frequency (40 MHz) ultrasonography have permitted characterization of structures as small as 70 μm and monitoring of follicular development in mice (Jaiswal et al. 2009).

ENUMERATION OF CL

Follicle counts will not predict ovulation rate in mammals. However, the ovary develops an unambiguous sign of ovulation: the CL, which in most species, grows to occupy most of the volume of the ovary. In large mammals, such as domestic cattle, the CL can be palpated through the rectum with a gloved arm and hand. This procedure, routinely used in the dairy and beef industry, has limited utility in wildlife studies because of size limitations, although it has been used on elk (*Cervus canadensis*; Greer and Hawkins 1967).

CL can be counted and ovulation rate estimated in medium-sized to large mammals through gross (or with the aid of a dissecting microscope) examination of sliced ovaries obtained at necropsy (Box 21.2; Fig. 21.6). This approach has been applied widely to many species, including American beaver (Provost 1962), moose (*Alces alces*; Simkin 1965),

Fig. 21.5. Ultrasound images of ovaries in cattle; arrows mark the periphery of the ovary. (A) Three medium follicles (5–7 mm in diameter) are visible as dark, round objects. (B) Several small (2–3 mm) follicles are visible to the right of a large (12 mm) follicle on this ovary. From Pierson and Ginther (1988) with permission.

BOX 21.2. PRESERVATION OF TISSUES AND GROSS OVARIAN ANALYSIS

Preservation of Tissues at Necropsy

Postmortem changes are slowed considerably at low temperatures (e.g., 4° C), and organs may be frozen before subsequent gross examination. However, ice crystals that form in the cytoplasm ruin cells for microscopic study. If histology is planned, organs and tissues must be placed in a fixative solution at necropsy.

Fixatives are used prior to histology to (1) prevent purification, (2) coagulate protein, and (3) protect the tissue against shrinkage and distortion in subsequent procedures. Buffered 10% formalin (1:10 dilution of 40% formaldehyde) is used widely, but it is only one among many options. A histology manual (e.g., Humason 1979) should be consulted for specific recommendations. The volume of fixative should exceed that of the tissue by 5 or 10 times to avoid excessive dilution of the fixative by water diffusing from the tissue.

Gross Examination of Deer Ovaries

1. Ovaries are removed by cutting the mesovarium, the mesentery that suspends the ovary in the body cavity, near the ostium of the oviduct. Ovaries are more easily manipulated if some mesovarium remains with the ovaries, and left and right ovaries can be identified later if extra mesovarium is routinely left on the ovary from one side.
2. After ovaries have been in a fixative, such as formalin, for 36 hours, they will harden sufficiently to withstand slicing. Each is removed from the fixative and rinsed thoroughly in tap water. Caution: formaldehyde is toxic, and so latex gloves should be worn and all work with formalin-fixed material should be done in a fume hood.
3. An ovary can be secured by grasping the mesovarium close to the ovary with curved forceps or hemostat. It is then sliced along the long axis with a scalpel or razor blade, cutting toward the mesovarium and forceps (Fig. 21.6). With practice, horizontal slices of about 2-mm thickness can be cut, stopping just before the mesovarium is reached. In this way, the sliced ovary will stay together like pages of a book, ready for thorough, repeated examination. Hawley (1982) described a razor-blade device used to slice moose ovaries into uniform 1.5-mm sections.
4. Ovaries collected during the breeding season will contain a number of follicles of mixed size and, perhaps, recently ovulated follicles or new corpora lutea (CL) with ovulation points still evident. New CL of pregnancy grow to near full size (7-mm diameter) in the first 2–3 weeks after ovulation and eventually occupy most of the ovarian volume during pregnancy in deer. Thus, they can be “followed” through several slices from one side of the ovary to the other. The sliced surface is solid, cheesy in texture, and creamy white in color. The color varies from yellowish to gray in other species.
5. Far less evident are the small corpora albicantia (CA), pigmented scars of the regressing CL of the previous pregnancy (Cheatum 1949). Each slice of ovary must be carefully examined on both sides for these small (1–3-mm diameter) rust-colored structures, which are often compressed into triangular or crescent shapes by surrounding follicles and growing CL. Color is the primary distinguishing characteristic, but it can vary from dark yellow to deep brownish orange.
6. If the ovary is to be saved for further macroscopic or microscopic examination, it should be stored in 70% ethanol to prevent excessive hardening.

red fox (*Vulpes vulpes*; Oleyar and McGinnes 1974), and eastern cottontail rabbits (*Sylvilagus floridanus*; Zepp and Kirkpatrick 1976). **Accessory CL** (i.e., unovulated luteinized follicles) and other structures unrelated to ovulation can, at times, be distinguished by size and appearance.

Counts of CL provide an accurate measure of **ovulation rate**, but are only an index to number of young in utero. This is because CL form during the normal course of each estrous cycle whether or not conception occurs, and even though most animals collected from the wild with active CL

will be pregnant, each ovulated follicle forms a CL—whether or not the egg from each follicle is fertilized—and undergoes embryonic development. Thus, if the fertilization rate in a given species is low or if embryonic or fetal losses are high, CL counts will overestimate number of young produced. For example, the Virginia opossum has a high ovulation rate (30 CL/ovary/cycle; Fleming and Harder 1983), but gives birth to only 10–20 young and weans 6–8. Although conception rates in most species are much higher than for opossums, fertilization rates and in utero survival

Fig. 21.6. (A) Procedure for slicing a fixed ovary with a razor blade. (B) A view of the sliced ovary, showing an antral follicle (AF) and a corpus luteum (CL). Photos by D. Dennis.

vary considerably among species and must be identified for each separately (Brambell 1948).

OVARIAN ANALYSIS OF DEER

All CL leave scar tissue in the ovary as they regress. In most mammals, they are visible only in microscopic examination as whitish bodies of connective tissue known as **corpora albicantia** (CA). However, the large, long-lived CL of pregnancy in cervids regress slowly after parturition and are grossly visible as pigmented CA (sometimes called corpora rubra; Cheatum 1949; Box 21.2). Ovaries of deer are most often collected at hunter check stations in October–December (i.e., often before all does in a population have had an opportunity to ovulate and before fetuses are visible in utero). Therefore, considerable attention has focused on CA as a basis for estimating number of fetuses carried to term in the previous pregnancy (preceding spring).

The value of CA counts in estimation of average litter size in previous pregnancies depends on knowledge of the fertilization rate and longevity of the CA. The **fertilization rate** (fetuses/CL) in deer is high and remarkably constant (85–90%; Roseberry and Klimstra 1970, Barron and Harwell

1973, Woolf and Harder 1979). Unfortunately, the longevity of CA is variable, sometimes remaining grossly visible for more than a year. Identifying the age of CA through histological examination (Mansell 1971) would largely eliminate biases in estimation of previous litter sizes, but this is seldom feasible for management surveys.

Examination of the ovaries of yearling does for CA has great value and utility for estimating the percentage of fawns breeding in a population. With few exceptions, the maximum ovulation rate for fawns that reach puberty and ovulate is 1 ovum per female. Thus, yearlings that are killed during the hunting season or in traffic accidents during July–February will yield reliable CA data, because, for all practical purposes, only 2 possibilities exist: 0 or 1 CA per doe. The proportion of females that conceive in their first year reflects the nutritional status of the herd and varies from 0 (Woolf and Harder 1979) to a high of 77–82% (Nixon 1971, Haugen 1975). This demographic parameter is important, because the 6-month age class is the largest in any population, and therefore, one that has great potential for impact on natality, population growth, and sustainable yield (Harder 1980).

Uterine Analysis in Reptiles and Mammals

Viviparous reptiles and mammals retain developing young in utero and thus, present evidence of reproductive performance equivalent to clutch size in oviparous vertebrates. Enumeration of embryos or fetuses in utero has long been a popular and convenient measure of the reproductive performance of a population. Popular, because the number in utero, especially during the third trimester of gestation, is often a reliable indicator of the number of young that will be born (i.e., **litter size**). Uterine examination for embryos or fetuses is convenient, particularly in later stages of gestation, because fetuses are grossly visible and can be reliably counted by hunters or personnel handling animals killed on highways. The entire uterus with fetuses may be collected and frozen or fixed for later study, or it can be inspected on location. Crown–rump length measurements can be used to estimate age of white-tailed deer (Armstrong 1950) and coyote fetuses (Kennelly et al. 1977) and, by backdating, to estimate breeding dates. The primary sex ratio for a population can be estimated from examination of fetuses, a parameter of practical value in population models and of considerable interest among theoretical and experimental ecologists (Trivers and Willard 1973, Austad and Sunquist 1986, Gosling 1986, Rosenfeld and Roberts 2004).

Fetal counts are most often done at necropsy, but in many instances, this information must be obtained from living animals, such as during investigations of rare and endangered species or animals in zoos. Uterine swellings, indicative of fetuses, and CL of pregnancy can be counted in living animals by laparotomy. This approach has been used on cottontails (Murphy et al. 1973), white-tailed and mule

deer (*Odocoileus hemionus*; Zwank 1981), and elk (Follis et al. 1972). Ultrasound readings were used to successfully diagnose pregnancy during the last trimester of gestation in mountain sheep (*Ovis canadensis*; Harper and Cohen 1985) and pronghorn (*Antilocapra americana*; Canon et al. 1997). Several noninvasive methods, based on hormonal and biochemical changes in blood, are available for diagnosing pregnancy.

Birth and Parental Care of Young

Nest Success

The number of young born or hatched per female is the most ecologically important reproductive parameter that can be measured. It is the basis for calculating gross natality and can be obtained with reasonable accuracy for many avian species and some herptiles. If the location of nests and clutch size is known, the number of live young can be obtained by repeated inspection of the nest. This is the basis of the **Mayfield method** for estimating nest success of birds (Dinsmore and Johnson 2005). The eggs of most viviparous reptiles are laid in spring and hatch by late summer, but in a number of turtles (e.g., painted turtles [*Chrysemys picta*]; Breitenbach et al. 1984), emergence of young from the nest is delayed until the following spring, when foraging conditions are more favorable (Fig. 21.7).

Amphibians, particularly frogs, exhibit the greatest diversity of modes of parental care among terrestrial vertebrates. What might be viewed as a typical pattern in north temperate regions (i.e., eggs deposited in vernal pools and hatching into free-foraging tadpoles) is just 1 of 27 different modes recognized by Zug et al. (2001). Seemingly every possible pattern has been observed: from tadpoles emerging from eggs laid on tree leaves and dropping into ponds or streams to eggs that are carried in the dorsal pouch of the female and develop directly into froglets. These diverse patterns present fascinating natural history and opportunities for expanding knowledge of traditional reproductive ecology of a

group that is undergoing an alarming decline in diversity and abundance (Semlitsch 2000, Hayes et al. 2010). The challenge is to devise search and sampling procedures that produce estimates useful for population models. The most common approach for estimating number of young at birth in amphibian populations involves use of funnel traps for tadpoles and larvae (Adams et al. 1997) or setting of pit-fall traps along a drift fence that encircles a breeding pond (Semlitsch et al. 1996).

The nests of many oviparous and viviparous species (some lizards, snakes, and mammals) cannot be located with statistical validity. Thus, the number of young born must be inferred from data collected in utero or, for some frogs, other parts of the body. Ovarian and uterine analyses described in some detail for white-tailed deer could be developed for other viviparous species. More studies of mammals and reptiles are needed to establish the relationship between ovarian scars of CL and the number of young carried and born. Thus, ovaries collected from females shortly after they give birth might provide a measure of litter size. The extent to which uteri of viviparous reptiles might reveal early implantation sites as indicators of potential litter size is largely unknown.

Placental Scars

These scars are pigmented areas of uterine tissue marking sites of previous placental attachment in mammals (Fig. 21.8). Their formation, described by Deno (1937) and Martin et al. (1976), is limited to taxa with deciduous placentae (Wydoski and Davis 1961). Erosion of the uterine endometrium by the embryonic trophoblast and an interdigitation of uterine and chorionic tissue is such that endometrial tissue is torn away when the placenta is expelled at birth (i.e., the placenta is **deciduous**; Vaughan et al. 2000). As the new uterine endometrium grows over this wound, stagnant pools of blood become trapped, and the hemoglobin in the red blood cells is degraded to hemosiderin (an iron-containing pigment) by macrophages. The entrapped hemosiderin remains visible as a placental scar for varying lengths of time.

Species known to develop prominent placental scars belong primarily to the mammalian orders (Insectivora, Chiroptera, Lagomorpha, Rodentia, and Carnivora). However, scarring also has been described in such divergent taxa as elephants (Laws 1967), and it is possible that some squamate reptiles, with mammalian-like chorioallantoic placentae (Blackburn 1993), also develop placental scars. Litter size has been estimated from placental scars in a variety of carnivores, including brown bears (*Ursus arctos*; Hensel et al. 1969), raccoons (*Procyon lotor*; Sanderson 1950), and gray fox (*Urocyon cinereoargenteus*; Oleyar and McGinnes 1974). Placental scars are most useful in mammals that have only 1 or 2 litters per year, such as American beaver (Henry and Bookhout 1969) or gray squirrels (*Sciurus carolinensis*; Nixon et al. 1975). The reliability of the method has been recently confirmed in the

Fig. 21.7. Arrangement of painted turtle hatchlings in an overwintering nest. From Breitenbach et al. (1984) with permission.

Fig. 21.8. (A) Uterine swellings of a pregnant white-footed mouse (*Peromyscus leucopus*). (B) Postpartum uterine horns compressed between the lid and the inverted base of a petri dish to reveal placental scars. Drawings by D. Dennis.

European hare (*Lepus europeus*; Bray et al. 2003). Observations of smaller rodents that have several litters in rapid succession often entail problems in separating scars into sets representing different litters or pregnancies (Rolan and Gier 1967, Martin et al. 1976).

In many species, placental scars can be seen easily in fresh, thawed, or preserved tissue without special treatment. They stand out as darkened spots or bands in the uterine horns. If females are collected soon after parturition, the tissue around the old implantation sites will still be swollen. With increasing time after parturition, however, the scars fade, and additional steps must be taken to clearly see them. A first step, at least with small mammals, is to compress the uterine horns between 2 microscope slides (or with larger uteri, between the nested lid and base of a petri dish; Fig. 21.8). The scars can then be viewed on a dissecting scope, and with backlighting, it is possible to distinguish and count scars in sets. With larger species, it usually is necessary to expose the endometrium of the uterus by cutting longitudinally along the length of each horn with scissors. The scars then appear as darkened bands or discs in the uterine lumen. In some species, placental scars are indistinct, and special clearing or staining procedures are required to make

them more visible (Henry and Bookhout 1969, Humason 1979, Bray et al. 2003). Placental scar count accurately estimated pregnancy rate and litter size in mink (*Mustela vison*) collected up to 3 months postpartum; but with longer intervals, the proportion of females judged to be barren was overestimated, and mean litter size was underestimated (Elmeros and Hammershoj 2006).

Lactation and Nursing

The transition from late gestation to lactation is a critical period in the reproductive cycle of mammals. **Mammary glands** of lactating females grow and fill with milk that can be expressed from the teats of all but the smallest species. If milk cannot be expressed from a female at necropsy, the mammary gland should be sliced open and inspected for pools of milk in the tissue. Nipples of lactating females become swollen and pinkish, and often the fur immediately surrounding the nipple is thin or absent. These and other indications of lactation are only indirect signs that a female is nursing or has recently weaned young. They should be verified, preferably through measurements of females with known reproductive histories, including those nursing young. Some progress has been made in this regard through studies of teat length of yearling white-tailed deer in autumn. Sauer and Severinghaus (1977) concluded that any yearling with 1 of 4 teats 10 mm was without young, and those with 1 teat >15 mm was nursing or had recently weaned a fawn. Both teat length and placental scars merit additional evaluation as indicators of reproductive success in other species, as in fisher (*Martes pennant*; Frost et al. 1999), particularly because data can be collected from carcasses on highways or those brought to hunter check stations.

Because lactating marsupials carry young in their pouch for an extended period (50–60 days in the Virginia opossum), they are attractive subjects for study reproductive ecology (Harder and Fleck 1997, Carusi et al. 2009), particularly of the effect of nutritional status on litter size. For example, Hossler et al. (1994) demonstrated a remarkably close correlation ($R^2 = 0.86$) between a hind-leg fat index and litter size in opossums living near the northern limit of their distribution in New York. Given the reality of substantial neonatal mortality in many wildlife populations, an estimate of the proportion of females in a population that are lactating is more relevant to reproductive success than are parameters measured earlier in the reproductive cycle (e.g., ovulation rate). Coupled with estimates on average litter sizes, lactation indices could substantially improve estimates of net natality (i.e., number of young weaned/female).

Reproductive Patterns and Performance in Males

Reproductive activity in male vertebrates in the breeding season is decidedly noncyclic and less complex than in females, particularly in regard to assessment of reproductive performance. **Spermatogenesis** begins at puberty, and except for periods of seasonal regression, testes normally re-

main active in production of sperm and secretion of testosterone throughout the life of the individual. Sperm are produced by the millions, well in excess of the few hundred that might be required to fertilize even the largest mass of frog eggs. In most species, **reproductive success** of fertile males is ultimately based on the number of females mated or eggs fertilized. It is often a function of courtship behavior or the outcome of interactions with competing males.

Because testes increase in mass with onset of spermatogenesis, testis weight is most often used to monitor the onset of breeding and as an index of the number of breeding males in populations of herptiles, birds, and mammals. Warm spring weather signals the onset of breeding in the Mexican leaf frog (*Pachymedusa dacnicolor*), when active spermatogenesis is coupled with increased testis weight and plasma androgen levels (Bagnara and Rastogi 1992). Testicular enlargement coincides with ovarian activation in some species of salamanders (Semlitsch 1985), but not all (Marvin 1996). Most reptiles have an **associated** reproductive pattern, in which breeding is associated with elevated androgen secretion and spermatogenesis. However, some squamates, such as the red-sided garter snake (*Thamnophis sirtalis*), have a **dissociated** pattern. In this species, sperm produced during summer are stored by the male for use during the following spring breeding season, when testes are actually regressed and androgen levels are low (Fig. 21.9).

Testis Weight and Counts of Spermatozoa

The **gonads** and reproductive tracts of birds generally remain in a regressed state during the nonbreeding season, but increase markedly during the breeding season. For example, the testis of a mature male white-crowned sparrow (*Zonotrichia leucophrys*) will grow from 10 mg to >600 mg during the breeding season (Wingfield and Farner 1980), and elevated plasma **testosterone** in pintail ducks (*Anas acuta*) coincides high ejaculate quality, as evidenced in number and morphology of sperm (Penfold et al. 2000). Seasonal growth and recrudescence of testes and accessory glands of mammals are much less pronounced and more variable across taxa than in birds. In some, such as tammar wallaby (*Macropus eugenii*) and brush-tailed possum (*Tricho-*

surus vulpecula), testis weight changes little throughout the year, although prostate weight and testosterone levels show marked seasonal variation (Gilmore 1969, Inns 1982). Most seasonally breeding mammals, however, show noticeable to marked increases in testis size as well as androgen levels (Mirarchi et al. 1977). Weight and volume (estimated by water displacement in a graduated cylinder) can be obtained at necropsy, but 2-dimensional measurements of scrotal testes on live males also provide a valid index of testicular volume and reproductive status. For example, the volume of testes of white-tailed deer increased from a low of 50 cc in June to >150 cc in November (breeding season), during the same time that plasma testosterone increased from basal (near 0) to >3 ng/mL (McMillin et al. 1974).

The presence of **spermatozoa** (sperm) in the testes or **epididymides** provides evidence of reproductive status and is particularly useful for examining age of puberty or onset of seasonal breeding. Sperm counts also have been used to examine seasonal differences in male reproductive activity (Mirarchi et al. 1977), social stress (Sullivan and Scanlon 1976), and exposure to environmental contaminants (Sanders and Kirkpatrick 1975).

An estimate of sperm density or total spermatozoa per testis or epididymis may be obtained by homogenizing a known mass of sliced tissue in a blender or tissue homogenizer with an appropriate culture medium, such as Hank's solution. Triton X-100 (J. T. Baker, Phillipsburg, NJ) can be added (0.01–0.05% by volume) to prevent foaming in the blender (Amann and Lambiase 1969, Sullivan and Scanlon 1976). Alternatively, testes or sections of epididymides of small species can be thoroughly minced with scissors and rinsed repeatedly with a known volume of culture medium to collect spermatozoa. An aliquot of homogenate or rinse is then removed and added to both chambers of a standard hemocytometer. Sperm density relative to tissue mass can then be calculated with the appropriate dilution factors (Box 21.3). A test for the presence of motile spermatozoa involves cutting the tail of the epididymis from a freshly killed specimen and making a smear on a slide for microscopic examination to detect sperm (Kibbe and Kirkpatrick 1971). Morphology and **motility** are commonly used to assess the

Fig. 21.9. The annual gonadal reproductive cycle of the red-sided garter snake illustrates a dissociated reproductive pattern. Males mate with females in spring, when testes are small and circulating concentrations of androgens are relatively low. Spermatozoa produced during the summer, when testes enlarge and androgen levels are high, are stored in the epididymis until the following spring. Adapted from Crews and Garstka (1982) with permission.

BOX 21.3. PROCEDURE FOR ESTIMATING DENSITY OF SPERMATOZOA AND OTHER TYPES OF CELLS WITH A HEMOCYTOMETER

A hemocytometer is a thick glass microscope slide with 2 identical counting chambers of known volume. It was originally developed to provide standard conditions for human blood cell counts, but it has found application in a wide variety of cytological work, including estimation of sperm density for assessment of male fertility. The highly polished floor of each counting chamber is gridded with fine lines spaced at exact intervals as discussed below.

Ridges on the sides of the hemocytometer hold the cover slip exactly 0.1 mm above the floor of the counting chamber. Consequently, cells counted in a given section of the chamber are related to volume, and cell density can be calculated. Counts can be made on fresh, frozen, or fixed material, but fresh material provides the option of rating spermatozoa for motility. In reality, a hemocytometer provides a convenient system of grids that can be readily applied to a wide variety of microscopic sampling problems.

Procedure

1. Spermatozoa may be obtained from a homogenized testis, but if mammalian sperm are to be evaluated for motility, they must be obtained from ejaculated semen or flushed from the tail of the epididymis. Semen or other material should be diluted with an appropriate culture medium, such as Hank's solution rather than saline, particularly if motility is to be assessed. Medium and the hemocytometer should be held on a slide warmer at normal scrotal temperature (e.g., 35°C).
2. The source material is diluted with a known volume of medium, and a drop is added to both chambers of the hemocytometer.
3. After spermatozoa have settled for 5 minutes, count the number of spermatozoa in sections A, B, C, D, and E of the center grid and multiply the total by 5 to obtain an estimate of the total number in the center grid (1 mm on a side or 0.01 cm²). Alternatively, select one of the 4 corner grids (comprised of 16 squares) at random and count all spermatozoa with heads inside the perimeter lines. If sperm density is high (>40 cells), count within a randomly chosen row of 4 squares and multiply the total by 4 to obtain an estimate of the total in all 16 squares (0.01 cm²).
4. This procedure should be repeated in a grid in the other counting chamber to permit calculation of mean and standard deviation and an estimate of counting precision.
5. The cover slip is held 0.1 mm above the floor of the counting chamber, which, in this example, creates a chamber volume of 1×10^{-4} cm³ or 0.1 μ L.
6. The concentration or density of sperm in the source material is calculated with the appropriate dilution factors. For example, a 150-mg epididymis is minced and rinsed with 600 μ L of medium, and a sample of the resulting cell suspension is placed in a hemocytometer. If 500 spermatozoa are counted in a 0.01 cm² section (0.1 μ L) of the hemocytometer; sperm density or concentration (C ; i.e., number of spermatozoa per mg of epididymis) would be calculated as: $C = N \times D / 0.1 \div S$, where N is number of spermatozoa counted in 0.1 μ L of the hemocytometer, D is volume of medium used to rinse or dilute the sample, and S is volume or weight of the original sample. In this case, $C = 500 \times 600 / 0.1 \div 150 = 20,000$ spermatozoa per mg of epididymis.

quality of sperm in human fertility clinics, livestock management, and zoo studies of endangered species (e.g., cheetahs [*Acinonyx jubatus*]; Wildt et al. 1993). However, these measures are made on sperm in semen, which is usually obtained by **electroejaculation**, an approach that is seldom taken in studies of wild animals.

Testicular Biopsy

Counts of spermatozoa are usually made from tissues or fluid collected at necropsy or in ejaculates. However, **needle biopsy** procedures offer an opportunity to obtain testicular

tissue and spermatogenic cells from living animals, as reviewed by Berndtson (1977). The animal is anesthetized, and the surface of the scrotum is thoroughly cleansed and disinfected. A testis is punctured with a 19–22-gauge needle, carefully avoiding the epididymis (Sundqvist et al. 1986). Slight pressure applied to the testis or negative pressure in an attached syringe will ensure aspiration of tissue into the needle. The needle is then withdrawn from the testis, and the material contained in the needle is spread onto a microscope slide, dried, and stained prior to examination of the cells. The biopsy smears are scored: low (1–2), when only

sertoli cells or **spermatogonia** are present, to high (9–10), when large numbers of mature **spermatids** are counted. This procedure, used in diagnosing human infertility, has been used with ranch mink, in which up to 20% of the males are infertile, as indicated by biopsy scores 7 (Sundqvist et al. 1986). The safety of this procedure has been assessed in mice: spermatogenesis, fertility, and paternity of mature mice were unaffected by their testicular biopsy at 4 weeks of age (Nakane et al. 2005)

ENDOCRINOLOGY OF REPRODUCTION AND STRESS

Background

The nervous and endocrine systems act in concert to coordinate physiological processes and behavior. Responses regulated by the endocrine system are generally slower and of longer duration (hours and days) than those provided by the nervous system, which acts on the scale of seconds and minutes. The complex of interrelated glands that compose the endocrine system responds to both internal signals and to external environmental cues by secretion of **hormones** that are carried in the blood stream, usually to other parts of the body, where they have their effect. Environmental stimuli (e.g., photoperiod or social interaction) are relayed through a basal part of the brain, the hypothalamus, which responds by secretion of releasing factors, including **gonadotropin releasing hormone** (GnRH), that control the secretory activity of the **anterior pituitary gland** (Norris 2007). The anterior pituitary gland secretes several peptide hormones, including **follicle stimulating hormone** (FSH) and **LH**, that control gametogenesis and hormone secretion by the gonads. The pituitary also secretes **adrenocorticotrophic hormone** (ACTH), which stimulates secretion of **corticosteroids** (e.g., cortisol and corticosterone) by the adrenal cortex. Control of circulating levels of hormones is achieved by feedback regulation. For example, when increasing blood levels of testosterone in a male exceed a threshold or set point in the **hypothalamus**, the release of GnRH is inhibited. Thus, less GnRH reaches the anterior pituitary, less LH is released and reaches the testes, and consequently, secretion of testosterone is reduced to appropriate levels.

Hormonal control of reproduction ultimately functions to coordinate development of the reproductive tract, expression of mating behavior, and gametogenesis, so that sperm and eggs are brought together to accomplish fertilization and conception. Each stage in the reproductive cycle is controlled by a sequence of endocrine signals that can be visualized with **hormone profiles** (i.e., plots of concentrations in blood [serum or plasma] over time). Although many hormones are involved, much has been learned about the reproductive processes in wildlife through study of relatively few pituitary hormones and gonadal steroids (Table 21.1). The extent to which endocrine responses to chronic stress

(i.e., corticosteroid secretion) affect reproductive processes is a longstanding question in wildlife population ecology. Thus, endocrine measures of stress also are considered in this section.

This introduction provides only a brief outline of the principles and terminology of reproductive endocrinology. Appreciation of information presented in this section will be enhanced with a basic understanding of the anatomic–functional axis consisting of the hypothalamus, pituitary, and gonads (**hypothalamic–pituitary–gonadal axis**) as described in most introductory biology textbooks. More extensive presentations of principles and related primary literature are available in a number of reviews and textbooks, including Austin and Short (1984), Tyndale-Biscoe and Renfree (1987), Bronson (1989), Nelson (2000), Foster and Jackson 2006, and Norris (2007).

Hormones and Reproduction

Hormones and Reproductive Cycles in Females

Peak ovarian mass and numbers of yolked eggs in frogs generally coincide with peak levels of ovarian steroids at the time of amplexus and oviposition, as in the Mexican leaf frog (Bagnara and Rastogi 1992). Similarly, in female reptiles with associated reproductive patterns, increased ovarian mass and elevated gonadal steroids also coincide with breeding behavior. One of the most thoroughly studied (particularly in behavioral endocrinology) lizards in this group is the green anole, as reviewed by Wade (2005). Unlike most lizards, which ovulate about half of each clutch of eggs from each ovary, the green anole (and other species of *Anolis*) ovulates a single egg, alternately from each ovary, every 14 days. Females are receptive to males during the 7 days preceding ovulation, when the estradiol:progesterone ratio is low (Jones et al. 1983; Table 21.1).

Less is known about factors controlling breeding behavior in dissociated breeders, such as the red-sided garter snake. Activation of courtship behavior in the male of this species does not depend on the presence of gonadal steroids, and for some time, there was little evidence that females were different (Whittier and Tokarz 1992). However, Mendonca and Crews (2001) demonstrated that low levels of circulating estradiol must be present during hibernation if females are to be receptive upon emergence in the spring. Following ovulation, the CL of both oviparous and viviparous lizards secretes progesterone (Norris 2007; Table 21.1).

Owens (1997) synthesized much of the sea turtle literature on gonadotropins and gonadal steroids in a graphic model for endocrine control of reproductive events and behavior in both males and females. Estrogen is highest during follicular growth, rising slightly with each oviposition. Testosterone also is high during migration and the nesting period. Both gonadotropin and progesterone surge during ovulation of each clutch (Table 21.1).

Table 21.1. Hormone data relevant to the assessment of reproductive activity in selected vertebrates. All values are for females, except as noted for males. Hormone concentrations are pg/mL serum or plasma for estrogens and ng/mL serum or plasma for all others, except steroid conjugates in urine (Kasman et al. 1986, Walker et al. 1988, Herrick et al. 2000), which are expressed in µg, ng, or pg per mg of creatinine or in µg/g or ng/g feces. Two concentrations indicate the approximate lows and highs associated with a given reproductive event.

Species	Hormone	Change in concentration	Reproductive event	Reference
Frog (M)	FSH	2–4	Peaks with spermatogenesis	Polzonetti-Magni et al. 1998
	Estradiol	0–8	Peaks with FSH	
	Androgen ^a	0–10	High in recrudescence and breeding	
Bullfrog (M)	LH		Seasonal, highest at amplexus	Licht et al. 1983
	Androgen	2–34	Seasonal elevation 2–4× >T	
	LH	4–32	Surges at the time of ovulation	
Toad	Progesterone	0.1–0.3	Low, highest prior to mating	Itoh et al. 1990
	Estradiol	1,000–3,900	High, peak early in breeding	
Anole lizard (<i>Anolis carolinensis</i>)	Estradiol	500–2,100	Lower during sexual receptivity	Jones et al. 1983
Lizard	Progesterone	2–13	Rises from preovulatory to gravid state	Norris 2007
Tortoise (M)	Testosterone	5–25	Low during mating and elevated during spermatogenesis	Kuchling 1999
Sea turtles (from general model)	Estrogen	200	Highest prior to nesting	Owens 1997
	Testosterone	300	Highest during mating	
	Gonadotropin	4	Surge levels at ovulation	
	Progesterone	12	Highest levels at ovulation	
Turkey (<i>Meleagris gallopavo</i>)	Prolactin	90–709	Elevated during incubation, low in laying and brooding hens	Wentworth et al. 1983
White-crowned sparrow	Estradiol	35–400	Increases with courtship and egg laying	Wingfield and Farner 1980
Japanese quail (M)	Testosterone	0–5	Increases with day length and onset of breeding season	Follett and Maung 1978
Woodchuck (M)	Testosterone	0–3	Increased during breeding season	Baldwin et al. 1985
(<i>Marmota monax</i>)				
Woodchuck (F)	Progesterone	0–60	Progesterone higher in post-partum than in pregnant females	Concannon et al. 1983
White-tailed deer (F) (<i>Odocoileus virginianus</i>)	Progesterone	0–6	Rises with CL formation in early pregnancy	Plotka et al. 1977, Harder and Moorhead 1980
	Estrogens	11–295	Increases near parturition	
White-tailed deer (M)	Testosterone	0–3	Increased with hardened antlers and rut	McMillin et al. 1974
Red howler monkey	Progesterone (urinary)	77–212	High in luteal phase of estrous cycle and highest during gestation	Herrick et al. 2000
Little brown bat (<i>Myotis lucifugus</i>)	Progesterone	7–136	Increased from early to late pregnancy	Buchanan and Younglai 1986
Indian rhino	Estrone sulfate	47–1	High at estrus and drops rapidly at ovulation	Kasman et al. 1986
Killer whale	Estrone conjugate	0–35	Increases prior to presumptive ovulation	Walker et al. 1988
	Pregnanediol-3-glucuronide	0–100	Elevated during pregnancy	
Tree kangaroo	Progestin ^c	200–900	Rises slowly after ovulation to high levels for 30 days of 59-day cycle	North and Harder 2008
White rhino	Progestin	40,000	Concentrations during gestation higher (100×) than in estrous cycle	Patton et al. 1999
Elk	Progestin	700–2,500	Varies among pregnant females, depending on habitat quality	Creel et al. 2007

^a CL = corpus luteum; FSH = follicle stimulating hormone; LH = luteinizing hormone; M = male; T = testosterone.

^b Testosterone and related hormones (e.g., dihydrotestosterone and androstenedione).

^c Progesterone and its metabolites (e.g., pregnanolone) in feces, expressed in µg/g (elk) or ng/g feces.

The sequence of hormonal signals responsible for the circadian cycle of **ovulation and egg laying** in birds is complex. A major component in the domestic hen is a positive feedback relationship between an increase in progesterone secretion from the ovarian follicle and a surge of LH from the anterior pituitary, which stimulates ovulation (Johnson 2004). Prior to ovulation, elevated estrogen also induces courtship behavior (Table 21.1) and stimulates mobilization of yolk precursors from the liver and their deposition in the egg while it is in the follicle (Van Tienhoven 1983). **Incubation behavior** and **brood patch** formation are stimulated by high **prolactin** levels in association with estradiol and progesterone. Prolactin from the anterior pituitary also stimulates production of “milk” in crop glands of doves and pigeons.

Measurements of circulating hormones are useful in studies of the effects of toxic substances on reproductive performance of birds. Progesterone levels peaked earlier relative to oviposition in mourning doves treated with dietary polychlorinated biphenyls than in controls (Koval et al. 1987). Nonlaying canvasbacks (*Aythya valisineria*) had lower serum concentrations of prolactin and LH than did laying hens. Progesterone levels in laying hens increased during the breeding season, whereas those in the nonlaying birds declined (Bluhm et al. 1983).

The estrous cycle of mammals is a sequence of interrelated physiological events in the hypothalamus, anterior pituitary, ovary, and reproductive tract marked by a period of sexual receptivity (estrus) and ovulation. Preovulatory follicles secrete large amounts of estradiol that stimulates estrus and a preovulatory surge of LH. The LH surge stimulates ovulation and formation of the CL (Figs. 21.4, 21.6). This general pattern appears to hold true for many mammals, as evidenced from data from such widely divergent taxa as tammar wallabies (Harder et al. 1985), rats (Nequin et al.

1979), deer (Plotka et al. 1980), and sheep (Hauger et al. 1977). The rise in estrogen around estrus confirms normal ovarian activity and is potentially valuable as a predictor of time of ovulation in mammals that ovulate spontaneously. This knowledge is essential for artificial insemination and embryo transfer, techniques that are being used with increasing frequency by zoos, endangered species programs, and modern game farms. Jacobson et al. (1989) achieved conception in 75% of 53 trials of artificial insemination in white-tailed deer.

Changes in estrogen levels prior to estrus and ovulation are often small, of short duration, and difficult to detect. In contrast, events following ovulation, namely CL formation and the luteal phase of the estrous cycle or gestation, are of relatively long duration (several days to months in larger species) and are characterized by elevated levels of circulating progesterone (secreted by the CL and/or placenta; Fig. 21.10). Therefore, useful progesterone profiles can be obtained with relatively a low-frequency blood sampling design that is feasible in many wildlife studies. If breeding is highly synchronized, much can be learned from single samples taken from a series of animals killed during the breeding season. With white-tailed deer, this approach revealed a shortened, nonfertile cycle that preceded the first estrus and normal luteal cycle during onset of the breeding season (Harder and Moorhead 1980).

Progesterone profiles are considered the most reliable means of monitoring the 15-week estrous cycles of captive Asian elephants (*Elephas maximus*) and African elephants (*Loxodonta Africana*; Plotka et al. 1988). Until accurate and sensitive progesterone **radioimmunoassay (RIA)** was applied to a long series of serum samples from the same cows by Hess et al. (1983), the now well-documented 15-week estrous cycle of the Asian elephant was believed to be only 3 weeks long. More recently, LH and progesterone profiles in Afri-

Fig. 21.10. Temporal relationships of estrus and ovulation to circulating levels of progesterone, estrogen, and luteinizing hormone (LH) during the estrous cycle of the ewe, which has preovulatory hormone dynamics similar to many mammalian species with spontaneous ovulation. From Short (1972) with permission.

can elephants (Kapustin et al. 1996) and Asian elephants (Brown et al. 2004) have revealed an anovulatory LH surge, followed low progesterone (no ovulation or CL formed) and, predictably, 3 weeks later by a second LH surge that stimulates ovulation. For decades, attempts to breed elephants using artificial insemination have failed, but with refined LH monitoring of the double LH surge and use of an endoscope-guided catheter and transrectal ultrasound to deliver semen into the anterior vagina, artificial insemination was achieved, followed by birth of an Asian elephant calf (Brown 2000, Brown et al. 2004).

The practical value of progesterone data for detecting pregnancy in live animals has been widely recognized, particularly for larger species, in which the gestation period extends well beyond the breeding season. Feces can be collected in the field, and blood can be obtained from trapped or anesthetized animals and assayed later, whereas other techniques (e.g., laparotomy or ultrasonography) require transport of the animal or equipment. Care must be used in selection of drugs and other methods of restraint, because they can affect progesterone levels. Plasma progesterone concentrations in pregnant white-tailed deer are generally >2 ng/mL, whereas those of nonpregnant deer are 1 ng/mL (Abler et al. 1976). The potential errors associated with this generalization (Plotka et al. 1983) notwithstanding, properly validated progesterone assays have permitted accurate ($>2\%$ error) diagnosis of pregnancy in white-tailed and mule deer (Wood et al. 1986). Gadsby et al. (1972) reported higher progesterone levels in domestic ewes carrying 2 fetuses than in ewes with a single fetus.

The uterus and placenta secrete numerous nutritive and regulatory proteins during gestation, some of them unique to gestation and therefore useful in identifying pregnant animals. Wood et al. (1986) used a qualitative test for pregnancy-specific protein B (bovine) to identify (4% error) pregnant mule and white-tailed deer. Similar results were reported for this pregnancy test in mountain goats (*Oreamnos americanus*; Houston et al. 1986) and elk (Noyes et al. 1997).

Spermatogenesis and Onset of Breeding in Males

The marked growth of the testis in vertebrates during onset of the breeding season is associated with rapid increases in secretion of FSH and LH from the anterior pituitary gland and testosterone and other androgens from the testes (Fig. 21.11, Table 21.1), but in bullfrogs (*Rana catesbeiana*), androgen levels show greater seasonal variation than does testis size. High androgen levels in spring stimulate breeding behavior in frogs, whereas a peak in FSH and estradiol levels is associated with onset of spermatogenesis (Polzonetti-Magni et al. 1998; Table 21.1). In most species, reproductive tract activation (increased size, sperm production, and androgen secretion) is closely associated with breeding behavior. However, some reptiles, such as tortoises (*Gopherus* spp.; Kuchling 1999) and red-sided garter snakes, exhibit dissociated re-

Fig. 21.11. Plasma levels of luteinizing hormone, testosterone, and testis size (solid ovals) in photostimulated male white-crowned sparrows (*Zonotrichia leucophrys*) and song sparrows (*Melospiza melodia*). From Wingfield and Farner (1980) with permission.

production, in which testosterone is relatively low during the spring mating season and elevated during spermatogenesis in late summer and early autumn.

In temperate regions of the world, photoperiod is the principle environmental cue for reproductive activation. In tropical regions, where day length is nearly constant, other factors (e.g., onset of the rainy season and increased food availability) stimulate reproduction. Gonad size and singing rate increased in male antbirds (*Hylophylax naevioides*) following addition of crickets to their diet, and even the sight (only) of live crickets increased their singing rate (Hau et al. 2000). Modern techniques permit hormone measurements of small blood samples (50–500 μ L), volumes that can be obtained from small wild birds. This ability has facilitated diverse experiments in avian field endocrinology. For example, circulating levels of testosterone in male song sparrows (*Melospiza melodia*) actively defending territories are elevated compared to those with uncontested territorial boundaries (Wingfield 1985). Similar social modulation of testosterone levels in males has been reported in other (e.g., antbird; Wikelski et al. 1999), but not all, avian species (Scriba and Goymann 2010).

In mammals, circulating levels of testosterone and other androgens also increase substantially during the breeding season (Table 21.1), a requisite condition for full spermatogenic activity and breeding behavior, for example, during the **rut** in white-tailed deer (McMillin et al. 1974) or during **musth** (an aggressive behavioral state) in Asian elephants (Cooper et al. 1990). In species as diverse as the hamster (*Mesocricetus auratus*; Richardson et al. 2004), tammar wallaby (Catling and Sutherland 1980), and human (Roney et al. 2007), elevation of testosterone and, at least in mammals (Paris et al. 2005), semen quality appear to be dependent on or influenced by direct association with females in breeding condition.

Hormone Metabolites in Urine and Feces

For many wild species, even pen-reared individuals, stress associated with restraint and venupuncture often precludes collection of blood samples, so that even minimal information about normal ovarian endocrinology is unavailable. Fortunately, another approach is available. **Steroids** (e.g., progesterone) are metabolized in the liver and excreted as conjugates (primarily sulfates and glucuronides). Considerable progress has been made in monitoring gestation and estrous cycles of many zoo and wildlife species, including tree kangaroos (*Dendrolagus matschiei*), red howler monkeys (*Alouatta seniculus*), killer whales (*Orcinus orca*), Indian rhinos (*Rhinoceros unicornis*), white rhinos (*Ceratotherium simum*), and elk, through assay of hormone metabolites in their urine and feces (Table 21.1).

Midstream collection is preferred for **urine samples**, and many species, even killer whales, can be trained for this procedure (Walker et al. 1988). It also is possible to collect samples from some arboreal species that urinate from predictable tree-branch locations. This approach was used with individually marked free-ranging red howler monkeys to monitor urinary progesterone concentrations (Table 21.1) and to develop progesterone profiles that characterize temporal features of an apparent 28-day estrous cycle and gestation in this species (Herrick et al. 2000). Individualized feces or urine can be collected from the floors of pens and small enclosures or even from open range. Kirkpatrick et al. (1988) described detailed validation experiments and procedures for estimation of estrone sulfate concentrations in soil soaked with urine by free-roaming feral horses with unique marks. Twelve of 15 mares with estrone sulfate $>1.0 \mu\text{g}/\text{mg}$ creatinine later produced foals, whereas no mares with lower concentrations foaled.

Collection of fecal samples from captive and wild animals is convenient, because the source animal can be observed from a distance and the sample collected at extended intervals after defecation. Consequently, hormone fecal analysis is currently the most widely used method for non-invasive (i.e., no restraint or venupuncture) monitoring of hormones in mammals (Safar-Hermann et al. 1987, Wasser et al. 2000, North and Harder 2008). The work of Sam Wasser and colleagues at the University of Washington, Seattle, with scat detection dogs represents some of the most imaginative and promising research to date in wildlife endocrinology. Dogs were trained to detect grizzly bear (*Ursus arctos* Linnaeus) and black bear (*Ursus americanus*) scats over a 5,200-km² study area in Alberta, Canada. DNA analysis of scats indicated sex and identities of individual of grizzly bears, and concentrations of progesterone and cortisol metabolites in fecal samples provided evidence of reproductive activity in females and an index of physiological stress, respectively (Wasser et al. 2004). More recently, Wasser et al. (2009) demonstrated the ability of dogs to identify scats of individual maned wolves (*Chrysocyon brachyurus*), thus re-

ducing or eliminating the need for DNA genotyping of samples.

Control of Reproduction and Wildlife Contraception

The demand for nonlethal control of nuisance wildlife populations has driven research in **contraceptive technology** for >40 years, an effort that has benefited from developments in human medicine and animal science. Contraceptive trials have been conducted on a large number (>100) of mammalian species, mostly ungulates, but also carnivores and rodents. The primary focus of this research has been white-tailed deer and wild horses in North America and elephants in Africa, while Australians have developed a major research program in virally vectored **immunocontraception** aimed at controlling vertebrate pest species (Hardy et al. 2006). Avian species have received less attention in contraceptive research, the notable exception being resident Canada geese (*Branta canadensis*). Bynum et al. (2007) demonstrated a 36% reduction in hatchability of eggs at sites treated with 2,500-ppm nicarbazin bait, a drug that received regulatory approval from the U.S. Environmental Protection Agency (EPA) in 2009 and is commercially available as OvoControl™ G (Innolytics, Rancho Santa Fe, CA) contraceptive bait for Canada geese and OvoControl for pigeons (*Columba livia*; Fagerstone et al. 2010).

Many options are available for interrupting reproductive processes in wildlife, but most fall into 2 categories: hormonal and immunological intervention in females. Males are seldom the subjects of contraceptive programs, because in polygamous species, control of nearly all males in a population would be required to achieve a meaningful reduction in conception rates. Longstanding questions regarding the practicality of wildlife contraception prompted early research on oral application of contraceptive (diethylstilbestrol) to a large, enclosed, but free-ranging population of deer that resulted in a reduction in ovulation rate, but was not as effective as an intramuscular application (Harder and Peterle 1974). Moreover, the relatively low species specificity of bait systems available for oral application of hormones and their analogs entails unknown risks to nontarget species, a disadvantage that has discouraged research in this area.

Subcutaneous implants provide slow, prolonged release of hormone into circulation and thus, have the potential to provide long-term (months to years) contraception. Bell and Peterle (1975) reported early evidence of the effectiveness of this approach in a population of white-tailed deer, and more recently, promising results of long-term fertility control in gray kangaroos (*Macropus fuliginosus*) have been obtained with a related compound, levonorgestrel (Nave et al. 2002). Although remote delivery of contraceptive in a ballistic implant (Jacobsen et al. 1995) might eliminate the need for restraining animals for installation of implants, other logistical problems remain. Also, hormones released from implants have the potential to accumulate in tissues of treated

animals and present an unknown health risk to wild animals and humans that might consume them (Grandy and Rutberg 2002).

Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), a hormone secreted by the uterus and other tissues, induces regression of the CL and is an important signal in hormonal control of parturition in mammals. The abortifacient effects of $PGF_{2\alpha}$ have been applied with success in terminating pregnancy in white-tailed deer (Waddell et al. 2001). One important advantage of using $PGF_{2\alpha}$ for wildlife is that it is rapidly metabolized in the lungs and thus, does not accumulate in tissues or present health risks for nontarget species or humans. The principle disadvantage of $PGF_{2\alpha}$ is that its effects are limited to a single reproductive season.

Immunocontraception has received much attention, because it is less physiologically intrusive than hormone treatments. Also, it does not present known health risks to nontarget species, and animal welfare groups have supported research in this area (Grandy and Rutberg 2002). Immunological methods can involve antibodies to hormones (e.g., GnRH and gonadotropins), but most techniques are directed toward preventing fertilization by interfering with binding of spermatozoa to the zona pellucida, which surrounds the egg. Stimulating production of antibodies against proteins in the **porcine zona pellucida (PZP)** is, by far, the most popular approach. Effective immunocontraceptive technology is currently available for a number of species, including wild horses (Kirkpatrick et al. 1997), white-tailed deer (Naugle et al. 2002), and elephants (Fayrer-Hosken et al. 2000). Animals injected with vaccines, often with dye marking darts, become infertile for periods ranging from 1 to 3 years. Frank et al. (2005) reviewed the biological efficacy of PZP immunocontraception and the timing of booster inoculations in 24 species of ungulates and 5 species of non-ungulates across 10 years of treatment. The collective contraceptive efficacy for 301 individuals in 517 contraceptive intervals was 93.3%, for which no technical problems were identified. The major hurdle in management applications of PZP immunocontraception is one of achieving adequate population control in free-ranging populations, which may be assessed by computer modeling (Mackey et al. 2009). Results of simulation analysis of data from trials on a suburban white-tailed deer population suggest that immunocontraception is useful only on small localized populations with 100 breeding females (Rudolph et al. 2000).

The literature on wildlife contraception has expanded considerably in recent years; several reviews are available, including Kirkpatrick et al. (2002) and Fagerstone et al. (2010). Two **antifertility agents**, an avian reproductive inhibitor containing the active ingredient nicarbazin and an immunocontraceptive vaccine for white-tailed deer, have received approval from the EPA and are commercially available in the United States. OvoControl G for Canada Geese and Ovo Control for pigeons are approved and are available as oral

baits. GonaCon™ immunocontraceptive vaccine (<http://digitalcommons.unl.edu/usdaaphisfactsheets/49>) was registered for injection in female white-tailed deer in September 2009. Several other compounds show promise and are being tested for use in wildlife in the United States, Europe, Australia, and New Zealand (Fagerstone et al. 2010). Fagerstone et al. (2002) concluded that wildlife managers of the future will face 2 challenges: (1) integrating contraceptive methods with traditional approaches to population control, and (2) providing the public with accurate information about the feasibility of fertility control compared to lethal methods for reducing wildlife populations

Endocrinology of Stress

Background and Effects of Stress on Reproduction

Decades of research stimulated by Hans Selye's landmark paper on stress and human health (Selye 1936) have provided both the technical foundation and a conceptual framework for understanding the biology of **stress**, which is defined as a significant disturbance of homeostasis caused by marked or unpredictable environmental change (Wingfield and Raminofsky 1999, Nelson 2000). A **stressor**, in this context, is an environmental change or stimulus, such as pain, fear, cold, blood loss, environmental contaminants, pathogenic microbes, and social tension (Selye 1976). Sudden life-threatening disturbances (e.g., a predator attack) stimulate release of adrenaline from the adrenal medulla and the well-known "fight or flight" response. Acute or short-term stress also activates the hypothalamic-pituitary-adrenal (HPA) axis, wherein release of corticotropin releasing factor (CRF) from the hypothalamus stimulates secretion of ACTH from the anterior pituitary. ACTH, in turn, stimulates secretion of adrenal cortex steroids (**corticosteroids**), including those that regulate glucose metabolism (i.e., glucocorticoids), primarily cortisol and corticosterone (Asterita 1985). This acute response is adaptive, because it allows individuals to maintain essential functions (e.g., by elevation of blood glucose) in the presence of the stressor. However, prolonged, chronic activation of the HPA axis may be associated with pathological conditions, such as gastrointestinal ulcers (Moberg 1985) and, in some cases, reduced reproductive performance.

Laboratory studies have clearly demonstrated the deleterious effect of stress on reproduction in a variety of vertebrates (reviewed by Pottinger 1999, Dobson et al. 2003). For example, social stress and subordination can lead to elevated corticosteroids (Sapolsky 1987) and alteration of reproductive function in some primates (Ziegler et al. 1995). Reduction of gonadotropin secretion has been associated with food restriction in some mammals (Bronson 1989) and overwintering stress in white-throated sparrows (*Zonotrichia albicollis*; Schwabl et al. 1988). Stress of transport and hypoglycemia reduced LH pulse frequency and delayed the LH surge in ewes (Dobson and Smith 2000). Rivier and Rivest (1991) present a model that explains the roles of CRF, ACTH,

endorphin, and corticosteroids in modulating the effects of stress on reproductive function.

Christian (1950) and colleagues were quick to recognize the potential relevance of Selye's (1946) observations for population ecology. They postulated that elevated corticosteroid levels interfered with hormonal control of reproduction and induced mortality in high-density populations (Christian 1963, Christian and Davis 1964). Numerous studies have addressed this hypothesis, and it now appears that emigration and other factors, such as nutrition, prevent most natural populations from attaining densities sufficiently high to evoke a response from the HPA axis that would be regulatory at the population level. Moreover, the critical nature of reproduction for the individual has favored evolution of reproductive strategies in some species (e.g., highly seasonal breeders, in which the adrenocortical response to stress is modulated or suppressed; Wingfield and Sapolsky 2003). Experiments with high-density snowshoe hare (*Lepus americanus*; Windberg and Keith 1976, Vaughan and Keith 1981) and deer populations (Seal et al. 1983) support this conclusion. Also, fecal progesterone concentrations in elk declined with increased exposure to wolves (Table 21.1), and progesterone concentrations were a good predictor of calf recruitment in the following year (Creel et al. 2007). However, across populations and years, fecal glucocorticoid concentrations were not related to predator:prey ratios, fecal progesterone levels, or calf production (Creel et al. 2009).

Modulation in responsiveness of the individual to diverse stressors obviously necessitates activation as well as suppression of the HPA axis. Studies that have focused on segments of a population (e.g., sex or social status) have produced some of the clearest evidence for endocrine responses to social stress (McDonald et al. 1981, Sapolsky 1987), which suggests that more attention should be given to stress as a factor in the natural structure and functioning of populations. For example, mating season glucocorticoid levels in adult, but not subadult, Assamese macaques (*Macaca assamensis*) were negatively related with dominance rank and positively related to the amount of aggression received (Ostner et al. 2008). From a meta-analysis of studies involving 7 species of monkeys, Abbott et al. (2003) found that subordinates most often had elevated cortisol levels when they (1) were exposed to high rates of stressors and (2) experienced decreased opportunities for social (including close kin) support.

Indicators and Measures of Stress

A wide range of measures is available for assessment of stress in free-ranging and captive animals. Some are indicators of acute stress, whereas others indicate chronic stress acting over a period of weeks or months. In planning research, it is useful to recognize stress indicators in 1 of 3 categories: (1) **noninvasive**, those that require little or no handling of animals; (2) **invasive**; and (3) **post-mortem**. Non-invasive indicators include behavioral observations, food and

water consumption, body weight, respiratory rate, and assay of hormones in saliva, urine, or feces.

Circulating levels of corticosteroids, such as cortisol or corticosterone, provide a direct measure of the endocrine response to acute stress, and with current assay procedures, it is possible to measure hormone concentrations in relatively small (0.05–0.3 mL) plasma samples. Consequently, such measures are increasingly used to assess stress responses in wild animals (e.g., birds during spring migration [Landys-Ciannelli et al. 2002] or care of hatchlings [O'Reilly and Wingfield 2001]) and to evaluate stress and welfare of laboratory animals (Broom and Johnson 1993). The major technical problem with such studies is that blood levels of corticosterone can rise rapidly within 2–3 minutes (Gartner et al. 1980) or less (Roy and Woolf 2001) following initial disturbance of the animal. Moreover, some species show clear diurnal rhythms and even marked hourly fluctuation in plasma corticosteroid levels (Tapp et al. 1984). Corticosteroid responses to stress should be first measured under controlled laboratory conditions (Carruthers and Path 1983) before conducting field trials. In this way, it is possible to assess the potential stress effect of acute environmental changes, such as changes in dove hunting regulations (Roy and Woolf 2001).

Corticosteroids and other hormones are secreted into the blood, continuously metabolized in the liver, and excreted in urine and feces. Because these metabolites accumulate during the hours between defecations, their concentrations in fecal samples represent an average of more variable corticosteroid concentrations in circulation. Fecal glucocorticoid concentrations show promise for assessment of stress in white-tailed deer (Millsbaugh et al. 2002), and because the subjects are undisturbed, the confounding effects of stress due to handling and blood collection are avoided. However, procedures for extraction and assay of hormone metabolites in feces can be more complex and interpretation of results more difficult than for hormones in blood. These and other factors to be considered when measuring stress with fecal glucocorticoids are reviewed by von der Ohe and Servheen (2002). Nearly all endocrine and **immune** (e.g., lymphocyte mitogenesis) indicators of stress are considered invasive, because they require restraint of the animal for blood sampling. However, once installed, an indwelling intravenous catheter allows for essentially non-invasive collection of blood samples.

Providing that animals are processed immediately after death, post-mortem examinations or necropsies provide a wealth of information, particularly if glands and organs can be examined for abnormalities (e.g., gastric ulceration) and histopathology. Moreover, all endocrine and immune parameters available in blood samples are available at this time. Increased secretory activity of the adrenal cortex in response to stress is accompanied by an increase in size of the gland and/or the cortico-medullary ratio (Adams and Hane 1972, Han et al. 1998, Terio et al. 2004). Methods for analy-

sis of adrenal gland weight and morphology were reviewed in detail by Harder and Kirkpatrick (1996), and Manser (1992) presented a comprehensive, yet concise and well-organized, guide to assessment of stress in animals. Stress is a complex biological concept, and anyone who hopes to contribute in this field should first read widely (e.g., the reviews of Broom and Johnson [1993], Sapolsky [1998], Balm [1999], and Nelson et al. [2002]); train, or at least consult, with established investigators; and then design their studies and experiments with the greatest of care.

Collection of Samples and Hormone Measurements Blood Sampling Procedures

Hormone concentrations can be measured in many tissue types and bodily fluids with application of appropriate tissue homogenization and hormone extraction techniques, but blood is by far the most commonly assayed substance. The goal in any sampling procedure should be to collect an adequate volume of blood quickly and efficiently while minimizing stress to the animal. The effect of restraint or anesthetics on hormone levels should be investigated with each species to be studied, and not just in studies of progesterone or adrenal hormones. For example, hormone concentrations in a series of plasma samples collected from bullfrogs recaptured in the field remained relatively constant, but if the frogs were held in a collecting sack, levels of gonadotropin and gonadal steroids began to decline within 2–4 hours, often to basal levels within 20 hours (Licht et al. 1983). Immobilization with succinylcholine chloride elevated circulating progesterone levels in white-tailed deer (Wesson et al. 1979), and certain anesthetics depressed serum concentrations levels of this steroid (Plotka et al. 1983). Apparently, stress from prolonged (15–45 min) restraint can induce significant release of corticosteroids, including progesterone (Plotka et al. 1983).

Blood samples can be collected from quiet animals fitted with an indwelling catheter to investigate the effects of restraint or anesthesia on blood hormone levels. Periodic samples will reveal the natural daily pattern of circulating levels, including episodic changes, which can be distinguished from those that might be related to stress of handling or anesthesia in the same animal. An alternative approach is to collect blood samples immediately upon restraint or sedation of the animal, followed by collection of blood samples at intervals over a period of time in excess of the maximum required for routine collection. If the blood sampling procedure alters secretion of the hormone(s) under study, blood concentrations will change in successive samples relative to that in the initial sample. These experiments will identify the need to standardize timing of blood collection (from time of restraint or anesthesia) in situations where stress to the animal being sampled cannot be avoided. Also, many captive animals, if handled in a consistent manner with gentle or minimal restraint, become conditioned to blood sam-

pling and appear to experience little stress during such procedures. Elephants, for example, can be trained to stand, unrestrained, for blood sampling (Brown et al. 1999).

Peripheral blood (i.e., from the heart or any vein not directly draining the endocrine gland under study) is usually collected from the jugular or a prominent leg or tail vein. The orbital plexus in the corner of the eye may be used to obtain small volumes from mice. The brachial (wing) vein is commonly used in birds, although Arora (1979) concluded the jugular vein was the best source of blood for Japanese quail (*Coturnix japonica*). Blood collection from living animals should be performed only by trained personnel. This is particularly important when blood is to be obtained by cardiac puncture, in which case, the animal must be anesthetized or sedated to alleviate pain and prevent movement of the animal while the needle is in the heart.

If **plasma** is to be separated from blood, the needle and syringe are rinsed with a sterile heparin solution or other anticoagulant. Syringes or tubes containing blood should be placed in crushed ice to cool before the plasma is separated by centrifugation. Alternatively, if **serum** instead of plasma is desired, blood is allowed to clot, and the serum can then be poured carefully from the tube or removed by pipet. Any cellular material remaining with the serum is separated by centrifugation.

Hormone concentrations can be measured in either plasma or serum, but plasma may be preferred, because blood can be chilled and centrifuged immediately after collection. This is important if the hormone under study is temperature sensitive or subject to degradation when it is in contact with blood cells before separation of serum or plasma, as is progesterone in cattle (Vahdat et al. 1984) and muskox (*Ovibos moschatus*; Rowell and Flood 1987). Blood destined for hormone assays, particularly gonadotropins, should be chilled immediately after collection and centrifuged as quickly as possible, with a uniform time interval between collection and centrifugation for all samples (Wiseman et al. 1982). Blood and other biological specimens should be protected from direct sunlight to avoid possible degradation of compounds under study. Plasma and serum also should be stored frozen at -15°C or lower and assayed as soon as practical to avoid degradation of hormones. However, steroid hormone concentrations do not appear to change in plasma and serum stored frozen over periods of 3–8 years.

Timing of collection of blood and other tissue samples for studies of reproductive physiology is important (Figs. 21.9–21.11). In most field studies, the exact stage of egg laying or estrous cycle is not known, and blood samples must be grouped to represent broad categories of reproductive activity (e.g., courtship, incubation, pregnancy, or lactation). The problem of temporal specificity in blood sampling is particularly complex relative to the ovulatory cycle of birds, because many changes occur within a 24–30-hour period.

Collection of Urine and Fecal Samples

Urine and fecal samples can be collected with less effort, if not less time, than blood samples and with little or no disturbance of the animals under study. Moreover, hormone metabolites accumulate in the urine and intestinal contents over time, and thus, their concentrations in urine and feces reflect circulating concentrations over a longer time interval than individual blood samples. The major challenge is identifying the source animal for a given sample, and with urine, this usually involves midstream collection, as described above (Walker et al. 1988, Herrick et al. 2000). Alternatively, when animals are under close observation, individualized urine can be collected from the floors of pens and small enclosures or even from open range (Kirkpatrick et al. 1988).

Feces are generally preferred over urine for hormone analysis. They persist longer in the environment than urine, and more options are available for collection of individualized samples. If captive animals are not individually penned or under prolonged observation, marking material (e.g., “glitter” or dye) can be fed to individuals to mark their feces. Collection of individualized fecal samples in field studies requires direct observation of animals or use of scat-detecting dogs and DNA analysis, as described by Wasser et al. (2004, 2009). Alternatively, feces can be collected (without regard to identity of source animals) over several study areas that differ in some variable of interest (e.g., food availability or predation pressure, as in the study of elk by Creel et al. [2007, 2009]).

Urine and fecal samples are stored in sealed containers at -15°C or lower and assayed as soon as practical to avoid degradation of the hormones. Steroid hormones are highly soluble and stable in ethanol. So, fecal samples may be stored in ethanol and should be, particularly if reliable freezer facilities are not available for storing samples.

Hormone Assays

Because **radioimmunoassay** and the closely related **enzyme-immunoassay** (EIA) are highly specific and sensitive, reliable measurement of hormone concentrations can be obtained from small plasma samples, typically 0.05–0.5 mL; in some cases, as little as 0.02 mL is adequate. Not surprisingly, **RIA** has not only revolutionized the study of reproductive physiology since its first wide application in the early 1970s, but it also has found ready application in field studies and has been a key factor in the development of the emerging field of wildlife endocrinology. In recent years, EIA has been widely applied to the measurement of hormone metabolites in feces (e.g., steroids excreted during the primate menstrual cycle and pregnancy [Wasser et al. 1988], LH in samples from elephants [Graham et al. 2002], and progesterone in feces from elk [Creel et al. 2007]).

RIA uses 2 key reagents: (1) an **antiserum** that selectively binds the hormone under study and (2) a **radiolabeled** form of the hormone (e.g., ^3H -progesterone). The antiserum is di-

luted to where it will bind only about 50% of a fixed amount of labeled hormone, so that addition of unlabeled hormone (from standard solutions or a plasma sample) to the same tubes will displace some of the labeled hormone from the antibody in a dose-related manner. Unbound steroid is adsorbed on charcoal, and the radiolabeled hormone bound to the antibody is decanted and counted in a liquid scintillation spectrometer. Alternatively, the antibody is coated to assay tubes, so that unbound hormone is decanted and the radioactivity adhering to the walls of the tube is counted. EIA is similar in principle; the major difference is the replacement of the radiolabeled hormone with an enzyme-linked hormone, and measurement of light absorbance on a plate reader, instead of radioactivity, is the end point of the assay. Both techniques are highly sensitive and capable of measuring 10 pg/mL plasma ($1\text{ pg [picogram]} = 1 \times 10^{-12}\text{ g}$; $1\text{ ng [nanogram]} = 1 \times 10^{-9}\text{ g}$).

Caution is in order regarding use of RIA or EIA in wildlife research. Underlying seemingly straightforward procedures are complex antigen–antibody interactions that can generate misleading data. Investigators contemplating use of these procedures should train in a laboratory specializing in hormone assays. Most importantly, each laboratory must establish and validate procedures for each hormone in each species under study. Results of validation experiments, designed to demonstrate accuracy, precision, and quality control (Abraham et al. 1977, Jeffcoate 1981) should be published. These procedures are required in manuscripts submitted to many endocrine journals (e.g., *Endocrinology*; <http://endo.endojournals.org/misc/itoa.shtml#statistical>). Reagents and procedures in commercial RIA or EIA kits most often have been established only for human, rat, or monkey plasma and should not be used for other species unless validated. Improper application of such kits to plasma or serum from other species can lead to highly erroneous and misleading results. Common problems include variable hormone extraction efficiency and nonspecific interference of hormone–antibody binding. For example, high lipid content of blood of laying hens can interfere with steroid extraction as well as the binding and charcoal separation phases of RIA. Gonadotropic hormones, such as **LH**, exhibit species-specific molecular structures that complicate assay validation based on antibodies raised to the gonadotropin of another species. For example, antiserum raised against LH from sheep has been used to measure LH in a wide range of mammalian species. These heterologous assays require rigorous validation and are usually less sensitive than when used to measure LH in sheep.

SUMMARY

The methodologies and techniques used in the study of reproduction in birds and mammals continue to expand more rapidly than for amphibians and reptiles, while the need for

research on herptiles is increasingly obvious, particularly as it relates to the worldwide decline in amphibian populations. These taxa exhibit fascinating reproductive patterns that offer opportunities for both basic and applied research. Reproductive processes in many amphibians are particularly sensitive to environmental change, and there is a critical need to understand the mechanisms by which pathogens, endocrine disruptors, and other environmental factors interact to affect recruitment and loss in populations. Methods developed for study of reproduction in birds and mammals (e.g., nest success, CL counts, and ultrasonography) also can be applied to some herptiles, but new methodologies also are needed, particularly for sampling designs and tissue collection techniques relevant to their diverse reproductive patterns.

Since publication of *The Wildlife Techniques Manual* in 1994, significant progress has been made in the application of endocrinology and other reproductive technologies to wildlife conservation, most notably in 3 areas: (1) noninvasive monitoring of reproductive cycles and stress with RIA and EIA of hormone concentrations in feces, (2) assisted reproductive technology, and (3) wildlife contraception. Hormone concentrations are most often monitored by blood sampling in biomedical studies. Indeed, our modern understanding of reproductive physiology is based on serial blood sam-

pling. However, hormone concentrations in saliva, urine, and feces reflect circulating levels, and they can be sampled with little or no disturbance to the animals under study. Of these, feces are most often the material of choice, primarily because they persist over time in the pen or field and can often be individually identified. Moreover, with use of scat detecting dogs and DNA genotyping of samples, the opportunities for research and management in this area seem boundless. Although reproductive technologies, such as artificial insemination and embryo transfer, have limited application to field-based wildlife conservation, they have proven to be invaluable in captive propagation of endangered species, notably, for example, with the first birth, in 2001, of an Asian elephant calf conceived by artificial insemination. Several decades of research in wildlife contraception recently came to fruition with the approval by the EPA of 3 commercial antifertility agents, available in bait for Canada geese and pigeons and in an immunocontraceptive vaccine for white-tailed deer. Wildlife biologists now have at their disposal reproductive techniques and methods for dealing with a wide variety of conservation issues, ranging from the critical need for a better understanding of causes underlying the global decline in amphibians to reproductive suppression of overabundant wildlife and assisted reproduction of critically endangered species held in captivity.

Conservation Genetics and Molecular Ecology in Wildlife Management

INTRODUCTION

PRIOR TO 1980, **genetic techniques** were not typically used in wildlife biology. With recent technological advances, straightforward and rather inexpensive genetic techniques have emerged that can be directly applied to wildlife studies. In this chapter, we discuss molecular genetic techniques and how they can be applied in wildlife biology. This material is intended for wildlife biologists and managers. Geneticists and those interested in detailed descriptions of each technique are referred to Avise (1994) and Hillis et al. (1996). Here, we present a compilation of ideas, techniques, and applications of use to wildlife students and professionals seeking to use molecular genetic techniques.

MOLECULAR GENETIC TECHNIQUES

Nuclear versus Mitochondrial Genomes

All genetic techniques and **molecular markers** described in this chapter examine portions of **DNA** at some scale. Two different genomes are used in genetic studies of animals. The **nuclear genome** is biparentally inherited and is found in the cell nucleus. It is large and not well mapped in most species. The **mitochondrial genome** is housed in the mitochondrion, an organelle involved in cellular metabolism. It is small compared to the nuclear genome and is a circular, maternally inherited molecule that has been well mapped in many species. Nuclear DNA on average evolves slowly, although some portions (e.g., microsatellites) evolve quickly. Mitochondrial DNA (mtDNA) on average evolves more quickly than the nuclear genome and some areas (e.g., control region) evolve very rapidly. These features make mtDNA and some regions of nuclear DNA suitable targets for certain genetic studies (Avise 1994).

Investigating Genetic Variation

Some molecular techniques consider **gene products** (e.g., proteins), and some examine DNA variation at the **nucleotide level** (e.g., DNA sequencing or fragment analysis). In the past, analysis of certain proteins has been easy and economical; however, quantifying variation at the nucleotide level has become a more powerful molecular tool for population genetics and systematics. Some techniques look for differences in actual nucleotide sequence, whereas others infer relatedness based on analysis of fragments and restriction sites.

The advent of the **polymerase chain reaction (PCR)** has revolutionized molecular biology. Essentially, PCR is a reaction in which a region of DNA is targeted and amplified exponentially (Awise 1994, Palumbi 1996). This reaction requires development of unique primers that flank both sides of the targeted region of DNA. Once amplified to large quantities, the targeted region (usually between 100 and 2,000 base pairs) is available for study with a wide variety of molecular techniques. We briefly review several techniques that have been and are currently used in wildlife studies (Table 22.1). More detailed and excellent reviews of these and additional genetic markers available for studying genetic diversity in wildlife populations have been presented elsewhere (Awise 1994, Smith and Wayne 1996, Haig 1998, DeYoung and Honeycutt 2005).

Analysis of Gene Products

Protein electrophoresis is a technique that can be used to examine population subdivision or structure. Proteins are a series of amino acids joined by peptide bonds. Each amino acid has a distinctive side chain, some of which are either positively or negatively charged. Thus, when an electric current is applied, these proteins migrate differentially through a matrix based on their charge, size, and shape. Proteins can then be visualized through histochemical staining or other methods (Murphy et al. 1996). **Mutations** cause changes in the DNA sequences of amino acids forming proteins that, in turn, cause changes in the shape, net charge, and migration rate of proteins. Such changes can be revealed through electrophoresis and provide information showing variability

among individuals, populations, or species. Although inexpensive, this technique can examine only a small proportion of the variation present in the DNA that codes for the proteins; differences in proteins are not necessary detected. The subset of proteins typically studied with this approach is called **allozymes**. These proteins, however, may be under selective pressure and may not represent the diversity and divergence present in other genes. Further, the tissue required for this type of analysis typically requires highly invasive or destructive sampling and is logistically difficult to manage in field situations.

Fragment Analysis

Fragment analysis comprises various genetic techniques that explore nucleotide variation indirectly by comparing the size of DNA fragments electrophoretically. Although fragment analysis offers less resolution than does direct DNA sequencing, it is cost effective when examining many individuals and many different loci. Among fragment analysis techniques, some cut DNA in certain areas (e.g., **restriction fragment length polymorphisms [RFLPs]** and **mini-satellite fingerprinting**), whereas others amplify many different loci (**amplified fragment length polymorphisms [AFLPs]** and **microsatellites**). With the exception of microsatellites, these techniques produce multiple fragments (bands) per individual (Fig. 22.1). In these cases, individuals are compared by the extent of band sharing among individuals. These markers, with the exception of microsatellites, are considered **dominant**, which refers to the fact they document presence or absence of an allele. **Codominant markers** are those that reveal both alleles at a given locus (i.e., heterozygotes can be distinguished from homozygotes). Thus, they provide much more information and allow for the documentation of heterozygosity and tests of **Hardy–Weinberg Equilibrium** and Mendelian inheritance.

For RFLP analysis, the template DNA is typically a small portion of the nuclear or mitochondrial genome that has been amplified using PCR. RFLPs characterize genetic variation using **restriction endonucleases**, which are enzymes that cut at specific locations in DNA sequences. Restriction enzymes cut at a specific recognition sequence, usually 4–6 base pairs long. The enzyme EcoRI, for example, cuts between G and A when it comes across the sequence GAATTC. Thus, every string of GAATTC in the PCR product will be cut in the same location and will produce many fragments of different sizes. Mutations that cause changes in the cleavage site (e.g., GATTC changed to GATAC) prevent the enzyme from cutting at that location, thereby producing a different series of fragments (different numbers or sizes of fragments). The series of fragments is then compared to examine the similarity of individuals or populations.

Whereas RFLPs look for variation in a single targeted segment of DNA, other fragment-based methods examine

Table 22.1. Applicability of common types of molecular markers for wildlife biologists. The number of Xs indicates the relative applicability (fair, good, very good, and excellent) of each technique to a specific question.

Type of marker ^a	Taxonomic delineations	Regional or subspecific population structure	Genetic diversity and subpopulation structure	Individual identity and paternity/maternity analysis
Allozymes	XXX	XXX	XXX	X
MtDNA sequences	XXXX	XXXX	XX	X
Microsatellites	X	XX	XXXX	XXXX
Minisatellites	X	X	XX	XXXX
AFLPs	X	X	XX	XXX
SNPs	XXX	XX	XX	X

Modified from Mace et al. (1996).
^a AFLP = amplified fragment length polymorphism; mtDNA = mitochondrial DNA; RFLP = restriction fragment length polymorphism; SNP = single nucleotide polymorphism.

Fig. 22.1. Example of variation at multiple minisatellite loci. This illustration shows variation in and among families of pukeko (*Porphyrio porphyrio*) detected using markers pV47-2 and 3'HVR. From Lambert et al. (1994).

variation throughout the genome. **Minisatellites** refer to portions of DNA that have variable numbers of tandem repeats (sometimes called VNTRs); the length of each repeat unit is approximately 20 base pairs long. Typically, genomic DNA is digested into many fragments with restriction enzymes. These fragments are then separated by size using

electrophoresis. The number of fragments produced by this process precludes visualization of individual bands, so radioactive or fluorescent probes specific for the minisatellite repeat are used to visualize and compare these sequences (Jeffreys et al. 1988). Because such “repeats” are commonly repeated in the genome, it is not unusual for this technique to produce dozens of bands. Although **DNA fingerprinting** with minisatellites has typically involved analysis with restriction enzymes and labeled probes, PCR-based approaches are becoming more common.

AFLP analysis is another multilocus technique that involves randomly primed loci and requires no a priori knowledge of the target genome (Hill et al. 1996). Analysis of AFLPs involves cutting the genomic DNA with restriction enzymes and ligating short “adapters” of known sequence to the fragment ends. PCR is then used to selectively amplify subsets of these fragments. AFLPs produce a series of hundreds of bands on a gel. Scoring is based on the presence or absence of a particular PCR product. AFLP analysis also is a dominant marker system, but it has the advantage of amplifying several hundred markers using only a few selective PCRs (Mueller and Wolfenbarger 1999, Meudt and Clarke 2007).

Microsatellite analysis, another PCR-based technique, differs from most other fragment analyses, because the attempt is to identify **diploid** (codominant) genotypes for specific loci. Like minisatellites, microsatellites are VNTRs; however, the repeated sequence is short (2–5 base pairs). Mutation rates of these regions are high, and the number of alleles (versions of a particular sequence) per locus in a population also is typically high. Allelic variation is usually in the form of length polymorphism, which can easily be detected on a high-resolution gel. Amplification results in either 1 (homozygote) or 2 (heterozygote) bands (or peaks) per individual (Fig. 22.2). Microsatellite primers are specific to a single locus and are usually specific to a particular species or group of closely related species. Because of this primer specificity, the development of primers for a particular species can be expensive. The advantages of microsatellite analysis include codominance and high levels of polymorphism. Typically, data from several microsatellite loci are used in a particular study.

Fig. 22.2. An example of microsatellite data. This locus is heterozygous in this individual, with one allele of 362 base pairs and one allele of 366 base pairs.

DNA Sequence Analysis

Direct **DNA sequencing** (nuclear or mitochondrial) is one of the most widely used techniques today, because it is highly informative and, recently, has become much easier and less expensive to perform. It also is appealing because evolutionary processes can be modeled and integrated into analyses. Further, because the genome is so vast, the amount of information gleaned from sequencing may be quite large. DNA sequencing involves amplifying a target region and then creating a series of labeled (either radioactively or fluorescently) DNA fragments that correspond to each nucleotide (Hillis et al. 1996). The DNA fragments are then separated using electrophoresis and visualized. Recent technological advances have automated the sequencing process using fluorescently labeled DNA fragments (reviewed by Hillis et al. 1996) that are read by a laser and interpreted by computer software.

Single Nucleotide Polymorphisms

Single nucleotide polymorphisms (SNPs) are an emerging class of genetic markers that show great potential for wildlife applications. A SNP is a specific site in a DNA sequence in which a single nucleotide varies, resulting in different alleles (Primmer et al. 2002). Because DNA is comprised of **nucleotides** (A, C, T, or G) strung together to form DNA sequences, each SNP site consists of 4 possible nucleotide variants. Additional variation at a SNP site might include a deletion or insertion of a nucleotide. Once the allele at the SNP site is identified in an individual, it is compared to alleles from other individuals, thereby allowing for the examination of levels of genetic variation or similarity among individuals.

The occurrence of SNPs in the genome is quite common, as they have been documented to occur every 100–300 base pairs in humans (Brown 1999). They occur throughout the genome in both coding and noncoding regions of DNA and their **mode of inheritance** is thought to be well understood, following simple mutation models (Morin et al. 2004). Limitations for this type of marker include difficulty identifying alleles in individuals heterozygous at a particular SNP site and the tediousness and expense of identifying and characterizing SNP sites in non-model organisms (Brumfield et al. 2003, DeYoung and Honeycutt 2005).

Genetic Sampling

For genetic data to be used in a wildlife study, material must be collected from animals in the field. The type of material sampled, sample size, and sampling regime vary according to the questions being asked and the molecular markers being used (reviewed by Baverstock and Moritz 1996). DNA can be extracted from a variety of different tissues, including muscle, heart, liver, blood, skin, hair, feathers, saliva, feces, urine, scales, bone, fins, eggshell membranes, and, po-

tentially, cervid antlers. **DNA extraction techniques** for most tissues are well established and involve the isolation of DNA from proteins and lipids using a digestion with the enzyme proteinase K followed by extraction with organic solvents (Sambrook et al. 1989). Modifications to traditional extraction methods, for example, are needed when using hair or feathers when the DNA is encased in the hardened tissue of the shaft and root (reviewed by Morin and Woodruff 1996). DNA has been successfully extracted and used from museum specimens (Mundy et al. 1997), although these techniques can be highly labor intensive and expensive. When considering what type of tissue to sample, several different factors must be addressed. It must first be decided what quantity and quality of DNA is needed to answer the question of interest. Second, the necessity, feasibility, and logistics of trapping and sampling animals must be examined. Finally, field preservation and sample storage issues should be addressed prior to the beginning of a study.

Some molecular techniques require a reasonable quantity of high-quality DNA (e.g., sequencing large fragments of mtDNA or DNA–DNA hybridization) whereas others (most PCR-based techniques) are much more forgiving. Samples of feathers, hair, feces, and urine may contain small amounts of DNA that may be of low quality (sheared into many fragments), whereas blood, skin, and muscle tissue often yield DNA of high quantity and quality.

The logistics of trapping and sampling wildlife vary greatly, depending on the species of interest. Some species are relatively easy to trap and sample, whereas others are difficult and/or dangerous. **Destructive sampling** refers to instances where the organism is killed during the process of sampling, such as for collection of muscle, heart, liver, or embryo tissue. If an animal is killed (hunting) or found dead (road kill or disease), samples can easily be taken for genetic analysis. **Nondestructive sampling** occurs when a genetic sample can be obtained without sacrificing the animal. Feathers, blood, shell membranes from hatched eggs, skin, hair, feces, and urine can all be collected nondestructively and provide potential sources of DNA for genetic analysis. Genetic samples also can be gathered without having to handle the animal in question (e.g., feathers, hair, feces, and urine); see the section on noninvasive sampling for more details.

In most cases, genetic samples can be stored on ice, refrigerated, dessicated, collected into a preservative buffer, or frozen almost immediately after collection (Table 22.2). When fieldwork occurs in remote areas, sampling certain tissues (e.g., skin or feathers) may be more feasible than such tissues as blood. When working with blood, only a small amount is needed (5 drops) and should be mixed with a preservative, such as ethylenediaminetetraacetic acid (EDTA), or with a blood buffer storage solution, such as Longmire buffer, or stored dry on filter paper. Muscle tissue should be

Table 22.2. Sources of DNA and how samples should be collected

Tissue type	Amount	Quantity	Quality	Preservation method
Blood	5–10 drops	High	Good	EDTA ^a coated tubes Lysis buffer (Longmire) Filter paper Buffer
Muscle	Square 2 cm on a side	High	Good	
Feather	At least 1	Low	Good	Dry
Eggshell membranes	As much as possible	Depends	Good	Dry
Hair	At least 1	Low	Good	Dry
Scat	Variable	Low	Poor	Ethanol or dry
Teeth	Variable	Low	Depends	Dry
Bone	Variable	Low	Depends	Dry
Buccal swab	Variable	Low	Good	Lysis buffer (Longmire)

^aEDTA = ethylenediaminetetraacetic acid.

either placed in a preservation buffer or frozen immediately. Contour or wing feathers provide the best source of DNA, but smaller downy feathers can suffice. Feathers from individual birds should be kept in separate bags. Eggshell membranes also can be a good source of DNA, as long as there is vascularization of the membrane. Each membrane should be stored dry in separate bags. Buccal swabs can be collected and stored at room temperature in buffer. Hair, bone, and teeth can be used as a DNA source if they are stored dry. For hair, only the follicle is needed. Scat also can be used, but the quantity and quality of DNA are often low. Scat should be preserved in either liquid ethanol or with silica beads. Detailed protocols for sample collections and descriptions of buffer are available at http://www.absc.usgs.gov/research/genetics/asc_usgs_samplingprotocols.pdf.

TAXONOMY

Species or Subspecies Identification

Taxonomists have been categorizing organisms into hierarchical groups ranging from kingdom and phylum levels to genus and species for hundreds of years. Past classifications have been defined using morphological and behavioral characteristics. Taxonomic delineations derived only from morphological characteristics can be erroneous (Avice 1989, Zink 2004), as they can either fail to recognize distant forms (Avice and Nelson 1989) or they can recognize forms that exhibit little evolutionary differentiation (Laerm et al. 1982). Classifications based on morphology and behavior have been acceptable in the past, yet the use of molecular genetic information can often help resolve discrepancies and refine taxonomic definitions. Although such neutral molecular mark-

ers provide important insight into historical and geographic patterns of variation in species, however, using them alone or elevating their significance relative to other forms of evidence, such as morphology or behavior, may, in some situations, mislead conservation efforts.

Although most taxonomic definitions are somewhat arbitrary (subspecies, genera, order), classification at the species level is perceived to be based on real, evolutionary units (Dobzhansky 1970). The debate as to how best to classify organisms into species has been ongoing for >150 years (Darwin 1859, Mayr 1942, Wiley 1978, Cracraft 1983, de Quieroz 1998, Wheeler and Meier 2000). New species concepts are added almost continuously (Hey 2001) to address perceived failures of prior ones, and the debate continues as biologists attempt to place discrete boundaries on a continuous process (Winker et al. 2007). Because the **species definition** is integral to the Endangered Species Act (ESA; U.S. Fish and Wildlife Service 1973) and protection and management of many species, we briefly mention the 2 most commonly used: the **biological species concept** (Dobzhansky 1937) and the **phylogenetic species concept** (Cracraft 1983). The major difference between these 2 species concepts is the biological species concept emphasizes **reproductive isolation**, and the resultant limitation and/or preclusion of **gene flow**, whereas the phylogenetic species concept defines species using the criterion of reciprocal monophyly and typically relies solely on genetic data.

Genetic data can be used to address the species question, regardless of which definition is used. Documenting an absence of gene flow among sympatric populations is one piece of evidence that can be used, along with morphological and behavioral data, to suggest delineation of a species. Constructing **phylogenetic relationships** among individuals to examine whether a monophyletic group exists also can be achieved by comparing DNA sequences.

Until recently, genetic information was difficult and expensive to acquire and, at times, could only be used to resolve differences between distantly related species. Protein electrophoresis (allozymes) became a useful genetic tool to distinguish differences between some species, but it is less useful when delineating the taxonomic relationship among closely related organisms (whether they are species, subspecies, etc.). The advent of PCR and automated sequencing has made it relatively straightforward to collect data at a high resolution in a cost-effective manner from a large number and variety of organisms. Further, sequence data from genes evolving at widely different rates can be gathered, which allows for taxonomic comparisons at immensely different levels (from kingdom/phylum/class to genus/species/subspecies). This ability allows for re-evaluation of taxonomic status using genetic information or for the addition of supplementary data to unresolved taxonomic questions.

There are several molecular techniques with which to assess taxonomic relationships (e.g., DNA–DNA hybridization

or protein electrophoresis). Perhaps the most widely used and most applicable to questions in wildlife biology is analysis of the mtDNA sequence, although more and more studies augment such data with multiple loci from the nuclear genome. The **mitochondrial genome** is small (15,000–20,000 base pairs) and contains approximately 37 genes, although the order of these genes is not constant (Avice 1994). It is maternally inherited and does not recombine, as does nuclear DNA. Although comparisons of the gene order of mtDNA have been used in investigations of taxa, direct comparison of sequences has proved to be an effective technique in finer level taxonomic questions (among more closely related species; Avice 1994) that are much more common wildlife management concerns. Mitochondrial DNA is well mapped in many animals (Bibb et al. 1981, Anderson et al. 1982, Roe et al. 1985) and evolves 5–10 times faster than single-copy nuclear genes (Brown et al. 1979, 1982). It also contains a noncoding control region, in which some areas are even more variable (4–5 times more variable than mtDNA as a whole) that can be used to delineate closely related species and populations (Greenberg et al. 1983). Each mtDNA gene evolves at a different rate, allowing for different level comparisons using genes with different mutation rates. Additionally, many studies are moving toward using both mtDNA and nuclear DNA sequences to better resolve taxonomic issues (Barker et al. 2001, Barker 2004).

Once an appropriate **gene** is chosen for the taxonomic issue in question, DNA sequence from that region is obtained, and the relationship among individuals is inferred by comparing the DNA sequences. Metrics, such as the **percentage sequence divergence**, provide some measure of how similar or different the DNA sequences may be. **Genetic distances** or **phylogenetic relationships** (trees) are then estimated using either algorithms (e.g., unweighted pair group method) or optimality criterion (e.g., parsimony or maximum likelihood). These methods are well established and reviewed extensively by Miyamoto and Cracraft (1991) and Swofford et al. (1996). Nucleotide substitution patterns in the mitochondrial control region are quite elaborate, and models that estimate the rate of nucleotide substitutions have been developed (Tamura and Nei 1993, Tamura 1994). Modeling substitution rates circumvents violations of assumptions used by parsimony methods.

Using genetic data to address taxonomic questions becomes important for wildlife management primarily at the species and subspecies level. Wildlife managers are often charged with managing species and subspecies while these definitions are yet unresolved. Further, some subspecies (and even species) are difficult to distinguish in the field without extensive morphological measurements and comparisons with museum type specimens (e.g., Prebles meadow jumping mouse [*Zapus hudsonius preblei*] or detailed analyses of behavior or song (Southwestern willow flycatcher [*Empidonax traillii extimus*]).

The **ESA** and other national and international environmental programs charge managers with protection of species, **subspecies**, and **distinct population segments** that are deemed threatened or endangered. At times, little is known about the taxonomic status of species or subspecies that are petitioned to be listed as threatened or endangered. This classification also is important for recovery of the species or subspecies, because funding priorities generally are based on taxonomic status (O'Brien and Mayr 1991). **Taxonomic delineations** are often based only on morphological characteristics and could be refined by adding behavioral and genetic characteristics.

The taxonomic status of many different species has recently been re-evaluated using genetic data. For example, sage-grouse (*Centrocercus* spp.) have recently been evaluated using behavioral, morphological, and genetic data, resulting in the recognition of a new species (Box 22.1). Other examples include the Kemp's Ridley sea turtle (*Lepidochelys kempii*), which has been recognized as a separate species qualifying for protection under ESA because of data from a mtDNA study (Bowen et al. 1991). The taxonomic status of right whales (*Eubalaena* spp.), which has historically been based on a single morphological character in the orbital region of the skull, has been redefined as the result of mtDNA data (Rosenbaum et al. 2000). Finally, 2 subspecies of blue grouse (*Dendragapus obscurus obscurus* and *D. o. fuliginosus*) have been elevated to full species as a result of analysis of mtDNA (Barrowclough et al. 2004, Banks et al. 2006).

Hybridization

Defining "hybrid" is as perplexing as is definition of the term species. Classically, **hybridization** and **introgression** are used to describe interbreeding between 2 distinct species. However, because a definitive definition of a species is still nonexistent, "hybridization" is sometimes relaxed to include interbreeding between 2 groups that are genetically different, whereas introgression refers to the movement of genes between 2 genetically differentiated groups (Avice 1994). Hybridization can be positive or negative (Haig 1998). In a positive sense, hybridization events can increase the overall **genetic diversity** of a taxonomic group, it can produce increased **fitness** (hybrid vigor) in some cases, and it can produce progeny that are more adaptable than either parent. However, in some instances, hybrids can have reduced viability and fertility. Further, the effects of **outbreeding depression** (decrease in fitness due to a loss of alleles that are locally adaptive) on a species due to a hybridization event can be quite negative. Because true hybrids are generally not protected by the ESA, hybridization provides interesting challenges for those charged with management and protection of species (O'Brien and Mayr 1991).

Molecular techniques provide an increasingly accurate estimation of taxonomic relationships and history of gene flow (Haig 1998). These techniques are being used to ad-

BOX 22.1. USING GENETICS TO HELP DEFINE TAXONOMIC DEFINITIONS FOR SAGE-GROUSE

Large-scale habitat loss and degradation have resulted in the decline of sage-grouse populations throughout their range (Braun 1998) and have caused an increased concern over their status. Historically, sage-grouse were classified into 2 subspecies: eastern (*Centrocercus urophasianus urophasianus*) and western sage-grouse (*C. u. phaios*), based on plumage and coloration differences in 8 individuals collected from Washington, Oregon, and California (Aldrich 1946). The western sage-grouse presumably occurred in southern British Columbia, central Washington, east-central Oregon, and northeastern California (Aldrich 1946).

Populations in other areas of the range were considered to be eastern sage-grouse. The validity of this taxonomic distinction has been questioned (Johnsgard 1983). Recently, sage-grouse from southwestern Colorado and southeastern Utah were found to be morphologically (Hupp and Braun 1991), behaviorally (Young et al. 1994), and genetically (Kahn et al. 1999, Oyler-McCance et al. 1999) different from sage-grouse throughout the rest of the range. This discovery led to description of a new species, the Gunnison sage-grouse (*C. minimus*; Young et al. 2000; see the figure).

With the validity of the 2 present subspecies in question, Benedict et al. (2003) sequenced a rapidly evolving portion of the control region of the mitochondrial DNA for 16 populations of sage-grouse on both sides of the

subspecific boundary. The sequencing results provide no genetic support for the subspecies distinction. The authors suggest that further morphological and behavioral comparisons need to be conducted before overturning the subspecific classifications. This study did, however, identify a population of sage-grouse in the Lyon, Nevada, and Mono, California, areas that was genetically unique from all other sage-grouse populations sampled throughout the species' range (Benedict et al. 2003). This group of sage-grouse is currently being studied morphologically and behaviorally.

Comparison of greater sage-grouse (left) and Gunnison sage-grouse (right).

dress questions of hybridization, introgression, and taxonomic status. For example, large canids occupying the southeastern United States have long been classified as the red wolf (*Canis rufus*). Extinction of red wolves in the wild has led to serious conservation efforts to preserve and restore them into the wild. However, mtDNA data and microsatellite data both strongly suggest the red wolf is a hybrid between the gray wolf (*C. lupus*) and coyote (*C. latrans*; Wayne and Jenks 1991, Roy et al. 1994). The hybrid origin of the red wolf has led to debate over its eligibility for protection under the ESA.

Molecular techniques also can be used to identify the maternity and paternity of hybrids. Aldridge et al. (2001) described 2 sage-grouse \times sharp-tailed grouse (*Centrocercus urophasianus* \times *Tympanuchus phasianellus*) hybrids in Alberta, Canada. Using analysis of mtDNA control region sequence, they demonstrated the mother of each hybrid was a sage-grouse rather than a sharp-tailed grouse. Similarly, hybrids

resulting from crosses in both directions of blue (*Balaenoptera musculus*) and fin whales (*B. physalus*) have been documented using both nuclear and mtDNA (Árnason et al. 1991, Spilliaert et al. 1991). The expansion of barred owl (*Strix varia*) into the range of the endangered northern spotted owl (*S. occidentalis caurina*) led to a study investigating the potential for hybridization between the 2 species. Haig et al. (2004) used AFLP data and mtDNA sequence data to confirm instances of hybridization, which has important legal consequences under ESA.

Evolutionary Significant Units and Management Units

Given that genetic analysis can help refine taxonomic relationships, how else can genetic data be used to address management issues? Recently, there has been debate about how to objectively prioritize conservation or management value below the species level. This discussion began with Ryder (1986:9), who defined the term **evolutionary significant unit**

(ESU) as “a subset of the inclusive entity species which possess genetic attributes significant for the present and future generations of the species in question.” In an attempt to develop an operational definition more useful to managers, Waples (1991) defined ESUs using 2 criteria. A population or groups of populations had to demonstrate substantial reproductive isolation from other populations of the same species, and at nuclear loci, it had to show significant divergence of allele frequencies. Moritz (1994b:373) further defined ESU as “a population (or set of populations) that is reciprocally monophyletic for mtDNA alleles” and “shows significant divergence of allele frequencies at nuclear loci.” Moritz (1994a) defined a second unit called a **Management Unit** as a group with less separation than an ESU, but deserving of specific management attention. This unit was defined to have significant divergence of nuclear or mtDNA allele frequencies, regardless of the phylogenetic differentiation of alleles. Although Moritz’s ESUs protect distinct units, allowing for preservation of their long-term genetic variability, his management unit concept allows for shorter term conservation goals. Several other scientists have put forth alternate ideas on the concept of ESUs (Dizon et al. 1992, Avise 1994, Vogler and DeSalle 1994, Crandall et al. 2000, Fraser and Bernatchez 2001). Although definitions of an ESU are as highly debated and diverse (Fraser and Bernatchez 2001) as the species concepts, the ESU is useful if one is aware of the lack of agreement surrounding the best definition. Most genetic studies with applications to management use Moritz’s (1994a, b) definitions, because they are well defined when using genetic data. Also, these definitions appear to be among the most well accepted and applied to date. These concepts have been applied to tiger quolls (*Dasyurus maculates*; Firestone et al. 1999; Box 22.2), spotted owls (*Strix occidentalis*; Haig et al. 2001), koalas (*Phascolarctos cinereus*; Houlden et al. 1999), and brown bears (*Ursus arctos*; Waits et al. 2000).

CONSERVATION OF GENETIC DIVERSITY

A focus of conservation genetics is preservation of genetic diversity in and among populations, especially in rare or endangered taxa. Genetic diversity can be estimated using molecular markers or morphological measurements. Although studies have examined the underlying genetic variation and heritability of specific morphological traits in both captive and free-ranging wildlife (Merilä 1997, Kruuk et al. 2000, Réale and Festa-Bianchet 2000), intensive investigations are difficult to implement for many species. Frankham et al. (2002) reviewed the use of **quantitative genetic approaches** in a conservation context to study the effects of multiple genes and environmental variation on such complex traits as morphology and behavior; Ellegren and Sheldon (2008) discuss new approaches useful for studying natural populations. Our primary focus in this chapter is on what molecu-

BOX 22.2. TAXONOMIC REDEFINITION OF TIGOR QUOLLS IN AUSTRALIA

Firestone et al. (1999) defined evolutionary significant units (ESUs) and management units (MUs) for tiger quolls, which revised taxonomic classification and management plans for these carnivorous marsupials in Australia. Previously, 2 allopatric subspecies of tiger quoll had been recognized. The smaller subspecies, *Dasyurus maculatus gracilis*, occurs only in northern Australia in northeastern Queensland. The larger subspecies, *D. m. maculates*, occurs in southeastern Australia and Tasmania. Each subspecies has been placed on the International Union for Conservation of Nature list as either endangered or as vulnerable to extinction.

Firestone et al. (1999) used both mitochondrial DNA (mtDNA) sequencing and nuclear microsatellites to survey the genetic relatedness of tiger quolls. Their mtDNA sequencing results show reciprocal monophyly and significant differences in nuclear microsatellite allele frequencies between Tasmanian and all mainland tiger quolls. These results suggest that, even though Tasmanian tiger quolls are recognized as the same subspecies as those in southeastern Australia, they are a separate ESU and that their taxonomic status should be revisited. The 2 subspecies on the mainland do not constitute different ESUs, even though they are considered separate subspecies.

Firestone et al. (1999) suggested that morphological differences between the 2 subspecies may reflect adaptation to climatic differences. Differences in microsatellite allele frequencies and mtDNA haplotypes exist between the 2 subspecies on the mainland, suggesting that they should be considered as distinct MUs. Thus, assessment of genetic data (Firestone et al. 1999) revealed differences between the 2 subspecies at the MU level in Australia, and the classification in Tasmania should be reconsidered to recognize and preserve the unique genetic makeup and evolutionary path of tiger quolls.

lar markers tell us about the demography and genetics of a population and how that information can be applied to issues in wildlife conservation.

Genetic diversity and genetic variation are often used interchangeably to refer to a dizzying array of population char-

acteristics. We use **genetic diversity** to refer to variation in frequencies of alleles at individual genes. It is difficult to quantify total genetic diversity in populations; most studies look at surrogates of this measure based on variation at molecular markers. Four processes are generally thought to influence patterns of genetic diversity: mutation, gene flow, drift, and selection.

Mutation

Normally, mutation does not have a major role in management issues. One exception is the case of exposure of populations to **environmental mutagens**. Animals exposed to radioactive or chemical mutagens might be expected to have more genetic diversity because of an increased number of genetic mutations. This hypothesis was tested using bank voles (*Clethrionomys glareolus*) and barn swallows (*Hirundo rustica*) from the vicinity of the Chernobyl nuclear accident site in Ukraine (Matson et al. 2000). Microsatellite analysis provided evidence of increased mutation rates in the swallows (Ellegren et al. 1997). In the voles, higher levels of mtDNA variation were found near Chernobyl than at reference sites; however, recent work indicates that it is difficult to attribute this increased genetic diversity to increased mutation (Meeks et al. 2007). Other investigations have failed to detect much evidence of increased mutation in wildlife from contaminated sites (Dahl et al. 2001, Stapleton et al. 2001, Berckmoes et al. 2005). Given that mutations are relatively rare events, it is not surprising that it is difficult to detect increased mutation rates in the face of other powerful genetic forces, such as gene flow and drift. Examinations of exposed populations for increased mutation rates will probably expand in coming years, as automated analyses have made it possible to screen large numbers of individuals and genes.

Gene Flow

When organisms disperse to new populations and reproduce, they contribute genetic material to their new populations. This process increases the genetic similarity of populations exchanging individuals. Reductions in gene flow allow populations to diverge through processes of **genetic drift**, the accumulation and spread of different mutations, and selection for local conditions.

Gene flow differs from dispersal as typically measured by studies of animal movement. Radiotelemetry or tagging studies can often provide insight into the proportion of individuals that depart from their natal areas, but they are inadequate for measuring the reproductive contribution of dispersing individuals to their new populations. Gene flow is typically measured through indirect methods using genetic markers (Slatkin 1985a). One of the most common approaches for estimating gene flow involves use of Wright's F_{ST} (1951). One common definition of F_{ST} is the proportion of the total variance in allele frequencies due to differences

among populations. An attractive feature of this measure of genetic differentiation is that F_{ST} can be expressed as a function of the **number of migrants per generation** (Nm). Mills and Allendorf (1996) and Whitlock and McCauley (1999) discuss the assumptions necessary to use F_{ST} to estimate Nm and the difficulties of obtaining unbiased estimates of gene flow.

Many estimators of F_{ST} have been developed, and there is a large literature evaluating their merits and performance (reviewed by Neigel 1997, 2002). For other approaches to estimating gene flow, see Slatkin (1985b), Slatkin and Maddison (1990), and Neigel et al. (1991). Recently maximum likelihood and Bayesian approaches have been developed to estimate gene flow and other population parameters (Beerli and Felsenstein 2001; Wilson and Rannala 2003; Kuhner 2006, 2009). These methods can be quite powerful, but demand considerable computational resources.

One problem with most indirect estimates of gene flow is that effects of recent gene flow on gene frequencies are often confounded with **historical gene flow**. If isolation is recent, populations might appear to have high gene flow even if they are completely isolated, because molecular differences have not had time to accumulate (Neigel 1997, 2002). Many estimators of gene flow are based on populations being in an **equilibrium** condition, where population size and number of successful migrants have not changed dramatically for many generations. In cases of population growth or decline, it is assumed the change is constant over time (see Kuhner 2006). These conditions are not typical of many settings in which resource managers wish to estimate gene flow, such as in recently fragmented landscapes. Thus, although often useful in a relative sense, the absolute values of estimates of Nm should be regarded with some caution.

The greater the exchange of individuals between populations, the more that **genetic similarity** of the populations will increase. However, the relationship between gene flow and genetic similarity is not linear (Fig. 22.3); a few successful individuals moving between populations each generation is often sufficient to retard the effects of genetic drift on the similarity of gene frequencies. A consequence of the nonlinear relationship of gene flow and differentiation is that once gene flow is sufficiently high to erase most genetic differences between populations, estimates of F_{ST} approach zero, and it is difficult to estimate the number of migrants per generation (Waples 1998). However, knowledge that gene flow is high enough to minimize F_{ST} should be sufficient for most management decisions—a precise estimate of Nm is not needed.

Sex-Specific Dispersal

Among wildlife species, there is considerable variation in the gender of dispersing individuals. Gender of dispersing individuals is typically beyond the control of wildlife biologists; however, it is important to understand that **breeding**

systems and gender-biased dispersal are likely to affect estimates of gene flow. Gender-biased dispersal and social structure in populations can alter effective population size, influencing rates of loss of genetic diversity (Chesser et al. 1993).

Gender-biased dispersal will have large consequences for data generated by maternally inherited markers, such as mtDNA. There is a large set of literature, reviewed by Avise (1994), documenting differences in spatial distribution of biparental nuclear markers (e.g., allozymes and microsatellites) and mtDNA. For example, frequencies of mtDNA genotypes of green turtle (*Chelonia mydas*) differ dramatically among some nesting beaches (Bowen et al. 1992). However, nuclear DNA in this species exhibits much less spatial subdivision than does mtDNA, suggesting that females, but not males, return to their natal beach (Karl et al. 1992).

Given the important contributions of mtDNA studies to understanding of female-specific gene flow, it is clear that markers tracing gene flow in males would be of great value. In mammals, an obvious choice for a paternally inherited marker would be the Y chromosome, which is only passed from males to their sons. Sequences from the Y chromosome have been used to show there was little male-mediated gene flow between a recently colonized population of wolves and more established populations (Sundqvist et al. 2001). Identification of microsatellite loci and other easy-to-assay markers on the Y chromosome has enhanced the ability to characterize gene flow by males in several mammals (Handley and Perrin 2007, Yannic et al. 2008).

Studying male-specific markers in birds is more complicated than in mammals, because birds have heterogametic (ZW) gender determination, where the females are heterogametic. Thus, there are no paternally inherited genetic markers similar to the Y chromosome in mammals. Scrib-

ner et al. (2001) provide an example of how information from different types of molecular markers, together with theoretical models, can be used to estimate male- and female-specific gene flow in birds. In their study of spectacled eider (*Somateria fischeri*), they used mtDNA, a gender-linked Z-specific microsatellite locus, and biparentally inherited microsatellites to document large differences in sex-specific gene flow. Information about sex-specific movements also can be gained by comparing the spatial genetic structure of adult males and females (Lee et al. 2009).

Population Structure and Fragmentation

Using F_{ST} to quantify population structure and gene flow assumes that sampling reflects the underlying population structure; however, choice of sampling locations is often based on other considerations, such as logistics or accessibility. Rather than assessing differences in gene frequencies among sampling locations, it is becoming more common to use assignment methods to determine the number of populations in a given sample and to assign individuals to those populations (reviewed in Manel et al. 2005). See Aspi et al. (2009) and Boessenkool et al. (2009) for recent examples of the use of these powerful assignment methods for assessing the structure of wildlife populations. Waples and Gaggiotti (2006) review different methods for identifying population structure based on genetic markers.

If gene flow is limited for many generations by natural barriers to dispersal, populations on opposite sides of the barrier can exhibit striking levels of differentiation. Fragmentation of habitat should, given sufficient time, also result in genetic differentiation among recently isolated populations, especially if sizes of populations inhabiting the habitat remnants are small. For example, gene flow was much lower in populations of Sitka deer (*Cervus nippon*) in areas of habitat fragmentation (Goodman et al. 2001). Sometimes even animals capable of long-distance movements, such as migratory songbirds (see Box 22.3) or black bears (*Ursus americanus*; Dixon et al. 2007), experience population subdivision due to habitat fragmentation, suggesting the capability for dispersal might poorly predict actual dispersal.

There is one caveat for most studies of the effects of recent habitat fragmentation on genetic differentiation: they lack temporal control. Although it might be true that recent fragmentation of continuous habitat reduced gene flow, it is often difficult to eliminate the possibility that observed patterns of genetic differentiation are due to events that occurred long before any human activities affected the populations. Analyses of genetic differentiation before and after a fragmentation event are possible, given the ability to isolate DNA from museum specimens. For example, Martinez-Cruz and Godoy (2007) found that differentiation among fragmented populations of the Spanish imperial eagle (*Aquila adalberti*) is much greater today than it was in the past, when habitats were presumably more continuous.

BOX 22.3. ASSESSING GENETIC DIVERSITY AND STRUCTURE IN 2 ENDANGERED SONGBIRDS

The golden-cheeked warbler (GCWA; *Dendroica chrysoparia*) and black-capped vireo (BCVI; *Vireo atricapilla*) are migratory songbirds facing a variety of threats to their long-term viabilities (see figure). Both species have restricted breeding ranges (GCWA: central Texas; BCVI: northern Mexico, central Texas, and southern Oklahoma). Within these distributions, the populations have been highly fragmented by habitat loss due to urban, suburban, and agricultural development (Grzybowski 1995, Ladd and Glass 1999). Each species also has been heavily affected by brown-headed cowbird (*Molothrus ater*) nest parasitism.

Microsatellite loci were used to determine whether population fragments had experienced loss of genetic diversity and increased interpopulation differentiation due to bottlenecks and associated genetic drift (see Lindsay et al. [2008] and Barr et al. [2008] for details). Both species had levels of genetic diversity similar to other related songbirds, suggesting that neither had experienced species-wide loss of variation. There also was little evidence that individual population fragments had experienced recent bottlenecks, even though some of them were quite small. However, using both F_{ST} and assignment tests, there was more genetic structure among population fragments than would be expected for songbirds capable of flying hundreds of kilometers during migration. The influence of fragmentation on genetic structure also differed between the species. The greatest genetic differences among GCWA populations were between those separated by agricultural lands; this species depends on mature forests with little edge (Ladd and Glass 1999). The BCVI had greater differences among populations than did the GCWA, but these differences were not strongly influenced by intervening habitat. As a species dependent on early successional shrublands, differentiation may be the result of small numbers of birds colonizing habitats that are only temporarily available. These studies illustrate that habitat fragmentation can restrict gene flow even in species capable of moving great distances and that the habitat requirements of a species will influence its response to fragmentation (Leberg 1991).

Gene Flow through Wildlife Translocations

One consequence of **translocation programs** is gene flow (Leberg 1990a). When such translocations might result in the loss of unique genetic characteristics of isolated populations, they should probably be avoided (Moritz 1999). However, when genetic differences have developed through habitat fragmentation resulting from land use, translocations can be used for **genetic restoration**. Many authors have discussed the possibility of using translocations to restore gene flow between populations isolated by habitat loss (Moritz 1999, Tallmon et al. 2004, Bouzat et al. 2009). Based on the relationship between gene flow and F_{ST} (Fig. 22.3), movement of only a few individuals per generation

should be adequate to minimize the tendency of isolated populations to genetically differentiate. Mills and Allendorf (1996) provide an excellent review of factors to be considered when designing programs to restore genetic connectivity of populations.

Genetic markers can be used to assess whether translocated individuals reproduced and contributed genetic variation to their recipient populations (Mock et al. 2001, Olsson 2007). For example, Arrendal et al. (2004) found that translocated Eurasian otters (*Lutra lutra*) made genetic contributions to 1 of 2 populations into which they were released. These observations can be useful, because it is often difficult to know whether individuals released in augmentation ef-

forts successfully contributed genetic material to the recipient population.

The success of a translocation program also can be examined by assessing whether patterns of genetic similarity expected from natural dispersal have been disrupted (Latch and Rhodes 2005). For example, Leberg et al. (1994) assessed whether genetic structure of white-tailed deer (*Odocoileus virginianus*) populations in the southeastern United States had been influenced by extensive translocations. They found populations connected by translocations to be more genetically similar than populations that had not had individuals transferred between them. With similar data, Ellsworth et al. (1994a, b) concluded that releases of white-tailed deer had little effect on the genetics of native populations, arguing that most translocated deer had not made genetic contributions to their recipient populations. Additional analysis led Leberg and Ellsworth (1999) to conclude that translocated individuals did contribute to the recovery of recipient populations; however, genetic contributions of the released individuals were restricted to the populations into which they were released. This set of studies illustrates the complexities of understanding the genetic and demographic consequences of translocations when only samples collected after the translocation event are available for analysis.

Considerably more information about translocations could be discerned by obtaining genetic information prior to a translocation (Leberg 1999). Bouzat et al. (2009) provide an excellent example of the insights that can be gained by studying both the genetics and ecology of populations before and after a translocation to restore genetic diversity. They found that although translocations of greater prairie-chickens (*Tympanuchus cupido pinnatus*) restored genetic variation to historic levels and reduced inbreeding depression, the benefits of the effort were limited by habitat conditions.

Drift and Bottlenecks

As a result of chance differences in **reproductive success** and **survival** among individuals with different genotypes, allele frequencies will change from one generation to another. Random change in the frequencies of alleles is referred to as **genetic drift**. The effect of drift on a population is expected to be small when population sizes are large. In large populations, small random changes in allele frequencies will occasionally cause an allele to be lost, but this loss is mitigated by formation of new alleles through mutation. However, when populations are small and isolated from other populations, **gene frequencies** can drift dramatically. A population that is maintained at a small size for several generations has different genetic characteristics than it had prior to the reduction in size. Because of large random changes in allele frequencies, alleles will be lost in a small population faster than they are replaced through mutation, reducing allelic diversity. The average number of genes at which an individual is heterozygous (mean multilocus hetero-

zygosity) also is expected to decrease if a population remains small, because matings between relatives will become unavoidable. Another consequence of drift associated with small population size is increased **genetic differentiation**. Genetic differences, based on neutral molecular markers, between 2 populations will increase rapidly if there is no gene flow between them and at least 1 of them is small enough to experience substantial genetic drift.

When a normally large population goes through a constriction in size, the event is referred to as a **genetic bottleneck**. During bottlenecks, drift is greatly accelerated. Bottlenecks often occur at the establishment of a new population. This type of bottleneck is referred to as a **founder event**. Founder events are often severe bottlenecks, as only a few individuals may establish a population; however, they tend to be of short duration.

The duration and size of the bottleneck have large effects on loss of genetic diversity. During severe bottlenecks of short duration, theory (Nei et al. 1975) and experiments (Spencer et al. 2000) indicate that many alleles will be lost. However, because most alleles are relatively rare in populations, there is no large loss of heterozygosity (Leberg 1992, Spencer et al. 2000). But if the bottleneck is of long duration, relatedness of individuals will increase, along with associated loss of heterozygosity (Nei et al. 1975). Thus, population growth rate can have a large effect on levels of genetic diversity through inbreeding following a reduction in population size.

Detecting Bottlenecks and Drift

A severe reduction in population size will lead to loss of heterozygosity, reduced allelic diversity, and drift of allele frequencies. Because prebottleneck samples are often absent, samples from populations that may have experienced a bottleneck are often compared to populations of the same or related species that are believed to have levels of genetic variation not affected by small population sizes (Leberg 1991, Whitehouse and Harley 2001, Nichols et al. 2001; Box 22.3).

This comparative approach requires the assumption the populations had similar levels of genetic variation prior to the putative bottleneck event (Bouzat 2000). Use of preserved materials provides a more straightforward way to estimate prebottleneck levels of diversity. Matocq and Villablanca (2001) used museum specimens to show that low genetic variation in an endangered species was due to bottlenecks that occurred prior to a known recent reduction in population size. Conversely, museum specimens of greater prairie-chickens provided strong evidence that recent population reductions in Illinois resulted in reduced levels of genetic variation (Bouzat et al. 1998b). Unfortunately, sizes of museum collections from localities of interest are often insufficient to make strong statistical comparisons with contemporary populations. For populations that are likely to

be of management concern, it would be appropriate to establish baseline genetic characteristics and preserve DNA samples for monitoring future changes in population size. Schwartz et al. (2007) discuss contributions that DNA from museum archived species have made to conservation biology and advocate for using genetic monitoring to better manage wildlife populations.

The commonly used genetic indices of bottlenecks differ in their sensitivities to population contractions. Loss of allelic diversity is much more sensitive to short population bottlenecks than is heterozygosity (Leberg 1992, Spencer et al. 2000). Not surprisingly, it is easier to detect loss of alleles when using loci with many alleles, such as microsatellites, than with less polymorphic allozyme markers (Spencer et al. 2000). Both simulations and experiments indicate that **temporal change in allele frequencies** also is a much better index of bottleneck severity when drift is estimated with highly polymorphic loci (Richards and Leberg 1996, Luikart et al. 1999, Spencer et al. 2000). Although **allelic richness** is strongly influenced by past size of a population, this parameter also is sensitive to sample size. Thus, when comparing allelic richness among samples, estimates should be adjusted to the smallest sample size of any population used in comparison (Leberg 2002).

Several approaches have been developed to alleviate the need to compare a sample of interest to a reference sample to see whether a population has experienced a loss of genetic variation. These methods are based on expectations of heterozygosity, distributions of frequencies of alleles, or **distributions of allele sizes** for populations that have not experienced bottlenecks (Cornuet and Luikart 1996, Luikart and Cornuet 1998, Luikart et al. 1998, Garza and Williamson 2001). These approaches are dependent on selection of the correct model of mutation used to generate the null distributions. An examination of populations that had experienced known reductions in population size suggests these approaches provide reasonable indices of a population's history of bottlenecks (Luikart and Cornuet 1998, Spencer et al. 2000). However, Larsson et al. (2008) showed these methods where not able to detect a bottleneck of black grouse (*Tetrao tetrix*) that was detectable by comparing contemporary and historical samples. Williamson-Natesan (2005) provides a comparison of these methods and a discussion of their merits.

When considering the effects of bottlenecks on genetic variation, it is critical to realize that not all population reductions will result in measurable losses of **genetic variation**. Population sizes often have to be quite small for several generations to produce a substantial loss of variation. Thus, a 90% reduction in size of a European rabbit (*Oryctolagus cuniculus*) population was insufficient to produce measurable genetic response, because the remnant population was not reduced below approximately 50 individuals and recovered rapidly (Queney et al. 2000). Likewise, experimental populations reduced to 16 individuals for one generation

exhibited almost no loss of variation when they rapidly recovered to a large size (Spencer et al. 2000). Gene flow also will make it very difficult to detect the effects of even severe bottlenecks (Busch et al. 2007).

Effective versus Census Population Size

One goal of conservation genetics is to understand how much genetic diversity would be lost from a population reduction or management activity. Genetic diversity is often lost more rapidly than would be predicted from the number of individuals in the population (referred to as the **census population size**, N_c). At times, many individuals in a population are not reproductively active because of age or social constraints, and some individuals are vastly more successful than others in transmitting their genes to the next generation. When individuals differ in their ability to successfully reproduce, genetic diversity will be lost more rapidly than expected on the basis of N_c . One way of understanding these issues is to estimate the **effective population size**, N_e . N_e is the number of individuals in an ideal population that would lose genetic variation at the same rate as the actual population being studied. An **ideal population** is one where all individuals have an equal chance of producing any progeny making up the next generation. The list of possible factors that can cause $N_e < N_c$ is large (Crow and Kimura 1970, Hedrick 2000, Leberg 2005). We discuss only those factors likely to have a large effect in wildlife populations, with emphasis on those that might fall under the control of managers.

Temporal variation in population size can have large effects on loss of genetic variation (Crow and Kimura 1970, Vucetich et al. 1997) and may have a strong influence on the effective size of wildlife populations (Frankham 1995a). A normally large population that occasionally experiences a large decline in numbers may lose considerable genetic variation during those periods when it is small; this variation is not immediately recovered when the population returns to a large size. Kalinowski and Waples (2002) provide a framework for examining the relationship between N_e and N_c over multiple generations when population size is not stable.

Unequal sex ratios reduce N_e (Wright 1931). If one gender is much more common than the other, members of the more rare gender will disproportionately contribute genes to the next generation. If sex ratios are highly skewed and the rare gender is only represented by a few individuals, then $N_e < N_c$. In species with nonoverlapping generations, highly polygamous mating systems also can result in small estimates of N_e (Nunney 1993).

The **age structure** of a population can complicate efforts to estimate effective population size in wildlife species. Most wildlife populations have overlapping generations; simple formulations of the effects of sex ratio and temporal variation of effective size assume nonoverlapping generations. In some age-structured populations, fairly large numbers of individuals might be too young or too old to reproduce. To

make the issue even more confusing, the influences of sex ratio and mating system on N_e are modified by **generation length** in complex ways (Nunney 1993). Methods assuming nonoverlapping generations should be applied with caution when attempting to estimate N_e of wildlife populations (Leberg 2005).

There are several genetic techniques for estimating N_e . One common approach is to quantify genetic changes through time by taking ≥ 2 temporal samples (Waples 1989, Jorde and Ryman 1995). If insufficient time is available to obtain samples separated by several generations, the genetic characteristics of contemporary populations can be compared to those of museum specimens (Bouzat et al. 1998b, Schwartz et al. 2007, Pertoldi et al. 2008). Recently, there have been a series of powerful methodologies developed to estimate N_e based on this temporal method (Wang and Whitlock 2003, Wang 2005). There are a number of other approaches to estimation of N_e based on genetic data from a single sample (e.g., Tallmon et al. 2008); see Leberg (2005) for a review of issues related to estimating N_e in wildlife populations. In addition to genetic approaches, demographic data can be used to estimate N_e (Harris and Allendorf 1989, Nunney 1993, Engen et al. 2007). When using any of these approaches, it is important to realize that “effective size” can refer to several population genetic parameters and, thus, measure loss of different components of genetic diversity (see Crow and Kimura 1970, Schwartz et al. 1998, Leberg 2005).

Drift and Bottlenecks from Human Activities

Reduced levels of genetic variation have been documented in large numbers of threatened species or populations (Rosser et al. 2000, Rico et al. 2008, Gebremedhin et al. 2009). Reductions of genetic diversity are often symptomatic of small populations that have become endangered through loss of habitat and other causes. Even in abundant species, individual populations can lose genetic variation when they become isolated in fragments of habitat incapable of supporting large populations (Bouzat 2001, Goodman et al. 2001). Creation of corridors between these fragments or the imposition of gene flow through **translocations** has been suggested as strategies for prevention of loss of diversity in fragmented populations (Hedrick 1995, Mills and Allendorf 1996, Epps et al. 2007).

By definition, **reintroduction programs** create **founder events**. Populations established through releases will often have less genetic diversity than those that are the source of released individuals; this loss is related to the number of individuals released (Stockwell and Leberg 2002, Mock et al. 2004, Sigg 2006). For example, Fitzsimmons et al. (1997) found that populations established with translocated bighorn sheep (*Ovis canadensis*) often had reduced genetic diversity compared to the source of the released individuals. Scribner and Stuwe (1994) found the amount of genetic drift experienced by populations of Alpine ibex (*Capra ibex*) was

related to the number and sex ratio of individuals used to establish a population as well as by subsequent population growth. Slow population growth following translocation appears to be responsible for a loss of heterozygosity in a population of elk (*Cervus canadensis*; Williams et al. 2002b).

Not surprisingly, **allele frequencies** of translocated populations often differ from those of their sources (Scribner 1993, Fitzsimmons et al. 1997, Stephen et al. 2005). However, caution should be used when interpreting differences in allele frequencies among translocated populations and their sources. Although differences might be the result of the founder event, they also could have occurred through drift after the translocated population became established (Williams et al. 2000b, Stephen et al. 2005). Vonholdt et al. (2008) provide an example of using genetic markers to monitor the genetic composition and social structure of a reintroduced population of wolves.

Reintroduction strategies that may make sense based on the species' ecology might have the unintended consequence of reducing the **effective population size** of the newly established population (Leberg 1990a). The benefits of such strategies, such as faster initial population growth by releasing more females than males, or of reduced dispersal through release of family groups, should be evaluated in light of their genetic consequences. For example, if it makes sense to release family groups to reduce post-release dispersal, it would be best to release as many groups as possible to avoid inbreeding and loss of genetic variation.

Harvest programs should have little effect on genetic variation, because loss of variation due to drift is small if the population is large. However, harvests can reduce effective population size far below the census population size, creating the potential for rates of drift that might be surprising if only the total population size is considered (Ryman et al. 1981, Laikre and Ryman 1996). For example, harvest regulations and hunter preferences resulting in greater harvests of males can have large effects on the N_e of ungulate populations (Ryman et al. 1981, Coltman 2008). Harris et al. (2002), Coltman (2008), and Allendorf et al. (2008) review the possible effects of game harvests on genetic diversity and effective population size.

Selection

Many genetic markers used by conservation geneticists are thought to be **selectively neutral**. Thus, the specific genotypes associated with these marker systems have little or no effect on the survival or reproduction of individuals. Although this assumption is violated occasionally, most genetic variation examined using many types of markers probably has little consequence for the **fitness** of individuals (Hedrick 2000). Because marker systems are unlikely to be under **direct selection**, they are useful for measuring such phenomena as gene flow, inbreeding, and drift that tend to affect variation throughout the genome and, thus, result in **genetic**

signatures that are detectable with molecular markers. Although the neutrality of molecular markers aids in their usefulness for studying many population processes, it also means the **linkage** of molecular markers and genetic traits of concern to the well-being of individual organisms is at best indirect. The lack of direct concordance often observed between patterns of variation at molecular markers and complex morphological, behavioral, or life history traits has led to calls for conservation geneticists to more critically evaluate whether molecular data are sufficient for designating conservation priorities (Pearman 2001, Reed and Frankham 2001).

In spite of the general assumption that much of the variation characterized by molecular markers is neutral, there is a large body of work attempting to understand the role of selection in maintaining marker variation in wildlife populations. Initial surveys of natural populations detected higher levels of allozyme variation than expected. This observation generated interest in examining whether individuals that were heterozygous for allozyme loci might have high fitness; such selection would promote high levels of variation (Allendorf and Leary 1986, Reed and Frankham 2003). However, there also have been studies that found no relationship between heterozygosity and traits related to fitness (Britten 1996). In red deer (*Cervus elaphus*), antler growth was actually lower in heterozygotes for some allozymes (Hartl et al. 1995). Furthermore, there is little direct evidence that it is the loci themselves that are producing variation in fitness components. The allozymes might be physically linked, through proximity on chromosomes, to genes producing the effect, or alternatively, high heterozygosity might indicate that an individual's parents were not closely related (Leberg et al. 1990). Understanding relationships between heterozygosity and fitness is being enhanced by examining similar relationships using molecular markers that are probably not under selection. Associations between fitness traits and microsatellite heterozygosity have been detected for several wildlife species (Coulson et al. 1998, Hansson et al. 2001, Höglund et al. 2002). Given that most microsatellite loci do not directly affect phenotype, such associations probably reflect the relatedness of an individual's parents or the physical proximity of assayed microsatellites to other loci affecting the traits of interest. In a recent review of the relationship of heterozygosity to traits related to fitness, Chapman et al. (2009) found that although there are many examples of such correlations, the amount of variance in traits explained by heterozygosity is generally small.

Recently, there has been considerable interest given to examining relationships between **individual viability** and loci in the **major histocompatibility complex**. These genes are involved in **immune responses**, and there is some evidence that selection maintains variation in populations (Hughes 1991, Hughes and Yeager 1998, Richman et al. 2001). For ex-

ample, Ditchkoff et al. (2001) found that specific genotypes of the major histocompatibility complex were associated with antler development, body mass, and serum testosterone in white-tailed deer. It is possible that such associations are due to variation in pathogen resistance of different major histocompatibility complex genotypes. Studies also have suggested the major histocompatibility complex might influence mate choice in mammals (Potts et al. 1991, Brown 1998, Penn 2002).

Although examination of correlations between **genotypes** at molecular markers and traits related to individual fitness has been a focus of wildlife genetics, there have been few attempts to apply knowledge in this area directly to management. Any program designed to increase abundance of certain genotypes would be difficult to implement in a natural setting and might be ill advised. Although it has been argued that breeding programs in captive populations should emphasize maintenance of allozyme or major histocompatibility complex diversity because these loci may influence individual survival or fecundity (Wayne et al. 1986, Hughes 1991), **selective breeding schemes** to favor variation at a few molecular markers could result in an increase in the rate of loss of genetic variation at all loci (Hedrick et al. 1986, Vrijenhoek and Leberg 1991, Miller 1995, Lacy 2000). Because there is little understanding of how different genes interact to affect individual well-being, most captive breeding programs advocate maintenance of overall genetic variation and reduction of relatedness. Models also have shown that selection of individuals, on the basis of marker genotype, to be used in reintroduction programs can result in an overall reduction in genetic variation in newly established populations (Haig et al. 1990).

There are promising applications for the use of molecular markers to elucidate variation in fitness traits, and thus improve our understanding of selective pressures faced by wildlife. For example, Slate et al. (2002) used a large number of maps to identify specific genes, referred to as quantitative trait loci for birth weight in wild population of red deer. Ellegren and Sheldon (2008) review using gene mapping and other genomic approaches to understand the genetic basis for variation in fitness traits in wild populations.

Genetic approaches can be used to better understand the implications of **selective harvesting** of wildlife based on hunter preferences or harvest regulations (Allendorf et al. 2008, Coltman 2008). For example, Coltman et al. (2003) used a partly genetically reconstructed pedigree to provide evidence that trophy hunting of bighorn sheep might be selecting for slower horn growth. Because genetic traits are often correlated, selection for one trait, such as horn size, might well affect others, such as body mass or fecundity (Coltman 2008, Sasaki et al. 2009). We are just beginning to understand the effects of selective harvests on wildlife, but at least in some cases, increasing the relative mortality of individu-

als with larger body sizes—or bigger antlers, tusks, or horns—is likely to reduce not only the sizes of those traits, but also influence other correlated traits that might affect population viability (Allendorf et al. 2008, Coltman 2008, Allendorf and Hard 2009).

Genetic Diversity and Population Viability

Observations of **inbreeding depression** in captive (Lacy et al. 1996) and field populations (Jiménez et al. 1994, Keller et al. 1994, Keller and Waller 2002), and studies of **heterozygosity-fitness relationships** (Reed and Frankham 2003) have led to the realization that loss of genetic variation could affect **population viability** (Gilpin and Soulé 1986, Lacy 1997). Simulation models (Mills and Smouse 1994, Robert et al. 2002) and laboratory studies (Leberg 1990b, Spielman and Frankham 1992, Frankham 1999, Reed and Bryant 2000) have demonstrated decreased population growth and increased extinction rates with loss of genetic variation. Furthermore, observations of wildlife populations that have experienced loss of genetic variation due to bottlenecks also support the conclusion that such losses can affect population productivity (Bouzat et al. 1998a).

Practices that lead to reduced genetic variation, such as establishing populations with only a few individuals or allowing populations to remain small and fragmented, might have serious consequences for population viability (see Chapter 35, Volume II). These concerns about effects of inbreeding on demography occur on a time scale relevant to management activities (e.g., Westemeier et al. 1998, Johnson and Dunn 2006, Ewing et al. 2008). On a longer time scale, managers must be concerned about **loss of allelic variation** that can affect the ability of populations to adapt to new environmental challenges (Allendorf and Leary 1986, Frankham 1995b).

Most conservation geneticists promote maintaining large effective sizes of populations to prevent loss of genetic variation and possible associated reductions in population viability. Recommendations concerning population sizes necessary to prevent adverse genetic consequences vary considerably; there is no general agreement on what appropriate minimum numbers are acceptable for long-term management goals (Gilpin and Soulé 1986, Simberloff 1988, Hedrick and Kalinowski 2000, Reed and Bryant 2000). Most published recommendations of minimum population size are in terms of minimum effective size; the number of breeding age individuals in most populations should be at least 2–4 times as large.

The relationship between loss of genetic diversity and population viability is not as straightforward as the discussion above might suggest. A population with a history of inbreeding might suffer from future inbreeding less than other populations (Fu et al. 1998), and **inbreeding depression** may be influenced by environmental conditions (Bijlsma et al. 1999); however, predicting future inbreeding depres-

sion based on population history and environment is difficult (Leberg and Firmin 2008). Furthermore, matings of individuals from genetically differentiated populations, as might occur through translocation, could under some circumstances increase genetic variation in a population while causing a decrease in individual viability (Templeton 1986, Leberg 1993, Edmands 2007). Additionally, other mechanisms besides inbreeding and the loss of genetic variants, such as slow accumulation of mutations with slight deleterious effects, may affect the long-term consequences for small populations (Lande 1995, Jaquiere et al. 2009). Reviews of the mechanisms through which genetic diversity can affect population viability can be found in Soulé (1986), Frankham et al. (2002), Leberg and Firmin (2008), and Chapter 35, Volume 2.

Captive Breeding Programs

When populations decline drastically and only a few individuals remain, biologists often capture some of the remaining individuals in attempts to establish a **captive population**. These animals are bred to expand the captive population, so that individuals can be released into the wild. Because most captive populations are limited in size, they are subject to inbreeding and drift. It has been shown that sound management of the genetic aspects of breeding programs is needed to be successful (Ralls and Ballou 1986, Foose and Ballou 1988, Hedrick and Miller 1992).

Once a captive breeding program has been established, **pedigrees** can be used to avoid matings between close relatives or the over- or underrepresentation of the genes of individual founders in the captive population (Lacy et al. 1995). However, because number of individuals brought into captivity is usually small, inbreeding can be a serious problem if the **founding population** includes related individuals. In such cases, it can be important to consider the genetic identity of animals bred in captivity, so that net genetic variability is maximized and inbreeding is minimized. Molecular genetic techniques have proven to be valuable for inferring relatedness and promise to be useful for examining relatedness of founders (Haig et al. 1994, 1995). Jones et al. (2002b) used microsatellite data to augment wild and captive pedigree information on whooping cranes (*Grus americana*), revealing unknown shared genotype information for founders. Rudnick and Lacy (2008) have shown that improvements in inbreeding avoidance obtained by supplementing information from pedigree relationships with genetic analysis of founder relatedness will be small, unless the founder population included close relatives.

Another issue in captive breeding is **adaptation** to captive conditions. Adaptations like extended reproduction periods and tameness can occur very rapidly and may make it difficult to successfully reintroduce captive bred individuals back into the wild. See Frankham (2008) for a discussion of this problem and possible solutions.

MOLECULAR ECOLOGY

In addition to addressing the traditional concerns of conservation genetics, genetic markers have increasingly provided insight into the ecology of populations. These applications are sometimes referred to as **molecular ecology**, a field that is interwoven with conservation genetics, but that includes applications extending beyond the conservation of genetic variation. As reviewed by Waits and Paetkau (2005), some of these approaches are quite relevant to investigations of wildlife populations.

Noninvasive Sampling

Many wildlife investigators attempt to determine **population size**, **survival rates**, and **movement patterns** (see Chapters 11 and 20, This Volume). **Mark-recapture methods** are often used to achieve these goals. These approaches usually require capturing individuals and marking them in some way that would allow for their identification if they are ever recaptured. Although these techniques work well for many species, there are others for which this type of study does not. Species that are dangerous and expensive to catch (e.g., bears) and those that are highly elusive (e.g., felids) do not lend themselves to conventional mark and recapture techniques.

Because DNA can be obtained from hair, feathers, shed skin, feces, and urine (Table 22.2), biologists have **non-invasive** ways to obtain genetic information (Waits and Paetkau 2005). Each individual animal has a **unique molecular fingerprint**, so it is possible to use this genetic fingerprint in the same way a biologist might a tag or band in a traditional mark and recapture study. One advantage of this **genetic tag** is that it remains with the individual throughout its lifetime and can even be used to associate the individual with its parents and offspring.

Collecting **noninvasive samples**, such as scat or feathers, often involves searches of locations the organism is expected to use, such as trails, tree rubs, nests, roosts, or den sites (Pearce et al. 1997, Kohn et al. 1999, Piggott et al. 2006). Collection of scat can be aided with the use of specially trained dogs (see Chapter 5, This Volume; Long et al. 2007a, b), some of which can distinguish between the feces of target and nontarget species (Smith et al. 2005). Hair snares have been used to sample a variety of mammals. Hair from bears has been sampled by placing barbed wire around an attractant (Triant et al. 2004, Kendall et al. 2008); a similar approach may work for white-tailed deer (Belant et al. 2007). Hair from felids and other carnivores has been collected from scented hair snares that elicit rubbing behavior (Weaver et al. 2005, Castro-Arellano et al. 2008; Box 22.4). Barbed snares or glue pads for small or medium-sized carnivores have been placed at den entrances (Scheppers et al. 2007) or at the entrance of baited enclosures (Belant 2003, Williams et al. 2009). Snares have even been propelled by a

blowgun to collect hair samples from primates (Amendola-Pimenta et al. 2009).

Often **systematic** or **random sampling** is needed for estimating population size or other demographic parameters. Dogs trained for scat detection can be used to sample transects (Smith et al. 2005, Long et al. 2007a, b). Hair snares can be placed along transects, on a sampling grid, or at ran-

BOX 22.4. DOCUMENTING THE PRESENCE OF LYNX USING MOLECULAR TECHNIQUES

When Canada lynx (*Lynx canadensis*) populations declined in the contiguous United States, the federal government implemented a survey based partially on DNA approaches. The survey was designed to learn where lynx did or did not occur. Across the potential range of the species south of Canada, transects were established, and hair snares (see figure), designed to snag samples of hair, and attractant were used to collect samples (McDaniel et al. 2000). The technique of Foran et al. (1997) could not be used, because it required amplification of a long fragment of DNA (approx. 900 base pairs) that could not be amplified using degraded DNA from hair samples. Instead, a shorter fragment was used, and sequences of that fragment from hairs were amplified with polymerase chain reactions. Restriction enzymes were then used to create DNA fragments, and hairs of lynx were distinguished from other samples by banding patterns (Mills et al. 2000a).

Baiting a hair snare with catnip.

dom points throughout a study area (Mowat and Paetkau 2002, Castro-Arellano 2008, Williams et al. 2009).

Another advantage of some **noninvasive sampling** is that it does not require handling the organism. Thus, an individual can be sampled repeatedly without influencing the individual's behavior, making it less prone to being sampled. Furthermore, when samples are collected without the aid of attractants, little or no behavior alteration is expected from noninvasive sampling. Behavioral changes following capture and tagging with traditional approaches have the potential for influencing estimates of demographic parameters (see Chapter 11, This Volume).

Estimating Population Size and Survival

For **mark and recapture methods** based on DNA, molecular biologists need to use a genetic marker (or series of markers) that is variable enough so that no 2 individuals will have the same **molecular tag**. Microsatellites are currently the most commonly used marker for this application: each individual's "molecular tag" is based on its genotype for a number of highly polymorphic loci. Using DNA to identify individuals, scientists have been able to estimate population size for a number of species, including humpback whales (*Megaptera novaeangliae*; Palsbøll et al. 1997), fishers (*Martes pennanti*) and American martens (*M. Americana*; Williams et al. 2009), eastern imperial eagles (*Aquila heliaca*; Rudnick et al. 2008), mountain lions (*Puma concolor*; Ernest et al. 2000), lesser horseshoe bats (*Rhinolophus hipposideros*; Puechmaile and Petit 2007), and brush-tailed rock-wallaby (*Petrogale penicillata*; Piggott et al. 2006). Estimates of survival rates, as well as population sizes, have been obtained for Arctic fox (*Alopex lagopus*; Meijer et al. 2008) and grizzly bears (*Ursus arctos horribilis*; Boulanger et al. 2004).

Methods for estimating population size and survival using molecular tags have been reviewed by Lukacs and Burnham (2005a). Software has been designed specifically to analyze capture–recapture data based on genetic tags incorporating features like **identification error** (Lukacs and Burnham 2005b, Knapp et al. 2009). Other approaches address the possibility of sampling an individual multiple times in the sample collection period and allowing population estimates from only a single period of sample collection (Miller et al. 2005, Petit and Valiere 2006, Puechmaile and Petit 2007). Robinson et al. (2009) found that such models performed better than did multiple occasion capture–recapture estimators. The ability to obtain a population estimate for a single intensive sampling occasion is advantageous when sampling remote study areas that would be difficult to visit multiple times.

Molecular tags have excellent potential for estimating population size (and potentially survival rates) of species that are difficult to trap; however, there are several limitations. The first is the quantity and quality of DNA that is extracted from hair, feathers, feces, and frozen urine. Typi-

cally, only small amounts of DNA can be extracted from such samples, and the DNA is often **degraded** (Taberlet et al. 1999; Table 22.2). With low quantity DNA, **contamination** becomes a serious issue, as does a phenomenon known as **allelic dropout** (Taberlet et al. 1999). Allelic dropout occurs when only 1 of 2 alleles of template DNA is amplified by PCR. The consequences are that only 1 allele of a heterozygous genotype is amplified, resulting in incorrect assignment of that individual as a homozygote instead of a heterozygote. Low quality DNA (severed into many short fragments) is undesirable, because it becomes difficult to amplify a microsatellite allele if the template DNA of a certain microsatellite is severed in that region. **Genotyping errors** and **amplification failure** of DNA from collected scat are influenced both by climate and age of the feces (Piggott 2004, Murphy et al. 2007). Such genotyping errors can result in large overestimates of population size (Waits and Leberg 2000). These issues can be addressed by using strict extraction protocols to avoid contamination, adopting repeated PCR amplifications to identify cases of allelic dropout, and using only short microsatellite loci to avoid problems with degraded DNA (Taberlet et al. 1999, Bonin et al. 2004). Alternately, there are statistical approaches to identify genotyping errors (Miller et al. 2002, McKelvey and Schwartz 2004); these approaches could prove useful in reducing costs associated with multiple PCR amplifications and when DNA is limited. Roon et al. (2005a) evaluated several approaches to identifying genotyping errors and noted that statistical approaches for filtering errors would provide inadequate resolution, unless genotyping error rates are very low.

The second issue deals with the assumption the method used can **uniquely identify individuals**. For this type of analysis, a sufficient number of highly polymorphic microsatellite loci are needed, so that no 2 individuals will share the same molecular tag. If too few loci are used to identify an individual, it is possible that multiple individuals will have the same molecular tag, resulting in underestimates of population size (Mills et al. 2000b, Waits and Leberg 2000). Of course, limited amounts of DNA and increased expense make it undesirable to analyze more loci than necessary to assign unique tags to individuals. There are several approaches for estimating the numbers of loci that should be examined in studies using noninvasive DNA samples (Waits et al. 2001, Hoyle et al. 2005).

Finally, noninvasive samples have the potential to include DNA from multiple individuals. This problem would be most common in cases where several individuals might use a common latrine or leave hair on the same hare snare. For example, Scheppers et al. (2007) found multiple genotypes of badgers at hair snares located at den entrances and along trails; they advocate using DNA from single hairs to identify individuals. This source of bias was examined by Roon et al. (2005b), who provide suggestions for addressing the issue of multiple genotypes in a sample.

Tracking Individual Movements

Because individuals can be identified with highly polymorphic markers and sampled through collections of scat or hair, it is possible to obtain information concerning their movements (Kohn and Wayne 1997). Movement data are obtained by “recapturing” individuals as a result of multiple collections of their DNA at different locations and times. This method has been applied to a number of mammalian carnivores (Kohn et al. 1999, Ernest et al. 2000, Lucchini et al. 2002). Walker et al. (2008) used DNA from scats to study individual movements and social interactions of the southern hairy-nosed wombat (*Lasiorhinus latifrons*). Smith et al. (2006a) present estimates of movements and home range sizes of kit foxes (*Vulpes macrotis*), based on DNA from scat, and discuss issues associated with using scat as a DNA source for tracking individual movements. Information obtained is often limited by **sampling protocols**: if sampling is confined to roads or paths, an incomplete picture of an individual’s use of space will be obtained. Use of specially trained dogs to find scat provides one approach for detecting scat in areas off roads and paths (Smith et al. 2001a). Using DNA from skin samples, Palsbøll et al. (1997) studied long distance migration of individual humpback whales.

At times, it is not necessary to identify “recaptured” individuals to obtain information on movements. If breeding populations differ in genetic composition, it is possible to identify the origin of dispersing or migrating individuals. **Genetic stock identification** allows estimates of the proportion of a sample of individuals that originated from different source populations (Smouse et al. 1990, Xu et al. 1994, Pearce et al. 2000). **Assignment tests** estimate the probability that a specific individual was a member of the different source populations in the sample (Cornuet et al. 1999; Manel et al. 2002, 2005). Variations on these approaches have been used to gain insight into migratory patterns of noctule bats (*Nyctalus noctula*; Petit and Mayer 2000); Wink (2006) reviews the use of DNA markers to study bird migration. Stock identification has proven useful in assigning samples of loggerhead turtles (*Caretta caretta*) collected in foraging areas to their nesting beaches (Bass and Witzell 2000), and in identifying which populations are most affected by incidental captures associated with commercial fisheries (Laurent et al. 1998). Using shed feathers, Rudnick et al. (2008) were able to quantify the degree of natal dispersal and movement in a population of eagles. Gardner-Santana et al. (2009) used assignment tests to examine movements of wild Norway rats (*Rattus norvegicus*) among sites and were able to identify individuals that had dispersed. This approach also has been used to document low amounts of individual dispersal by black bears among habitat fragments (Dixon et al. 2007). In another example, Blanchong et al. (2002) were able to ascertain whether individual white-tailed deer were likely to have been harvested from a specific manage-

ment unit. These approaches require the genetic composition of possible source populations to be well characterized by a large number of genetic markers and individuals; sampling requirements decrease as genetic differences among populations increase. Although stock identification and assignment tests can be powerful, levels of genetic differentiation in many species, such as northern pintails (*Anas acuta*; Cronin et al. 1996) and double-crested cormorants (*Phalacrocorax auritus*; Green et al. 2006), are sufficiently small to make identification of breeding populations impractical.

Another approach useful for identifying dispersing individuals is **parentage analysis**, a special case of assignment testing (Manel et al. 2005). By determining parent offspring relationships through intensive genetic sampling, it is possible to determine which individuals have dispersed from natal sites (Nutt 2008). Waser et al. (2006) show how estimation of parentage can improve on estimates of natal dispersal rates and distances, even in organisms that can be readily captured and tagged.

Species Identification and Detection

Although accurate individual identification can sometimes be challenging with some noninvasive samples, **species identification** is less problematic (see Foran et al. [1997] for an early example). Wildlife biologists often find **signs** of wildlife, such as feces, tufts of hair, feathers, blood, and even frozen urine, and need to know what species (or individual of a known species) left that sign. This information is particularly important for programs monitoring status of regulated or protected species. DNA extracted from these materials can provide such identification. If a species has **uniquely identifiable populations**, this technique also may be applied to identify which population is the source of a sample.

Species identification can be used to sample for the presence of a rare species, such as in the National Canada Lynx Survey (Box 22.4). Other examples of surveys of the occurrence of a species at a sample site using noninvasive DNA include Dalen et al. (2004), Bidlack et al. (2007), and Ruell and Crooks (2007). A range wide survey of DNA from rabbit droppings was used to determine the current distribution of New England cottontails (*Sylvilagus transitionalis*), a species that has been declining for several decades (Litvaitis et al. 2006).

Other applications of species identification include investigations related to the **illegal harvest** of wildlife (Baker 2008). Cassidy and Gonzales (2005) discuss the need for careful standards when processing samples that might be used in criminal cases. Wasser et al. (2008) discuss the use of assignment tests to help trace poached ivory back to its population of origin.

DNA-based species identification can assist in a variety of other wildlife investigations. Smith et al. (2006b) gained information on habitat use by kit foxes based on the distri-

bution of their scat. Analysis of saliva from bite wounds to sheep was used to determine the predator was a dog rather than a wolf (Sundqvist et al. 2008). Onorato et al. (2006) showed that analysis of scat and hair from the vicinity of ungulate carcasses sites greatly enhanced the ability to determine which predators had visited the site or were involved in the depredation. DNA analysis of tissue remnants has been valuable in identifying which species are involved in bird collisions with aircraft (Dove et al. 2008).

Dietary Analysis

Molecular probes can be used to examine food habits in the absence of recognizable remnants of plant and animal parts, such as hair or seeds (Symondson 2002, Waits and Paetkau 2005, Tollit et al. 2009). Possible sources of dietary information useful for such analyses include stomach contents, mammalian scat, and bird regurgitant. For example, Scribner and Bowman (1998) used microsatellite analysis to distinguish among several species of juvenile waterfowl in stomachs of glaucous gulls (*Larus hyperboreus*). Analysis of scat was used to verify predation by dingos (*Canis familiaris dingo*) on an endangered wombat (*Lasiorninus krefftii*; Banks et al. 2003). In such analyses, care must be used to select genetic markers with an appropriate level of resolution. If markers only work on a small number of species, some prey will not be identified. However, using approaches that can identify a wide range of species also might detect nondietary items. For example, while attempting to identify large felids from scat, Farrell et al. (2000) detected dipterian DNA that could be the result of flies visiting the feces. Although biases from DNA degradation may result, causing some food types to be over- or underrepresented in molecular analyses of scats, such errors may not be greater than those observed in conventional diet studies (Deagle and Tollit 2007). Clare et al. (2009) give an interesting example of how molecular analyses of bat feces can provide new insights into foraging ecology of species that are difficult to study using traditional analyses of food habits.

Another significant advantage of DNA-based **analysis of scat** is the ability to trace multiple samples back to single individuals. This makes it possible to determine whether individual predators of the same species differ in their **food habits**. For example, Fedriani and Kohn (2001) found that groups of coyotes, and even coyotes within groups, differed in their diets. In a similar study, Prugh et al. (2008) found that spatial and temporal variations in prey availability could explain some of the diet variation among individual coyotes.

Gender Identification

Wildlife biologists studying animals in the field typically need to know the **gender** of individuals to examine differences between males and females. For example, studies of population dynamics often compare survival rates between

males and females. In sexually dimorphic wildlife species, it is straightforward to differentiate males from females. However, for some species, it is difficult to accurately assign gender to an individual without invasive procedures. The same problem arises with gender identification from wildlife signs, such as feces, urine, feathers, or hair. Molecular genetic techniques can be used on a variety of different species to assign gender to individuals using only a small sample (e.g., blood, feathers, feces, urine, or hair). Forensic scientists can use **DNA-based identification approaches** when gender of a tissue sample or blood stain might indicate a violation of wildlife harvest regulations (Gilson et al. 1998, Wilson and White 1998, An et al. 2007).

Mammals

Gender can be identified from DNA samples for many groups of mammals, including wombats, rabbits, ungulates, carnivores, seals, primates, and whales (Aasem and Medrano 1990, Griffiths and Tiwari 1993, Reed et al. 1997, Taberlet et al. 1997, Sloane et al. 2000, Wallner et al. 2001, Ensminger and Hoffman 2002, Huber et al. 2002). There are 2 main strategies for detecting gender in mammals using molecular techniques. The first approach is to use PCR to amplify a region specific to the **Y chromosome**, such as the SRY locus, to identify males. If the marker is not detected, the sample is assumed to be from a female. However, because degraded DNA or inhibitory compounds found in some samples can prevent detection of a locus (Kohn and Wayne 1997), it is necessary to have **controls** with other markers to verify there is nothing about the sample that would prevent correct gender identification (Taberlet et al. 1997, Wilson and White 1998). A second approach is to amplify **homologous fragments** of the **X and Y chromosomes**, such as the amelogenin gene (Sullivan et al. 1993, Brinkman and Hundertmark 2009) or zinc finger proteins (Shaw et al. 2003). This approach produces 2 different sized bands, thereby alleviating the need for additional amplification controls. Generally, genetic methods of gender identification have proven to be quite reliable for mammals. However, an approach that works for one set of species might not work for others (Ensminger and Hoffman 2002). Thus, the reliability of any protocol should be verified with samples for which the gender is known. Care also must be taken when using DNA markers from scat to identify the gender of carnivores. Ernest et al. (2000) found that scat from 3 of 4 female mountain lions contained male genotypes. They hypothesized the male genotype might be the result of DNA from male prey, since the SRY marker is not species-specific. This issue can be circumvented in felids by using primers designed for the zinc-finger and amelogenin regions, where deletions in Y-chromosome regions are absent in a wide range of prey species, thus minimizing potential contamination from prey DNA (Pilgrim et al. 2005).

Birds

Gender of birds is typically difficult to assign, as the majority of the world's bird species have males that look identical to females (Griffiths et al. 1998). To address this issue, Griffiths et al. (1998) designed primers around homologous regions in the chromo-helicase-DNA-binding (CHD) gene on **sex chromosomes W and Z** in birds. This technique takes advantage of the fact that chromosomes W and Z evolve at different rates. Homologous regions on sex chromosomes typically are different sizes due to mutations involving insertions and deletions of DNA nucleotides. Their method simultaneously amplifies homologous regions on the W and Z chromosomes followed by a restriction digest that allows for differentiation of males (ZZ – 1 band) and females (ZW – 2 bands) in many species of birds, with the possible exception of Struthioniformes. Ellegren (1996) developed PCR primers for collared flycatchers (*Ficedula albicollis*) in the CHD gene that resulted in gender identification of closely related species without the restriction digest step. Kahn et al. (1998) designed a different set of primers in a more conserved region of the CHD gene that works in most avian species. Bello and Sanchez (1999) further modified this technique to allow for gender identification in ostriches (*Struthio camelus*). This technique has been used to identify gender of many species, including mountain plover (*Charadrius montanus*) using feathers (Dinsmore et al. 2002) and kakapo (*Strigops habroptilus*) from feces (Robertson et al. 1999).

SUMMARY

Molecular genetic techniques represent a relatively new and powerful set of tools that can address both research and management issues in wildlife science. These approaches have shown their utility in wildlife management by helping identify species and appropriate units for conservation. Knowledge gained about the factors affecting distribution and loss of genetic variants has led to refinements in population management, such as maintaining effective population sizes and connectivity between reserves. More recently, the introduction of PCR has allowed noninvasive collection of genetic material from a variety of sources, such as hair, feathers, and feces. Together with the ability to examine highly polymorphic loci and gender-specific markers, noninvasive sampling has allowed genetic assays to contribute to ecological studies of sex ratios, food habits, population size, and mating systems. In this chapter, we provided general theory of population genetics and have identified those techniques and applications currently used in wildlife studies. This body of literature is expanding rapidly, and readers are referred to more detailed accounts of population genetic theory, techniques, and applications. With rapid development of DNA-based technologies, it is likely that currently unforeseen applications of genetic approaches will soon be available to assist wildlife scientists addressing a wide variety of problems.

ACKNOWLEDGMENTS

Chapter 23

We are grateful to anonymous reviewers and D. Palmer for useful comments and suggestions. North Carolina State University supported our efforts.

Chapter 24

Sections in this chapter are excerpted from S. K. Jacobson (2009), *Communication skills for conservation professionals*, Second edition, Island Press, Washington, D.C., USA (www.islandpress.org). I am grateful to C. Browne-Nunez, J. Solomon, S. Espinosa, C. Braun, and N. Silvy for helpful review. I thank J. Morris, J. Wu, and A. Posada for research and secretarial assistance.

Chapter 25

We are grateful to J. W. Enck and S. S. Stevens for providing assistance in development of this chapter. The views expressed in this essay are the authors' and do not necessarily represent those of the U.S. Fish and Wildlife Service, Department of the Interior.

Chapter 26

Our ideas presented in this chapter are based on research funded over the years by the GPU/Penelec, Hammermill Paper Company, International Paper Company, Max McGraw Wildlife Foundation, Minnesota Agricultural Experiment Station, National Park Service, National Rifle Association, Pennsylvania Agricultural Experiment Station, Pennsylvania Game Commission, Pennsylvania Wild Resource Conservation Fund, Ruffed Grouse Society, U.S. Environmental Protection Agency, U.S. Forest Service, and Western Pennsylvania Conservancy. We thank W. M. Healy and R. W. Mannan for earlier reviews of the manuscript, and particularly C. E. Braun and N. J. Silvy, for their cooperation and helpful suggestions in the preparation of this chapter.

Chapter 27

We thank G. M. Foote, P. L. Kiddoo, C. W. Milliron, B. M. Pierce, and J. T. Villepique for assistance with manuscript preparation, A. W. Stephenson for proofreading and attention to detail in checking literature citations, and 2 anonymous reviewers for helpful comments on drafts of the chapter. This chapter appeared in earlier form as Professional Paper 067 from the Eastern Sierra Center for Applied Population Ecology.

Chapter 28

M. W. Weller, P. L. Errington, F. C. Bellrose, L. R. Jahn, C. C. Cottam, and G. Jones stimulated a life-long interest in wetland management in L. H. Fredrickson. The ideas in this chapter reflect over 95 years of collective experience with wetlands and their management. Interactions with wetland managers have been of great importance over the past 50 years on hundreds of federal, state, and private wetlands extending across North America, as well as those in Hawaii, Europe, and Australia. Exposure to wetlands from low to high elevations, from the tropics to the arctic, and from sites with little to great amounts of rainfall, has helped us understand wetland dynamics and management challenges. Foremost among the biologists and managers that have been generous in sharing their ideas across a large spatial scale have been B. Allen, R. K. Baskett, S. S. Berlinger, J. L. Boyles, P. R. Covington, J. M. Davis, M. B. Epstein, T. Foti, D. A. Graber, M. E. Heitmeyer, D. L. Helmers, D. D. Humburg, T. Joanen, K. K. Karrow, H. P. Laskowski, W. R. Leonard, J. M. Minnerath, P. W. Norton, J. B. Pagan, R. Palermo, F. L. Pavaglio, C. Ryan, D. W. Sharp, M. D. Silbernagle, C. Smith, J. P. Taylor, J. E. Toll, J. Vradenburg, D. J. Widner, and G. R. Zahm. B. Ederington, B. W. Schuster, K. K. Kyle, and M. A. Hartman provided assistance with tables and figures. N. H. Euliss, Jr., M. E. Heitmeyer, R. A. Laubhan, B. Minser, and S. N. Oswalt provided suggestions to improve an earlier version of the chapter. The use of trade, product, industry, or firm names or products is for informative purposes only and does not constitute an endorsement by the U.S. Government or the U.S. Geological Survey.

Chapter 29

Preparation of this chapter was supported by the Louisiana State University Agricultural Center. We thank 3 anonymous reviewers and N. J. Silvy for suggestions that helped improve the essay.

Chapter 30

We thank N. J. Silvy, C. E. Braun, W. D. Snyder, and an anonymous reviewer for their constructive reviews.

Chapter 32

We thank N. J. Silvy for suggesting improvements to a draft of this chapter. We also thank K. J. Gutzwiller and D. N. Cole for their work on this important topic.

Chapter 33

We appreciate the thoughts and ideas of the many state and federal wildlife biologists, and university faculty, which have influenced and continue to influence our thinking on harvest management. Although we did not always agree, we always listened. We also appreciate the discussions and sometimes surprising insight provided by hunters, undergraduate students, and graduate students over the years.

Chapter 34

We thank M. J. Lavelle, J. W. Fischer, H. VanRoekel, and T. Camenisch-Ruby for assisting in many aspects of the development of this chapter. We also thank the many colleagues who provided the images and other information. The National Wildlife Research Center and the Airport Wildlife Hazards Program of the U.S. Animal and Plant Health Inspection Service, Wildlife Services, Department of Agriculture supported this effort.

Chapter 35

A small portion of this chapter is based in part on Chapter 20 in Bookhout (1994) and we thank D. L. Harlow and M. L. Shaffer for their contribution to that effort. KMS and LSM acknowledge support from the Strategic Environmental Research and Development Program (Project SI-1477) during their work on this chapter. LSM further acknowledges NSF 0841884, California Department of Fish and Game, and the Montana and Wyoming Bureau of Land Management State Offices. Any use of trade names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Chapter 37

We thank M. J. Peterson, N. J. Silvy, I. M. Mendez, and C. W. Roberts for providing reviews of and improvements to this chapter.

Human Dimensions of Wildlife Management

M. NILS PETERSON AND
SHARI L. RODRIGUEZ

INTRODUCTION

HUMAN DIMENSIONS of wildlife management (HDW) are the portions of wildlife management that focus on the interactions between people and wildlife or between people regarding wildlife. Manfredi (2008) suggested several key reasons that a HDW approach is needed in wildlife management: (1) professional imperative, (2) moral imperative, (3) learning from constituents, (4) investing in social capital, and (5) contributing to long-term conservation solutions. The **professional imperative** to consider HDW stems from **the North American model of wildlife management**, in which wildlife are a public resource and managed for the benefit of the public by state agencies (Geist et al. 2001, Prukop and Regan 2005). Wildlife managers must know what the public considers beneficial if they hope to manage wildlife for the benefit of the public. Studies addressing public attitudes, values, concerns, and preferences reflect the need to understand the intended beneficiaries of management actions.

The **moral imperative** to use HDW emerges from the impact of wildlife management on human well-being. Changing wildlife management can change the quality of life for diverse stakeholder groups. These effects can be minor (as in the case of affecting the ability of some demographic groups to participate in recreational hunting and fishing) or major (as in the case of clearing human residents from nature reserves and creating millions of conservation refugees in Africa, India, and Central and South America; Dowie 2005, Brockington et al. 2006). Wildlife managers must know the social effects of their decisions before they can follow the moral imperative to consider those effects when crafting management plans.

Scientists have come to accept that indigenous people have an accumulated ecological wisdom that can contribute to wildlife management. This indigenous technical knowledge can help scientists estimate population trends, habitat use, and how wildlife respond to management or disturbance (Huntington 2000). Using a survey of literature, Berkes et al. (2000) found indigenous cultures developed systems of multispecies management, resource rotation, succession management, landscape patchiness management, resource pulse management, and used local ecological knowledge to assess and respond to feedback from the environment (i.e., adaptive management).

Elements of HDW associated with **participatory governance** (e.g., comanagement, community-based conservation) hold promise for cash-strapped wildlife management agencies because they promise to reduce administrative overhead by paying for management with social capital (Kollock 1998, Wondolleck and Yaffee

2000, Peterson et al. 2004). **Social capital** is “the aggregate of the actual or potential resources, which are linked to possession of a durable network of . . . relationships of mutual acquaintance or recognition” (Bourdieu 1985:248). Social capital motivates observance of group norms, and makes traditional command and control systems for wildlife management less necessary to fund.

The most important reason for including HDW perspectives in wildlife management is that HDW is necessary to achieve sustainable wildlife conservation solutions. Complex global challenges including climate change, population growth, household proliferation, increasing energy consumption, and zoonotic disease create an unprecedented need for HDW (Millennium Ecosystem Assessment 2005). Climate warming within predicted ranges (1.1–2.2° C) may eliminate a third of all species from their current range (Parry et al. 2007). One million of those species may fail to find suitable habitat and, consequently, vanish (Thomas et al. 2004). The world’s 100,000 nature reserves may lose their remaining ability to protect wildlife species they were designed to conserve (Chape et al. 2003). Historical reliance on fossil fuels is rapidly being supplemented by previously biologically available energy in the form of wind, biomass, and solar energy development. Wildlife scientists are documenting direct effects on wildlife from emerging energy infrastructure (e.g., bird and bat strikes associated with wind turbines), but the indirect effects of energy monopolization are probably much more important. Massive removal of wind energy with wind farms can change weather and climate at both local and continental scales (Barrie and Kirk-Davidoff 2009) and alter ocean currents (Brostrom 2008). Potential changes include diurnal temperature and humidity shifts, reduced intensity of storms and spatiotemporal shifts in wind patterns and intensity (and the moisture associated with them). Some scholars predict future energy scarcity will shift funding and research priorities from studying and protecting pristine habitats essential for protecting endangered wildlife to creating and sustaining productive agricultural systems (Day et al. 2009). The interacting effects of globalization, housing development patterns, and climate change make zoonotic disease another major challenge for wildlife management (Wolfe et al. 2007).

As a discipline rooted in the interactions between people and wildlife, HDW plays a major role in wildlife management’s ability to systemically address these global wildlife conservation challenges. In fact, HDW emerged with a focus on coupled human–natural systems (CHANS) before the approach was touted as a solution to complex global conservation challenges (Liu et al. 2007a, b). “**Human dimensions**” was coined by Hendee and Schoenfeld (1973) in a special session of the 38th North American Wildlife and Natural Resources Conference that included CHANS research papers addressing topics including interactions between elk behavior and human activities (Brown 2009).

The broadest definitions of HDW suggest the field addresses how people “affect or are affected by wildlife and wildlife management decisions” (Decker et al. 2001:3). Such definitions suggest HDW can describe much of human history and culture since the emergence of our species. After all, humans evolved from hunter–gatherer societies and all wildlife, except perhaps species living in association with thermal vents deep in the ocean, are affected in some way by humans today. In this chapter, we omit elements of HDW related to documenting how people impact wildlife, the history of human–wildlife relationships (Gray 1993), wildlife-related laws (Goble and Freyfogle 2002a, b), wildlife communications (Jacobson 2005), and urban wildlife management (Adams et al. 2005), which are reviewed in this volume and in other outlets. Although we cite articles describing most relevant methodologies associated with HDW, we do not describe them explicitly. Introductions to quantitative and qualitative HDW research methodologies can be found in *Survey Research and Analysis: Applications in Parks, Recreation and Human Dimensions* (Vaske 2008) and *The Sage Handbook of Qualitative Research* (Denzin and Lincoln 2005), respectively. In this chapter, we focus on how HDW have coevolved with the modern discipline of wildlife management, and how the social component can be more fully integrated into wildlife management. We finish by describing HDW research themes and how they can contribute to creating sustainable wildlife conservation solutions.

THE EVOLUTION OF HUMAN DIMENSIONS OF WILDLIFE MANAGEMENT

Because human and nonhuman aspects of wildlife management are so intertwined, this outline of the evolution of HDW may reflect a human-focused review of wildlife management itself. We suggest the evolution of HDW is marked by responses to 3 landmark events: (1) the decimation of North American game species in the 1800s, (2) the social movements of the late 1960s and 1970s, and (3) the ballooning global threats to nongame wildlife conservation in the 21st century. Although overlap exists between periods marked by the events, and elements of management philosophies entertained in each period persist today, the events mark major transitions in HDW.

The Client Model

Modern wildlife management emerged as a response to agriculture, industrialization, and poorly regulated hunting (subsistence and market hunting) nearly wiping out most common game species in the 1800s (Harrington 1991). In the 1800s, states formed wildlife management agencies, promulgated harvest regulations, and hired game wardens to enforce the regulations. At the national level, influential figures including Gifford Pinchot, John Muir, George Grinnell, and Theodore Roosevelt captured public concern regarding

the decimation of wildlife and other natural resources and directed it toward the conservation movement. The period following the initiation of the conservation movement was characterized as “the era of scientific wildlife management” (Decker et al. 2001:10). Leopold (1933:411) argued policy-making based on argumentation and personal opinion “must be broken down,” and replaced with policy-making based on experimentally derived facts. The science of wildlife management was applied to produce “sustained annual crops of wild game for recreational use” (Leopold 1933:3). The Federal Aid in Wildlife Restoration Act of 1937 helped fund a cadre of professionally trained wildlife scientists to coordinate the wildlife cropping.

State wildlife-management agencies evolved to serve the needs of the sportsmen who agreed to support agencies and management through self-taxation (Decker et al. 1996, Peterson 2004). Several HDW scholars described this early period of wildlife management as **the client model**, where sportspersons paid for and received services from wildlife managers (Decker et al. 1996). Wildlife managers assessed what populations to increase, studied the populations, and manipulated the environment to increase populations using scientific information. Within the client model, human dimensions experts were relegated to (1) assessing what populations clients wanted to grow, (2) assessing how game populations responded to manipulations using “surrogate biology” involving creel and bag surveys (Decker et al. 2001:24), (3) tracking hunter numbers and expenditures (the *National Survey of Fishing, Hunting, and Wildlife-Associated Recreation* started in 1955), and (4) assessing challenges faced by hunters such as gaining access to private land (Short 1939, Morrow 1950). These findings were used to make agencies more responsive to hunter needs. It is worth noting that other natural-resource-related fields (e.g., forestry) followed a similar path of scientific resource cropping directed by social assessments of client interests conducted by their respective human dimensions experts (Buttel 2002). During this period, wildlife managers saw the intrusion of an uninformed public (nonscientists) into the client-manager relationship as a bottleneck, hampering efforts to grow and harvest game populations (Huboda 1948). Accordingly, early HDW efforts worked to provide public relations tools for alleviating problems associated with stakeholders’ involvement (Gilbert 1964, Manfredo 2008).

The Stakeholder Model

The client-based model of wildlife management did not survive the growing distrust of government, demands for governmental accountability, and demands for public participation that emerged in the 1960s and early 1970s (Brick 1998, Schulman 2001). The National Environmental Policy Act (NEPA) of 1969 and Endangered Species Act (ESA) of 1973 gave U.S. citizens opportunities to review and comment on policy before decisions were made and gave them standing

to legally challenge management after decisions were made. During this period, many similar laws were passed internationally and at state and local levels in the United States, further expanding the power of stakeholders in wildlife management. Groups including animal rights advocates, non-consumptive wildlife users (e.g., birdwatchers, photographers), advocates for nongame wildlife species, and neighborhood organizations used this leverage to force their way into wildlife management decision-making. The DAD (decide, announce, defend) model of natural resource management represents an effort to maintain the privileged status of science-based decision-making (Daniels and Walker 2001). The perception of the public as a bottleneck for science-based wildlife management has persisted and some wildlife managers still yearn for a day when one can “remove politics from decision making” (Peterson et al. 2007:2500).

Politics (social relations involving power), however, cannot be separated from wildlife management (Peterson et al. 2007). In the early 1970s, wildlife managers began to realize wildlife management involved politics, and HDW emerged as a formal discipline to help address the challenges associated with social power being wielded within wildlife management (Hendee and Potter 1971, Hendee and Schoenfeld 1973). Hendee and Potter (1971) outlined 4 priorities for HDW: (1) examination of hunter satisfaction, (2) exploring nonconsumptive wildlife uses, (3) developing wildlife economics, and (4) developing politically relevant knowledge. The first priority reflected the client-based model, but the other priorities reflected a prescient view of the stakeholder model. In the 1970s, government agencies began funding HDW research in efforts to make mandated stakeholder involvement more productive. The HDW field was initially constituted by social scientists within natural-resource management agencies, outdoor recreation researchers, rural sociologists, and agricultural economists (Buttel 2002, Manfredo 2008). Much of the early HDW research was published in the *Transactions of the North American Wildlife and Natural Resources Conference* (1915–current) and the *Wildlife Society Bulletin* (1973–2004). In 1981, several HDW scholars started the Human Dimensions of Wildlife Study Group and its newsletter. The journal *Human Dimensions of Wildlife* was started in 1996. With the loss of the *Wildlife Society Bulletin* (WSB) in 2005 (WSB was reestablished in Apr 2011), *Human Dimensions of Wildlife* became the sole flagship journal for HDW research. Journals including *Conservation Biology*, *Society & Natural Resources*, *Environment and Behavior*, and the *Journal of Wildlife Management* provided additional outlets for some HDW research.

Decker et al. (1996:70) defined stakeholders as people or groups with a “vested interest” in issues, programs, or actions associated with wildlife management. Being vested means a stakeholder is entitled to a right or privilege. The stakeholder model of wildlife management still focused on managing wildlife with scientific information but progressively evolved to give stakeholders the privilege of having a

voice in decision-making. Decker et al. (1996) suggested 5 key elements of **the stakeholder model**: (1) identifying stakeholders, (2) flexible methods for incorporating stakeholder input into decision-making, (3) resisting the efforts of special interests to co-opt public processes, (4) using methods for weighing stakeholder opinions, and (5) employing effective communication strategies among managers and stakeholders.

These key elements have proven difficult to operationalize for several reasons. First, flexible methods for stakeholder involvement exist (see Public Involvement section later), but one of the least effective and least flexible approaches, public hearings (Depoe et al. 2004), is used most often in wildlife management (Lord and Cheng 2006). Institutional inertia, doing what you did in the past, and interpreting mandates for public comment as mandates for public hearings may explain this phenomenon. Second, stakeholders can be difficult to define. In many cases all people and groups have a right to comment on wildlife management decisions, but the weight given to each perspective is not necessarily equal. As stakeholders diversify to include birdwatchers, biodiversity advocates, animal rights groups, civic associations, and a host of other groups that do not make as significant or reliable financial contributions to wildlife management agencies as hunters and anglers, managers are faced with a dilemma. Can they ignore the client model and give equal weight to all perspectives, or should the perspectives of those who pay more for the management receive more consideration? Finally, wildlife managers ranked scientific surveys as the most important technique for public involvement (Lord and Cheng 2006). Surveys may produce reliable information, but probably do not represent an effective communication strategy.

The Citizen Model

The stakeholder model is ill-prepared for the mounting wildlife conservation challenges of the 21st century. Today's wildlife managers face anthropogenic decimation of wildlife species just as Aldo Leopold's generation did, but the extent of damage is greater, the diversity of species affected is broader, the changes are less reversible, no major stakeholder group has stepped forward to cover the conservation costs, and no single stakeholder group could provide a solution even if its members wanted to. The only way wildlife management can succeed in these contexts is by adopting **the citizen model** and adding the duties associated with citizenship to the entitlements associated with being a stakeholder. The monumental task of wildlife conservation in the 21st century requires support of citizens who are expected to pay for the entitlements their government protects with social and financial capital. Exclusive reliance on the declining 4% of the U.S. population that hunts (U.S. Fish and Wildlife Service and U.S. Census Bureau 2007), in the face of mounting wildlife conservation challenges, is a recipe for failure.

Several U.S. states have used carefully orchestrated political campaigns to expand funding responsibility from hunters and anglers to the general public. Sources for wildlife conservation funding included lottery proceeds, multiple taxes (e.g., outdoor gear, sporting goods, general sales tax, real-estate transfer tax), license plates, income-tax check-offs, state general funds, industry taxes, and trust funds (McKinney et al. 2005). Tax check-offs and license plate sales only provided long-term benefits when they did not compete with other interests (e.g., schools, health care, animal shelters). Missouri's 1976 passage of a general sales tax dedicated to wildlife conservation was a landmark case in spreading responsibility for wildlife management beyond sportspersons. Although the political and economic climate may seem more problematic for such progressive policy-making today, Arkansas passed a general sales-tax increase for wildlife conservation in 1996 with strong backing from a Republican governor, and Minnesota passed a sales tax increase for clean water, wildlife, cultural heritage, and natural areas conservation in 2008. Successful strategies have varied greatly from state to state, but a seminal assessment of public support, stakeholder support, and political support for multiple funding mechanisms was always used (McKinney et al. 2005). Successful funding campaigns identified how much the public, key stakeholders (e.g., sporting goods manufacturers), and politicians (e.g., the governor) valued wildlife conservation and how their support for funding wildlife conservation varied by funding mechanism (e.g., lottery proceeds versus a sporting goods tax). Successful campaigns also built coalitions among nongovernmental organizations (NGOs), legislative supporters, key stakeholder groups, and the governor's office prior to unveiling plans to the public.

In the United States, state fish and wildlife management agencies face mandates to protect and manage nongame wildlife species. The **State Wildlife Grants** (SWG) program represents the primary funding source used to achieve this mandate. McKinney et al.'s (2005) extremely conservative estimates suggest adequate nongame wildlife management will require ≥ 10 times more funding than currently exists, even with the US\$470 million SWG appropriated for division among all states on an annual basis since 2005. Although nongame conservation challenges are mounting, the limited SWG funds are becoming more difficult to obtain. Since 2002, the U.S. Congress annually appropriated funds for the SWG program with a 3:1 match of state funds. The appropriation for the 2008 fiscal year required a 1:1 match, effectively tripling the state funding needed to receive the full federal match. The North Carolina Wildlife Resources Commission was forced to appeal to lifetime hunting-license holders for donations to support the nongame conservation program as a short-term stop-gap. The situation is direr in developing countries, where in many cases no formal struc-

tures exist for wildlife conservation. Developing nations faced a shortfall >US\$1.3 billion for managing existing protected areas in 2004 (Bruner et al. 2004).

Market- or donor-based (e.g., foundations) models may be needed to augment citizen-based models because governmental support for wildlife research, conservation, and management appears to be declining (Hutchins et al. 2009). In the 1980s, Ehrlich and Ehrlich (1981) coined the term “ecosystem services,” and the idea quickly morphed into an effort to assign a dollar value to nature and commoditize it (Costanza et al. 1997, Daily and Ellison 2002). Hypothetically a capitalist approach that places wildlife into ecosystem service markets reflects the cheapest, most efficient means to ensure wildlife are conserved in a manner congruent with social preferences. Further, market solutions provide an essential contribution to the future of wildlife conservation in nations without adequate institutional capacity within government to protect wildlife (Alexander and McGregor 2000). Even in politically unstable and economically impoverished nations, however, broad-based citizenship in wildlife conservation is a necessary prerequisite for credible government protection of market and nonmarket means for wildlife conservation. Further, as the repetitive market booms and crashes (e.g., 1973, 1991, 2001, 2008) demonstrate, conditions required for the invisible (and free) hand of the market to work correctly are rarely met. Corruption, graft, and power imbalances create environmentally detrimental behavior in markets (Cox 2004), and wildlife conservation NGOs and foundations typically face drastic declines in revenue when drops in stock markets occur (Pergams et al. 2004). Species that go extinct during a recession won’t rebound with the market. The unwavering support of sportspersons, involvement of market-based solutions, and extension of citizenship (and its duties) to diverse stakeholder groups will all be needed to address current wildlife conservation challenges. HDW can contribute in the citizen model by developing and coordinating the coalition building and advocacy efforts needed to mobilize citizens to achieve conservation goals (Cox 2006).

Successful implementation of a citizen-based model requires HDW capacity within wildlife management institutions. Although that capacity has been lacking in the past (Decker et al. 2001, Manfredo et al. 2009), universities, NGOs, and wildlife management agencies have rapidly developed formal HDW programs since the 1970s. The political and advocacy-based goals of wildlife NGOs drove them to rapidly integrate staff with policy, economic, and social science expertise. Now most major Wildlife Science programs at universities offer HDW courses and have formal or informal HDW graduate programs. The Wildlife Society requires HDW coursework for people to gain certification as a wildlife biologist. Many state wildlife management agencies have HDW specialists on staff.

HUMAN DIMENSIONS RESEARCH

As a practical discipline HDW defines itself by the challenges it hopes to address. The challenges faced by HDW can be distilled to (1) people living their lives with limited awareness of human effects on wildlife, and (2) people who are aware of human effects on wildlife choosing not to engage in wildlife conservation efforts or failing when they do engage. The former problem occurs because people produce and consume goods and services without recognizing the effects on wildlife, and the latter problem occurs when advocates fail to align their efforts with appropriate political and legal channels, public audiences, and consumers (Cox 2006). These challenges create a list of research questions HDW can and should address (Table 23.1). The remainder of this section addresses research themes in HDW, and the key questions necessary to address the 2 fundamental wildlife conservation challenges.

Social Structural Approaches

The **social structural approach** uses concepts associated with social structure (e.g., class, patriarchy [men having authority or responsibility inside social units]) to analyze social phenomena affecting wildlife. These approaches are well suited for exploring key HDW questions involving human effects on wildlife and human awareness of those effects.

Political Economy

The most influential stream of social structural research, sometimes called **political economy**, addresses how production, buying, selling, and governance interact to shape society. Thomas Malthus, Adam Smith, and Karl Marx were notable political economists whose theories laid the foundation for both modern ecology and sociology (Worster 1994, Dunlap and Michelson 2002). According to Smith, all com-

Table 23.1. Research questions that emerge from the need for wildlife biologists and/or managers to address the lack of public awareness about wildlife conservation challenges and the biologists’ and/or managers’ lack of success in addressing them

Lack of awareness:

1. What are human effects on wildlife?
2. What conditions shape awareness of human effects on wildlife?
3. Who is most or least aware of human effects on wildlife and why?
4. What sociostructural changes will increase awareness of human effects on wildlife?

Lack of success:

5. What conditions shape public engagement in wildlife conservation efforts?
 6. Who attempts to engage in wildlife conservation efforts?
 7. What sociostructural changes can make wildlife conservation efforts more successful?
-

modities were produced using 3 factors of production: land (natural resources including wildlife), labor, and capital stock (human-made goods used to produce commodities; Smith 1776). Wildlife management obviously relies on land, but **labor** (e.g., field biologists, private landowners, and hunters) and **capital stock** (e.g., Leopold's proverbial axe, cow, plow, and gun; Leopold 1933) are essential for producing commodities associated with wildlife management, including opportunities to see, photograph, and shoot wildlife. Recent scholarship has added human capital, intellectual capital, and social capital into the cornucopia of factors of production, but these factors could be lumped into labor in many cases.

The combination of capitalism and industrialization can promote **commodity fetishism**, a situation where social and material relationships are viewed as relationships between commodities and money (Marx 1976, Hudson and Hudson 2003). In such contexts, value inheres in the commodities themselves, rather than being associated with the labor, raw materials, and instruments used to produce those commodities. Commodity fetishism associated with human food production, industrial agriculture, Chinese medicine, and even housing development creates a lack of awareness of human effects on wildlife. Home buying is seen as getting a house for money, not as a relationship between builders, raw materials, and wildlife habitat. Commodity fetishism leads to situations where people with environmentally oriented attitudes are more likely than less environmentally oriented people to build homes on critical wildlife habitat (Peterson et al. 2008). In the case of food production, the commodities found in grocery stores show no signs of the wildlife deaths caused by conventional agriculture. Precious few people realize the habitat conversion and tillage practices required to produce their morning bowl of cereal leads to more wildlife deaths per calorie than does hunting (King 1991). Future HDW research could explore ways to awaken consumers to the effects of commodity production on wildlife by studying and reproducing the material, economic, and production conditions hiding behind commodities such as homes and food (Gouveia and Juska 2002, Ateljevic and Doorne 2003, Hudson and Hudson 2003).

Political economy theory also provides a key basis for HDW research addressing the effects of economic growth on wildlife conservation by focusing on the tendency of social elites to invest excess capital in new capital stock (tools for additional production; Schnaiberg 1980) or assets (e.g., houses) instead of natural resource conservation or labor. During the global recession starting in 2008, excessive investment in houses did more than create a real-estate bubble that collapsed the global economy; it spurred rapid suburban sprawl that consumed vast tracts of wildlife habitat. The effects of economic growth on wildlife are rarely considered in market models; therefore, they are labeled externalities. An entire subdiscipline in HDW has emerged to

measure the value of wildlife and its habitat through non-market means (see Economic Valuation below).

Ecological economists within HDW have tackled the challenge posed by economic growth by advocating a steady-state economy (Daly 1991, Czech 2000, Czech et al. 2003). A **steady-state economy** occurs when human population and consumption of energy and raw materials stabilize, hopefully at a sustainable level. The Wildlife Society's position statement on the subject (expired in 2009) defines economic growth as the product of population and per capita consumption, and suggests economic growth may cause degradation and loss of wildlife habitat. The statement suggests principles of ecology and physics place limits on economic growth. The ecological claim ties to one of the earliest political economists, Malthus. Various permutations of his principle of population suggest most species' populations grow faster than their food supplies (Malthus [1798] 1970). The physics claim ties to the fact that if energy cannot be created, then humans are limited to appropriating energy stored on the earth and energy provided by the sun. Logically, the unlimited potential for population growth and energy consumption is not matched by resources on the earth. Given, the history of technical solutions for both food and energy production and declining rates of population growth, however, some optimists foresee technical solutions allowing long-term economic growth.

Biological Bases of Human Interactions with Wildlife

In 1842, Charles Darwin and Friedrich Engels crossed paths in London. They both saw a "war of all against all" where the weak were crushed by the powerful (Worster 1994:148). Engels attributed the situation to industrial capitalism and Darwin saw inescapable laws of nature (e.g., competition and survival of the fittest) at work. Accepting either perspective in isolation has proven problematic. Social Darwinists who attributed human behavior primarily to natural laws were implicated in classism, racism, eugenics, and the Holocaust (Young 1985, Murphy 1999). Conversely, believing humans are exempt from ecological principles contributed to unprecedented threats to wildlife populations and perhaps the collapse of historical societies (Diamond 2005). The atrocities associated with social Darwinism emerge not from attributing human behavior to genetics, but from making claims about what ought to be based on claims about what is, a logical fallacy. If society can resist using the is-ought fallacy, then research addressing the biological bases of human relationships with nature can help address wildlife conservation challenges.

The social stigma associated with the legacy of social Darwinism has faded enough in recent decades that studying biological bases of human-wildlife relationships has re-emerged as an exciting topic (Manfredo 2008). The most influential work in this arena, however, relies on circumstantial

evidence and lacks empirical support. Manfredo (2008) divided wildlife-related elements of this research into 3 themes: humans as hunters, humans as hunted, and biophilia. The **humans as hunters** body of research suggests humans became preprogrammed for inter- and intraspecific aggression due to selection for hunting success. This body of research exhibits the same dangerous tendencies seen in historical social Darwinism in that it gives unscrupulous interpreters the opportunity to blame evolution for human violence. Further, historical accounts contradict the theory by suggesting early agricultural societies were often more exploitative and violent than hunting societies (Megarry 1995). The **humans as hunted** body of research suggests natural selection makes people fear wildlife because humans were hunted by large carnivores for millions of years before becoming serious predators themselves. This hypothesis gives rise to questions about genetic fear of snakes and spiders. People, however, seem to like wildlife, and even demonstrate less caution than a healthy genetically induced fear of dangerous animals would predict (e.g., creeping up to dangerous animals for a close-up photograph). The **biophilia hypothesis** attempted to explain this by suggesting an evolved desire to hunt gave people a genetic predisposition to love living systems or biodiversity (Wilson 1984; Fig. 23.1). Some empirical evidence does suggest heritability of interest in leisure activities including hunting, but the heritability may be indirect through factors such as temperament or personality (Lykken et al. 1993).

Although fascinating, these branches of research probably have limited utility for wildlife management. Genetic makeup may influence peoples' hunting participation or interest in wildlife feeding, but barring genetic manipulation, genetic makeup does not provide solutions. Knowing that people are preprogrammed to feed wildlife may suggest education programs will be less effective than placing barriers between people and wildlife, but most managers will choose between barriers and informational flyers based on what people do instead of the extent to which people are biased toward a particular behavior by their genetic makeup. Simi-

Fig. 23.1. The biophilia concept suggests humans have a genetically induced attraction to wildlife.

larly, if biophilia exists, that may imply that giving people intimate experiences with wildlife is therapeutic. That assertion, however, will always need context-dependent verification independent of the assumption that humans have a preprogrammed need to interact with wildlife.

Coupled Human–Natural-Systems Modeling

Coupled human–natural-systems modeling entails simulating human society, its environment, and interactions between the 2 systems, by using physical or mathematical models. This approach provides another means for exploring relationships between biological and social systems. In the mid-1990s, wildlife researchers pioneered an approach using rational actor theory to integrate quantitative ecological systems models with social models (Grant and Thompson 1997). Later wildlife researchers developed models including interactions between human age structure and population growth, farming preferences, cropland area, fuel wood consumption, and changes in giant panda (*Ailuropoda melanoleuca*) habitat (Liu et al. 1999, An et al. 2001). This research suggested relocating local residents from core panda habitats would be more effective if younger residents were targeted instead of moving entire households. In 2001, a special issue of *Ecological Modelling*, edited by a wildlife scientist, was dedicated to models integrating biology and sociology (Liu 2001). This special issue highlighted understanding patterns and processes of habitat fragmentation, identifying mechanisms of population dynamics, predicting human behaviors and their effects on wildlife populations, developing sustainable strategies for balancing development and biodiversity conservation, and management of conservation areas as key roles for CHANS modeling. In this issue, Cramer and Portier (2001) assessed feasibility of Florida panther (*Puma concolor coryi*) reintroductions using a model that integrated simulations of human, deer (*Odocoileus virginianus*), and panther population dynamics. Ahearn et al. (2001) went a step further in their model of tiger (*Panthera tigris*) conservation in Nepal by including simulation of how human behaviors (e.g., poisoning tigers and guarding livestock) emerged from attitudes toward tigers.

Within the next few years, the modeling of complex interactions between social and biological factors to simulate future conditions emerged as a major force in wildlife science, ecology, geography, and anthropology (Liu et al. 2007a, b; Lehrer 2008). Predictions of CHANS models are being used to guide policy-making in regard to some of the most high-profile wildlife conservation issues, including restoration of the Florida Everglades and assessing effects of climate change on wildlife. Soft-systems versions (models used for problem-solving instead of quantitative predictions) of CHANS models are emerging as an important form of public participation (see Public Participation below). Grant and Swannack (2008) provide a useful primer for those interested in the fundamentals of CHANS modeling.

Economic Valuation

Unless one is a recreational hunter, an economist, or a policy-maker, one may not think about economic valuation of wildlife. **Valuation**, the act of assigning value to an object, often involves determining the potential market value of an object. Although values can refer to many things, this section focuses on assigned values that relate to the meaning, goodness, or worth people place on wildlife (Brown 1984). In the United States, assigning value to wildlife has been practiced formally since 1946, when the Fish and Wildlife Coordination Act (FWCA) required federal agencies to include fish and wildlife values in benefit–cost analyses for public water projects. Valuation of wildlife came about as a response to the need to assign value to wildlife in a way that would allow wildlife to be compared to other resources. The National Environmental Policy Act of 1969 requires consideration of wildlife, alongside all other natural resource values, prior to any decision-making involving projects funded all or in part from federal funds. Other wildlife policies invoking valuation of wildlife include the 1973 Endangered Species Act and the 1980 Fish and Wildlife Conservation Act.

Two broad categories of wildlife values exist: option values and exercised values. **Option values** involve willingness to pay to maintain the option of wildlife being available for future use (Steinhoff et al. 1987). **Exercised values** can be broken down into 2 major subcategories: direct benefits and indirect benefits. Direct benefits come from an individual's personal experience with wildlife. Direct benefits can be further broken down into consumptive ("taking" wildlife for food or sport) or nonconsumptive (activities such as viewing or photographing wildlife) types. Indirect benefits arise without any direct contact with wildlife (e.g., viewing wildlife documentaries or photographs). Indirect values can be further subdivided into bequest (value of passing wildlife on to future generations) and existence (value of knowing wildlife exist) values (Steinhoff et al. 1987).

Assigning a monetary value to wildlife, however, is difficult because many valuable benefits associated with wildlife are not traded in private markets. Scholars have developed several methods for valuing wildlife: (1) gross expenditures, (2) market value of catch or harvest, (3) replacement cost, (4) willingness to pay, and (5) hedonic. The first 3 are problematic for economic and pragmatic reasons. **Gross expenditures** are defined as: "expenditures as an index of wildlife values that were the object of spending" (Steinhoff et al. 1987:42). The gross expenditures method was largely abandoned because it estimates minimal benefits needed to justify expenditures, but a large and unmeasured surplus benefit may exist (Sorg and Loomis 1985). Although you may spend US\$2 to see wildlife, the opportunity might be worth US\$200 (yielding US\$198 in unmeasured consumer surplus). Market value methods also tend to underestimate the value of wildlife. For instance, the market value of venison and

hides may be much lower than the actual value associated with participation in hunting or trapping. Replacement cost may overestimate the value of wildlife because estimates for replacement costs are based on prices paid for animals by labs or zoos, and transportation and collection costs do not apply to wild populations. Conversely, replacement costs may underestimate wildlife value because commercially raised animals typically have far lower survival rates than animals native to a wild population (i.e., many replacements may be required to make the same population contribution of one native individual).

Willingness-to-pay methods are currently the most commonly used nonmarket valuation techniques for wildlife. Contingent valuation (CV) is probably the most frequently used and most adaptable willingness-to-pay method (Steinhoff et al. 1987, Decker et al. 2001). The **contingent valuation method** uses bidding scenarios in which people are asked to respond to hypothetical price changes of nonpriced goods and amenities (e.g., wildlife existence, opportunity to hunt, wildlife viewing opportunities). CV questions typically ask how much an individual would pay (or bid) to have an experience, object, or privilege (i.e., willingness to pay) or how much payment that individual would require to give up an experience, object, or privilege (i.e., willingness to sell). This ability to estimate values for anything that can be described in a survey is a major strength of CV. Strategic bias represents a weakness of CV. For instance, a survey respondent who thinks her reply may affect her hunting license fees may understate her willingness to pay. Although most research demonstrates CV research is reliable, people can overestimate willingness to pay for existence and bequest values by a factor of 2 (Loomis 2000).

With **travel cost (TC) methods** random visitors to a site are asked about their residence, distance traveled, and expenses for the trip (e.g., food, travel, and hotel). These variables are then used to generate site-specific values for wildlife, and can be used to create demand curves showing how many people will visit a site given various travel costs and how much the particular site is worth to consumers (Loomis 2000). Assuming travelers incur all expenses for the purpose of wildlife-related activities, however, can introduce bias. Travelers often have diverse sources of satisfaction on a trip including the travel itself. Thus, TC would produce more reliable results for estimating the value of hunting in a field of corn stubble where only the targeted species was visibly present than it would for estimating the value of hunting adjacent to a national park with awe-inspiring vistas and diverse species of charismatic megafauna sharing the landscape with the target species.

Hedonic pricing can be seen as a version of TC that estimates willingness to pay based on multiple characteristics of a site, and is often used for goods with characteristics that can only be sold in aggregate (Rosen 1974). The basic premise of the hedonic method is that the price of a mar-

keted good is related to its characteristics, or the services it provides. A number of recent hedonic valuation studies have addressed valuation of site characteristics associated with hunting leases (Livengood 1983, Hussain et al. 2007, Rhyne et al. 2009). These studies use the hedonic approach because it allows for comparisons of lease sites with varying characteristics, and values can be estimated for each characteristic (Brown and Mendelsohn 1984). As one might guess, extensive data requirements are a drawback of hedonic methods. In the case of hunting leases, researchers must collect information on all relevant attributes of a site (e.g., distance to city, property size, land cover, population density of a game species, perceived quality [e.g., size] of game animals). Inference about a given attribute (e.g., presence of big game) requires data from cases with varying levels of the attribute. Further, typical analysis methods require parameterization of 2 regression models, one predicting expenses and one predicting demand for the good.

Social Psychology

Social psychology, the study of how human values, attitudes, and behavior emerge from a given social context, has emerged as among the most important branches of HDW research and is definitely the most prevalent (Manfredo 2008).

Attitudes

Attitude studies are popular because they are easy to conduct, easy to interpret, allow behavioral predication, and provide insight into methods for changing behavior. Appealing to people through media coverage and incentives can be particularly effective at inducing pro-environmental attitudes and behaviors if managers understand attitudes (Buttel 1987). For example, careful alignment between public attitudes and campaigns to stop the killing of dolphins (*Tursiops* spp.) as bycatch during tuna harvesting led to a consumer boycott of canned tuna, new harvesting practices, and today's "dolphin safe" label.

Studies typically utilize survey methods involving closed-ended questions and fixed-format response scales (e.g., Likert scales [strongly agree to strongly disagree; Likert 1932]). Analysis of these studies requires basic descriptive statistics, which can be easily and accurately interpreted by community members and wildlife professionals. Results of attitude studies can be used to help predict and influence wildlife-related behavior (Manfredo 2008).

Despite the fact that attitudes are fundamentally important, widely discussed, and frequently measured, they are poorly understood (Heberlein 1981). **Attitudes** are positive or negative evaluations of an object. Heberlein (1981) noted that attitudes and opinions are often used interchangeably, but are not the same thing. According to Heberlein, attitudes are multifaceted dispositions toward objects that can shape many opinions: they have an **affect dimension**, which refers to emotional elements and feelings toward an object,

and **cognitive dimension**, which refers to dispassionate evaluation of facts. If a person feels ambivalent or conflicted about the attitude-object, they may hold both positive and negative attitudes about it. Kellert (1976:536, 1980) found that most subjects typically held 1 attitude; he noted that subjects were "feeling and behaving a certain way in one situation while manifesting a different attitude under other circumstances."

Models focusing on this dualistic view of attitudes are based on the idea that explicit and implicit attitudes can exist simultaneously and be conflicting. Smith and DeCoster (2000) suggest explicit and implicit memory systems evolved to help people meet 2 competing survival demands. Explicit attitudes are based on object evaluations that an individual is consciously aware of and can express and arise from active cognitive engagements (Manfredo 2008), which can be formed after a single experience and allow people to adapt quickly to their environment. Implicit attitudes, on the other hand, are outside of an individual's conscious awareness or control and are created through associative learning that creates long-term and enduring knowledge.

Explicit attitudes are measured using attitude scaling methods (e.g., Likert's scales, Thurstone scales, Guttman scales, and Osgood Semantic Differential scales; Brace 2008) that allow for self-reporting of attitudes. In a study of attitudes toward wolves in Utah, Bruskotter et al. (2007) used an 11-point Likert scale to solicit agreement or disagreement to statements like "I would like to see wolves in Utah" and "Utah is better off without wolves." Implicit attitude measurement, on the other hand, focuses on unacknowledged attitudes that are outside of the conscious awareness of the person and are measured using sophisticated association tests. The most commonly used implicit attitude measurement test is the Implicit Association Test (IAT), developed by Greenwald, McGhee, and Schwartz (Greenwald et al. 1998). The IAT measures the reaction times for positive and negative associations to words or topics using computer software. Quicker reaction times generally indicate a stronger implicit association to the tested words or concepts. As applied in HDW, the IAT might measure reaction times associating the words "good" and "bad" with the words "predator" and "prey." For a practical example of the IAT, visit Project Implicit at <https://implicit.harvard.edu/implicit>, where you can test your own implicit attitudes on a number of contemporary social topics. Correlations between explicit and implicit attitude measurements are typically low (Hofmann et al. 2005). Manfredo (2008) suggested implicit attitudes should have significant influence over human responses toward wildlife if ability to respond quickly to wildlife threats conferred evolutionary advantage to humans in the past. Attitude strength also is an important aspect of attitudinal studies. The strength of an attitude can affect the intensity of behavior, the consistency of one's action over time and the likelihood that an attitude will be

changed. Strong attitudes tend to remain relatively unchanged over time and are more likely to affect behavior than weak attitudes.

Associative Network Theory addresses inter-attitudinal structure. Judd and Krosnick (1989) suggested memories of attitude-objects and, therefore, their respective attitudes, are stored as nodes. Nodes can be positive or negative, and cognitive or affective. Attitude-objects are linked into balanced and consistent networks. Thus, one may have a node for happiness, which is associated with attitude-objects that make one happy. Nodes also can inhibit one another (a form of negative association). Thus, when one is happy, it is difficult to think of sad things, and vice versa.

Values

Researchers have noted the ambiguity of the word “value” and distinguish between 2 separate uses and meanings of the word (Shaw and Zube 1980, Rohan 2000). **Assigned values** relate to the meaning, goodness, or worth people place on an object (Brown 1984). A **held value** is “a stable, meaning-producing super-ordinate cognitive structure” (Brown 1984, Rohan 2000:257). The latter definition suggests values are deep-seated, formed early in life, and are difficult or impossible to change among adults (Heberlein 1981, Inglehart 1990, Naughton-Treves et al. 2003). Assigned values are addressed in the Economic Valuation section of this chapter. Held values play a key role in representing an individual’s personal goals, are the criteria used to differentiate good from bad and right from wrong, and guide an individual’s evaluations and interpretations of events and information, as well as their approach to conflict resolution and decision-making (Rokeach 1973, Manfredo 2008). Values are ever-present and provide a foundation for attitudes, intentions, and norms, which in turn guide behavior (Manfredo et al. 2003). According to Rokeach (1973), values transcend the objects or situations that are the focus of attitudes, and while attitudes are an arrangement of several beliefs around an object, values are single, distinct beliefs. Lastly, the central role that values play is such that they function as determinants of attitudes (Rokeach 1973, Schwartz 1992). Schwartz identified 9 broad motivational constructs as societal values (e.g., hedonism, self-direction, benevolence, universalism [equality], and power). Values cannot be observed or measured explicitly, so researchers use behavior or attitudes to guess what values people hold. If a survey respondent indicated they believed equal resources should be used to conserve all wildlife species, and that the benefits should be shared equally by all people, one might guess the respondent holds a universalism value. This approach, however, can be risky when people express their values using different belief systems. In the case of a **universalist**, the person may value equality, but be opposed to animal rights because they believe only humans have moral standing.

Value Orientations

Value orientations refer to the basic beliefs a cultural group brings to bear on decision-making. They can be seen as themes encapsulating the personality of a cultural group (Manfredo 2008). Worster (1994) suggested that value orientations toward nature in western nations have swung between mutualistic and dominionistic since the late 1700s. On an individual level, value orientations give meaning to core values and link those values to attitudes and behaviors (Zinn et al. 2002). Research on the subject typically evaluates contrasting value orientations (e.g., domination versus mutualism). Kluckhohn (1951) contrasted mastery over nature value orientations of Mormons (members of The Church of Jesus Christ of Latter Day Saints) with harmony with nature value orientations of the Navaho. Schwartz (2006) contrasted egalitarianism and harmony orientations in Switzerland with hierarchy and mastery orientations in the United States. Manfredo and Teel (2008) contrasted domination orientations in states such as Alaska, South Dakota, and Utah with mutualism orientations in states including California, Hawaii, and Oregon.

Value orientations refer to patterns of belief; therefore, they cannot be measured explicitly. Researchers use a series of questions to identify beliefs people bring to bear on an issue (e.g., wildlife use), and aggregate responses into a value orientation. Several scales have been developed to measure wildlife-related value orientations (Fulton et al. 1996). Manfredo’s (2008) domination value orientation is based on aggregated responses to questions regarding the acceptability of killing wildlife for various reasons, placing human needs above wildlife protection, and managing wildlife for human benefit. Trends in wildlife value-orientation research and methods used to generate orientations can, however, reflect cultural stereotyping. Finding conservative religious groups believe in dominating nature, indigenous cultures believe in living in harmony with nature, Americans (U.S.) believe in mastery over nature, and people in Republican-dominated states believe in dominating nature, reflects long-standing cultural stereotypes for the groups in question.

Value orientation studies stratified by political system, time, and industrialization level can provide insight into how political systems and industrialization impact social belief systems (see *Human Dimensions of Wildlife* 12[5]). Among other things, these studies suggest that as societies enter the postindustrial phase, people develop more mutualistic value orientations and become less tolerant of lethal wildlife management and hunting. Value orientations allow strong predictions of attitudes because they are generated by aggregating attitudinal information. Core values are typically very broad and, thus, not conducive to predicting specific attitudes and behaviors, but wildlife value orientations have been highly correlated with attitudes toward hunting and fishing (Fulton et al. 1996), responses to potentially dangerous wild-

life (Zinn and Pierce 2002), participation in wildlife-related recreation, and even political ideology (Bright et al. 2000). Value orientations reflect patterns of belief; therefore, they provide a flexible framework for interpreting previous research that was not conducted within a theoretical framework. For example, the dominionistic and humanistic orientations described in Kellert's (1976, 1980) wildlife orientations (Table 23.2) clearly fit in the value orientation framework even though they were not originally framed clearly in one theoretical framework (they were called values, attitudes, perceptions, and evaluations when proposed).

Behavior

Behavior can be defined as an individual's conscious or involuntary action or reaction to an object or environment. Behaviors can be measured by asking people to describe what they do (e.g., Have you ever fed a bear?) or through directly observing what people do (e.g., watching people to see whether they feed bears; Fig. 23.2). Large-scale social survey studies rely primarily on self-reports of behaviors. This approach can be problematic because what people say they do often differs significantly from what they actually do (Argyris and Schön 1978, Argyris 1992).

Models for Predicting Wildlife-Related Behavior

Psychologists developed 2 primary models for predicting human behavior. **The norm-activation model** (Schwartz

Fig. 23.2. Direct observation is the most reliable method for assessing wildlife-related human behavior.

1977) suggests people attempt to engage in what they perceive as pro-social behavior. **Rational choice models** (Fishbein and Ajzen 1975, Ajzen 1991) suggest people weigh positive and negative consequences to generate an attitude (positive or negative evaluation of an object) toward a behavior option. The relationship between attitudes and behavior is constrained by perceived ability to successfully perform the behavior. Permutations and combinations of these models have proliferated in environmental sociology and psychology literature (Stern et al. 1995, Dietz et al. 1998, Bamberg and Moser 2007). Although these models place varying emphasis on social norms and locus of control (the degree to which people consider themselves [versus outside forces] in control) they have similarities. The models all suggest social context (e.g., age, class, race, and gender) influences values, which influence attitudes, and that attitudes shape intentions to act or behave in a particular manner. Although most HDW research is descriptive, it can still use this cognitive hierarchy. Zinn et al. (2000) described how traditional studies assessing public opinions about wildlife population levels could be improved by understanding the interactions among values, attitudes, behavior, and social context. They suggest exploring public acceptance capacity for wildlife populations using sociopsychological theory will allow managers to predict and alter public responses to various wildlife population levels.

Fishbein and Ajzen's Theory of Reasoned Action (Fishbein and Ajzen 1975, Ajzen and Fishbein 1980) and Theory of Planned Behavior (Ajzen 1985, 1991) are 2 of the most prominent models for predicting human behavior. **The theory of Reasoned Action** (TORA) suggests behavioral intention is a function of an individual's attitude toward the behavior and subjective norms. Subjective norms refer to perceived expectations from other individuals or groups. In

Table 23.2. Kellert's typology of human orientations toward wildlife

Orientation	Defining characteristics
Naturalistic	Profound interest in and attraction to wildlife and the outdoors
Ecologicistic	Principle interest in and affection for wildlife species in their natural environment
Humanistic	Strong personal affection for individual animals, typically pets, which are viewed as friends, companions and/or family members
Moralistic	Primary concern is for the ethical treatment of animals, both domestic and wild
Scientistic	Interest in animals as physical objects of study for physiological, biological, and taxonomic knowledge acquisition
Aesthetic	Primary interest in the beauty and symbolic properties of nature
Utilitarian	Interest in the practical and material value of animals in terms of their benefit to humans
Dominionistic	Principle interest in dominance and control of animals, particularly in sporting competitions
Negative	Strong desire to avoid animals due to fear or dislike
Neutralistic	Passive desire to avoid animals due to lack of interest or indifference

From Kellert (1976, 1980).

this context, behavioral intention is a measurement of how much effort an individual plans to exert in order to perform a behavior and emerges from beliefs about the consequences of performing that behavior. **The Theory of Planned Behavior** has the same components as TORA yet distinguishes actual behavioral control from perceived behavioral control. Behavioral control is dictated by the availability of resources and opportunities necessary to perform the behavior. Perceived behavioral control refers to an individual's perception of the ease or difficulty of performing the behavior, and can be independent of the actual resources and opportunities available to an individual.

Fazio (1995) suggested people often make behavior decisions somewhat instinctively and do not think explicitly about attitude-objects they encounter. When deliberate consideration of the attitude-object is absent, **the MODE model** suggests motivations (M) and opportunity (O) serve as determinants (DE) of how attitudes influence behavior (Fazio 1995). According to the MODE model, automatically activated attitudes can guide behavior in a relatively spontaneous manner without the individual's active consideration of the attitude or awareness of the influence of the attitude. The more direct the attitude-object experience, the more easily accessible the attitude will be as a memory; thus, attitudes formed by watching an instructional video on bear hunting will be less accessible as a memory than attitudes formed from experiencing bear hunting in person. Additionally, those attitudes that are repeatedly reinforced by direct experience are more likely to be automatically activated in the future. For instance, rural residents who frequently experience property damage from beavers would be more likely to automatically activate negative attitudes toward the species than residents who infrequently experience property damage from beavers. **Cognitive Dissonance theory** (Festinger 1957) proposes that people are motivated to reduce dissonance, caused by behaviors that are inconsistent with the individual's perception of self or how they wish to be seen by others (Festinger 1957, Petty and Wegener 1998). One could imagine a wildlife biologist who feeds wildlife to improve viewing opportunities for his or her family would face cognitive dissonance because they view themselves as a person who behaves in an ecologically responsible manner, and they know feeding wildlife can increase odds of disease transmission.

Risk Studies

Modern society has produced unprecedented hazards and insecurity leading to what Ulrich Beck labeled a "risk society" (Beck 1992). Modern society increasingly revolves around concerns about the future and safety (Giddens 1999); therefore, wildlife managers must learn to assess and respond to public risk perceptions. **Risk** refers to the possibility that actions or events lead to consequences that harm people or things humans care about (Klinke and Renn 2002). Risk perception can be **cognitive** (e.g., rational assessment of proba-

bility and severity) and **affective** (e.g., feelings of fear; Gore et al. 2005). Risk perception has 2 fundamental dimensions: unknown and dread risk (Slovic 1987, Klinke and Renn 2002). Risks high on the **unknown dimension** would be characterized by being nonobservable, new, unknown to those exposed, having delayed effects, and lacking scientific risk assessments. Risks high on the **dread dimension** would be characterized by being uncontrollable, being dreaded, being catastrophic, being fatal, creating risk to future generations, being difficult to reduce, demonstrating increasing levels of risk, and having involuntary exposure. Research on zoonotic disease (Peterson et al. 2006a) and wildlife damage (Gore et al. 2005, 2006) suggests risks high on dread and unknown dimensions elicit support for lethal wildlife management, desire for responsiveness on the part of managers, and demand for trusted decision-makers.

Risks associated with zoonotic disease have emerged as a major topic within HDW in the last 2 decades (Vaske et al. 2009). The simultaneous outbreaks of bovine spongiform encephalopathy (mad cow disease), Creutzfeldt-Jacob disease in humans, and chronic wasting disease (CWD) in free-ranging deer and elk during the 1980s, and ensuing outbreaks and scares associated with severe acute respiratory syndrome (SARS) and avian influenza have kept interest in wildlife-related zoonotic disease at a fever pitch. Diseases including bovine brucellosis, *E. coli*, and bovine tuberculosis might be seen as having low levels of unknown risk and low levels of dread risk. Prion-associated diseases, however, have high levels of unknown risk, and dread risk. Temporal and cultural contexts shape how the public perceives risk. For instance, West Nile virus was new to U.S. citizens in 2002, but old for people in areas where the disease was previously endemic (e.g., the Nile Delta in Egypt).

As a persistent risk with high dread and unknown dimensions, CWD has proven fertile ground for HDW research. In the last 5 years, >20 HDW studies on CWD have been published (Vaske et al. 2009). Studies found that hunters would avoid eating meat from animals in areas where CWD was found, and found that over half of hunters would quit hunting if CWD was implicated in the death of hunters. The effect of CWD was higher in areas where the disease did not exist, suggesting either that CWD has hit areas with the most avid hunters, or that once the risk becomes more familiar hunters become less concerned. Studies also found novice hunters were more likely to quit hunting in the face of CWD than more experienced hunters, which is bad news for hunter recruitment efforts.

Descriptive Research

Although **theoretical and hypothetico-deductive science** is paramount in scientific circles, descriptive HDW research has probably made the largest contributions to wildlife management. Day-to-day management decisions require assessing opinions of those conducting wildlife management and

publics affected by wildlife management. The simple fact that wildlife managers need descriptive HDW research more than any other type may explain, at least in part, why McCleery et al. (2006) found a troubling lack of social psychological frameworks in HDW studies, and Heberlein found “attitude” research often describes opinions instead of attitudes (Heberlein 1981). Wildlife management agencies both need and pay for descriptive studies of opinions.

Questions beginning with “what percent of” and “do you support” must be answered with descriptive research. Examples include what percent of hunters can identify a zoonotic disease and what percent of the public supports allowing hunting on Sunday. No future elaboration of social science theory will obviate the need for descriptive public opinion research. Such descriptive research can, and should, be integrated into theoretical models, but is valuable in its own right. Surveys measuring hunter effort, success, and harvest attributes have helped wildlife management agencies set bag limits, and place geographical boundaries on harvest regimes (Decker et al. 2001, Manfredo 2008). **Descriptive studies** document how much money is spent on wildlife-related recreation (U.S. Fish and Wildlife Service and U.S. Census Bureau 2007), and that dollar amount may mean more for wildlife advocacy than theoretical models predicting who spends money and how spending behavior might be modified. Similarly, descriptive research documenting the effects of wildlife damage (Conover 2002) has generated social support and funding for management and conservation of many species. Most major human infectious diseases have origins in wildlife; therefore, descriptive research documenting the extent of human interactions with wildlife will be a central piece of research protecting humans from future pandemics (Wolfe et al. 2007). In fact, monitoring of hunters and any people they enlist to butcher game is a key element of the global early warning system recommended by Wolfe et al. (2007). Future descriptive research documenting the social costs associated with changes in wildlife distributions caused by global warming would play a major role in advocacy efforts targeting climate change policy. Finally, documenting trends in social phenomenon requires repetitive descriptive research.

Philosophy

Philosophy relies on systematic reasoned argument to provide foundations for defining existence, knowledge, truth, validity, ethics, and justice. As such, it plays a fundamental role in wildlife management. One might question why philosophy is categorized as “human dimensions research.” After all, an ecologist provided the ethical philosophy that grounds our discipline today (i.e., the land ethic; Leopold 1949). We would argue that such wildlife philosophers were choosing to focus on people and people issues when conducting their work, and were, thus, welcome visitors within the human dimensions field.

Ethics

Leopold’s *Land Ethic* provides the basis for environmental ethics in many natural resource fields, and revolves around the moral value of promoting biological integrity (Leopold 1949). Most ethics philosophy in HDW addresses hunting. Leopold (1933) advocated game-cropping systems engineered by wildlife managers using several tools (including hunting) to sustain the system (Worster 1994). His later descriptions of hunting in the *Sand County Almanac*, however, suggested more ambiguity regarding recreational hunting and included viewing wildlife as “citizens” in the land community: “We reached the old wolf in time to watch a fierce green fire dying in her eyes. . . . I was young then, and full of trigger-itch; I thought that because fewer wolves meant more deer, that no wolves would mean hunters’ paradise. But after seeing the green fire die, I sensed that neither the wolf nor the mountain agreed with such a view” (Leopold 1949:130).

Clarke (1958) helped pioneer the philosophical defense of hunting rooted in promoting ecological integrity. Peterson (2004), however, questioned the ecological integrity arguments by noting a system requiring perpetual supervision by human hunters probably lacks ecological integrity. Shepard (1959) blended the ecological integrity defense with a naturalness defense by adding the argument that hunting allowed people to participate in their evolutionary role in nature. Other philosophers argued wild animals were not primary participants in human ethical systems, but suggested humans held a responsibility to demonstrate reverence for all life (Schweitzer 1950).

The animal rights and animal welfare movements (Singer 1975, Regan 1983) spurred another wave of wildlife-related philosophy. **Animal rights** views suggest animals have rights similar in some ways to those accorded to humans and **animal welfare** views focus on improving well-being of animals without taking an explicit stance on rights. Callicott’s (1980) groundbreaking “Animal Liberation: a Triangular Affair” essay documents the philosophical *mêlée* associated with a collision of animal rights and welfare, traditional ethics, and Leopold’s land ethic. Traditional ethical humanists argued animals were somehow less than humans and, thus, lacked moral standing. Animal rightists argued the categories used to rank beings were flawed. The battle surrounding animal rights began with categories of insentient, sentient, and conscious or self-aware animals. Animal-rights apologists pointed out that according to these criteria, mentally retarded humans, babies, and even humans rendered unconscious are less important than higher mammals (Singer 1975). Accordingly traditional ethics were twisted to suggest killing mentally retarded humans or inarticulate infants to save chimpanzees (*Pan troglodytes*) or dolphins (*Tursiops truncatus*) was ethical. This argument knocked self-consciousness off the animal-measuring stick, leaving all sentient animals equal, and the logical rationale for animal rights sprang forth. Callicott (1980) suggested Leopold’s land ethic provided a third

alternative for environmental ethics. Callicott's argument that rightness of decisions should reflect their contribution to ecological integrity followed early defenses of hunting within HDW philosophy (Clarke 1958). Callicott ended the essay by reiterating naturalness arguments developed by wildlife philosophers (Shepard 1959, 1973; Gasset 1972). He called livestock a "ruinous blight of the landscape" and argued they were "bred to docility, tractability, stupidity, and dependency (Callicott 1980:330)." Similarly he described modern humane ethics as an "anti-natural prophylactic ethic of comfort and soft pleasure" and glamorized the flesh eating, pain tolerance, and virtue of tribal peoples (1980:334).

From the naturalness perspective, accepting a natural disposition to hunt prevents mental disorders (by making our behavior more congruent with genetic predispositions; Swan 1995), and provides an honest relationship with nature (e.g., demonstrates supplying humans with any type of food leads to animal deaths; Dizard 2003). The naturalness philosophy, however, has been impugned for misogynous implications (e.g., women need to assume Paleolithic roles to achieve mental stability; King 1991, Peterson 2004). Hunting currently provides major political support for wildlife management; therefore, future philosophical work exploring its contributions to human welfare in modern society remains critical (Peterson 2004).

Justice

A body of HDW philosophy associated with distribution of benefits and costs of wildlife management is beginning to take root, and may help reduce conflict over allocation of costs and benefits associated with wildlife management. This literature emerges from various interpretations of the public trust doctrine. According to the **public trust doctrine** (PTD) the state acts as a trustee and manages wildlife for the benefit of the public. The typical formula for PTD scholarship entails tying PTD to ancient Roman law, documenting evolving case law supporting the notion of PTD, documenting how PTD guided North American conservation during the age of game restoration, and describing threats and opportunities for using the PTD in the future. The PTD has been argued from economic, historical, legal, and political perspectives (e.g., Sax 1970, Geist 1988, Kreuter and Workman 1997, Horner 2000, Geist et al. 2001).

The implications for social justice are beginning to be addressed indirectly by scholars interested in the social effects of nature reserves (Dowie 2005, Brockington et al. 2006). The ethical claim, "wildlife *should* be public (or private) property," is a philosophical claim with profound implications for distributional justice (Rawls 1971, 1993). Currently the PTD is used selectively to mandate maintaining public benefits from wildlife, but not public responsibility for costs associated with wildlife damage or protecting endangered species. Conflict over wildlife management could be ameliorated by future HDW scholarship contributing to a coher-

ent philosophy of distributional justice for allocating the benefits and burdens afforded by wildlife conservation.

Science

The inherent subjectivity in any human endeavor means HDW scholarship can help wildlife management as a whole reflect on its own biases, norms, and methods. Although philosophy of science is less developed in wildlife science than many other fields (Jasanoff et al. 1995), it has instigated profound changes in our discipline. Romesburg's (1981) critique of predominantly descriptive wildlife research promoted a renewed focus on the scientific method and experimental design within wildlife science. **Deducing** outcomes from hypotheses and testing for their occurrence (hypothetico-deductive science) is now more prevalent within wildlife science. Several wildlife science philosophers have questioned the "fixation on statistical methods. . . . quantitative trap-pings," and argued for more emphasis on thoughtful studies and research hypotheses (Romesburg 1981:307; Guthery et al. 2001, 2005). Human dimensions scholars have played a similar role within HDW outlets by advocating for research framed within theory (Manfredo 1989, 1990; Decker et al. 2001; Vaske 2008). They emphasized how theory extends inference, improves reliability, and provides a framework for building on previous findings, and have helped the HDW research field move beyond a cycle of repetitive descriptive research. The HDW research field has progressively moved from purely descriptive research to theoretical and even experimental research during the last decade.

Wildlife science largely focuses on middle number systems with too many parts for individual counting but too few parts to substitute averages for individual components; therefore, statistics and modeling play a central role in research (Allen and Starr 1982). The centrality of statistics is reflected in much of the philosophy of science produced within HDW. Philosophy of science arguments have tackled lack of statistical independence in studies of animal movements (Swihart and Slade 1985), identified rampant abuse of null hypothesis testing (Burnham and Anderson 1998, Cherry 1998, Anderson et al. 2000), and highlighted similar trends with information-theory-based model-selection algorithms (i.e., model selection; Guthery et al. 2005). This body of philosophical work has instigated a broad-scale shift from null hypothesis testing to multimodel inference in the wildlife science field, and may facilitate another shift to more diverse methods tailored to exploring specific research hypotheses (Guthery et al. 2005).

A final body of wildlife science philosophy addresses ways to integrate ethics, management, and science. Conflicts between responsibility to scientific objectivity, following public preferences, and protecting biotic integrity, create an incoherent foundation for wildlife managers (Peterson et al. 2007). Initial efforts to address this conundrum were reflected in expressions of adaptive management that included a fo-

cus on citizen engagement (Lee 1993a). Riley et al. (2002, 2003b) developed an approach labeled **adaptive impact management** that explicitly acknowledged the anthropocentric focus of wildlife management. This approach targets management actions on **impacts**, significant effects of interactions between humans and wildlife. Unless at least one human recognizes an event and considers it important, it does not enter the realm of wildlife management. From this perspective only recognized events with effects deemed important by people enter the realm of management. When the human element is integrated fully within management, credibility becomes as important as objectivity within science, and managers must represent the needs of both wildlife and people in decision-making (Peterson et al. 2007).

Public Involvement

In this section, we describe best practices for involving the public in wildlife management decision-making, and list potential triggers for involving the public in wildlife management. Public involvement (PI) is critical because politics drives every decision made in wildlife management. Because **politics** involves wielding power to make decisions, giving science more power doesn't remove politics from its dominant role. Social relationships and power interact to determine what wildlife studies occur, which methods are used, what findings are published, what species receive attention and resources, and how decisions are made. Wildlife managers can distribute power more equitably by utilizing PI, as in the case of comanagement or community-based management (Chase et al. 2000, Treves et al. 2006), or attempt to maintain control over power as in the case of command and control models for decision-making (Chase et al. 2000, Walker 2004). Similarly, wildlife managers can shape how power is exerted in decision-making with advocacy campaigns, by controlling information, and by influencing the constitution of stakeholders with a seat at the decision-making table (Jacobson 2005, Cox 2006). These tools and strategies change the politics, but do not remove them.

Emerging PI approaches can help facilitate a move to the citizen model of wildlife management, improve civic engagement, diffuse conflicts, improve trust in agencies, reduce management costs and improve decision-making. Although PI may initially escalate conflicts, participation from diverse interests can lead to greater support for the final decisions (Laird 1993, Lin 1996). Greater support among stakeholders carries benefits, including lower enforcement costs, higher compliance rates, less conflict, and higher community satisfaction (Lee 1993a, Chase et al. 2000). Further, PI promises to reduce administrative overhead by paying for management with social capital (Ostrom 1990, Kollock 1998).

Public involvement, however, can just as easily backfire and create more problems than it solves. Social capital has an oft forgotten negative side; it can lead to exclusion of outsiders and may lead to the restriction of personal free-

doms (Peterson et al. 2006b). Although it is reasonable to assume that greater support among stakeholders translates into lower enforcement costs, higher compliance rates, less conflict, and higher community satisfaction, this does not necessarily enhance conservation. There is no intrinsic advantage to efficiency; even when bad policy is efficient, it remains bad policy. Finally, wildlife managers face several immediate and pragmatic risks with PI: (1) mobilization of antagonistic groups, (2) temporal and financial expenses, (3) near impossibility of truly representative participation, (4) undermining agency authority, (5) citizens with inadequate knowledge of issues and poor communication skills, (6) difficulty weighing public opinions, (7) special interest takeovers, (8) insufficient institutional capacity to offer PI, and (9) legal risks associated with nontraditional decision-making (Senecah 2004).

How to Use Public Involvement

The formulaic PI processes associated with public hearings, the most common form of PI, do little to allay the aforementioned concerns of wildlife managers. In the 1970s, Heberlein (1976) noted the theater-style proxemics of public hearings intimidated citizens not accustomed to public speaking. Since then many reports and studies have documented how public hearings trigger conflicts, anger, and frustration (Senecah 2004). Participants view such processes as "designed to shroud an elitist policy-making process in the cloak of democracy (Persons 1990:121)." Many PI models have been developed in recent decades. Community-based conservation alone refers to PI models ranging from truly community-based approaches to those influenced by centralized governments (such as Habitat Conservation Planning for endangered species; Reilly 1998), and projects influenced by the global marketplace (such as the Communal Areas Management Programme for Indigenous Resources [CAMPFIRE] in Zimbabwe; Alexander and McGregor 2000). Rather than delve into the myriad PI models and their variants, we focus on describing key elements necessary to ensure legitimacy for any model managers choose to employ.

Making PI efforts more legitimate requires giving participants a voice. Senecah's (2004) **trinity of voice theory** suggests voice includes: access, standing, and influence. Case studies by HDW scholars support this assertion by highlighting communication and education (access), fair treatment of citizens (standing), and influence on decisions as key elements of PI valued by participants (Chase et al. 2002, 2004). **Access** implies more than sufficient opportunity to express opinions. Citizens can only gain access if they are equipped with enough knowledge and understanding to enter the process proactively. Providing access requires using convenient times and places, making educational material readily available, providing technical assistance, early and widely disseminated notice, early public involvement, and long-term opportunities for public involvement. Raik

et al. (2006) found knowledge and leadership as particularly important dimensions of capacity for collaborative suburban deer management. Equipping participants with sufficient knowledge is a major challenge. In the case of CWD management, Eschenfelder and Miller (2007) suggest government websites equipped citizens to make personal decisions and perhaps to police agency decisions, but not to engage in productive policy debate. Most states managing CWD provided lists of recommendations for management and personal behavior and summaries of management strategies, but did not provide information to facilitate citizen participation in deliberative processes (e.g., acknowledging debates, reviewing conflicting claims, describing risks and benefits of alternative decisions, documenting uncertainty, and identifying who is responsible for decision-making).

Standing refers to the respect and legitimacy given to participant perspectives. Providing standing requires active listening, dialogue, debate, and clear parameters for how outcomes of participation will be used in decision-making (Senecah 2004). Access and standing are highly related, and providing either in isolation tends to promote anger and frustration among participants. Public hearings to address changes in game management regulations often typify this dynamic. Hunters are given access, but not standing, because dialogue and discussion of how their opinions will be integrated in the final decision rarely occurs. Participants then adopt boisterous, disruptive, and theatrical tactics in an effort to gain standing. These attempts to gain standing should not be interpreted as evidence that argumentation or debate should be eliminated from PI. Dissent and debate are essential for wildlife-related PI in democratic nations (Peterson et al. 2005). Rather, managers should work to provide the necessary access (information and forum) and standing for productive democratic debate (Peterson et al. 2005, Eschenfelder and Miller 2007).

Providing influence does not require managers to do what participants want. Rather, **influence** means participant ideas are considered in management decisions (Senecah 2004). Truly considering participant input, however, requires meaningful decision space (flexibility in allowable solutions). If a decision cannot be changed based on participant input, then the input is not really being considered. Using a transparent decision-making process, creating opportunities for participants to evaluate options, and providing careful responses to participant concerns all help foster legitimate influence. Managers should be skeptical of any PI strategy that appears unlikely to provide participants a voice. Such strategies may fill PI mandates, but are unlikely to bring any other benefits.

Wildlife managers hoping to develop PI forums face the challenge of balancing competing demands for scientific management and democratic participation (Chase et al. 2000, Senecah 2004). If science is ignored, serious unanticipated consequences may emerge from public decision-making, but

ignoring the public may lead to civic disengagement, rancorous conflicts, and managing for ultimate effects not desired by society. Giving participants a voice in contexts characterized by scientific complexity requires helping them cope with large amounts of empirical data and high levels of complexity. The Communication for Wildlife Professionals chapter in this volume addresses several important modes of public education including media interviews, public talks, scientific presentations, and print media development (Jacobson 2005). These forms of outreach, however, typically do not equip citizens, or managers, to make decisions requiring the integration of complex ecological, economic, and social aspects.

Humans build mental models in almost all decision situations (Costanza and Ruth 1998), but we are typically incapable of including nonlinear relationships, feedback, or causal nets in our mental models (Vennix 1999). Further, a series of cognitive shortcuts including the **availability heuristic** (predicting likelihood based on ease of recall) and **anchoring and adjustment** (basing estimates on familiar positions [relative thinking]) make mental models unreliable in complex systems. Mediated systems modeling has been used to address these challenges within wildlife management since the 1980s, but because the approach blends management with research, published accounts are rare. In one example, facilitators helped experts with backgrounds in sheep ranching, fire, and wildlife ecology develop an integrated model for sage grouse (*Centrocercus urophasianus*) population dynamics in southeastern Idaho (Pederson and Grant 2004). In **mediated modeling** a skilled facilitator helps participants build a qualitative or quantitative model of the management system and participants use the model to evaluate management interventions. Both quantitative and qualitative models help increase group information-processing capacity, identify feedback loops, place the entire management challenge on one piece of paper or computer screen, and create group memory for longer term decision-making requiring multiple sessions (Vennix 1999). The facilitator translates what participants say into variables, system boundaries, and feedback structures. The facilitator also helps participants evaluate model structure and, with quantitative models, outputs. Qualitative versions of mediated modeling have been criticized for promoting conclusions about systems based solely on a diagram (Vennix 1999). Unfortunately, quantification often requires more data than are available, models based on simulated data can be misleading, and many participants find system diagramming cognitively easier than generating a quantitative model. The field of mediated modeling is rapidly evolving, but van den Belt (2004) provides a summary of best practices.

When to Use Public Involvement

Developing high-quality PI approaches is difficult and time-consuming; so, when should it be attempted? Three strategies for choosing when to implement PI seem particularly

relevant to HDW: one from business management (Lawrence and Deagen 2001), one from risk management (Klinke and Renn 2002), and one from wildlife management (Chase et al. 2002). Although many examples could be employed to illustrate the utility of the decision trees, we focus on issues associated with wildlife disease to promote comparability. Lawrence and Deagen (2001) tweaked a business-based model to fit natural resource management contexts (Fig. 23.3). Within this model, if managers know enough to make a quality decision and either don't need public acceptance to succeed or know the public backs their decision, PI is not used. Other contexts involve progressively soliciting public opinion without any expectation of following it, soliciting opinion and making decisions reflecting its influence, using public hearings and making decisions reflecting group opinions, and sharing problems with the public and working together toward a collaborative solution. All options avoid the dangerous tendency to solicit public opinion or involvement when alternative solutions are not available for negotiation (Depoe et al. 2004).

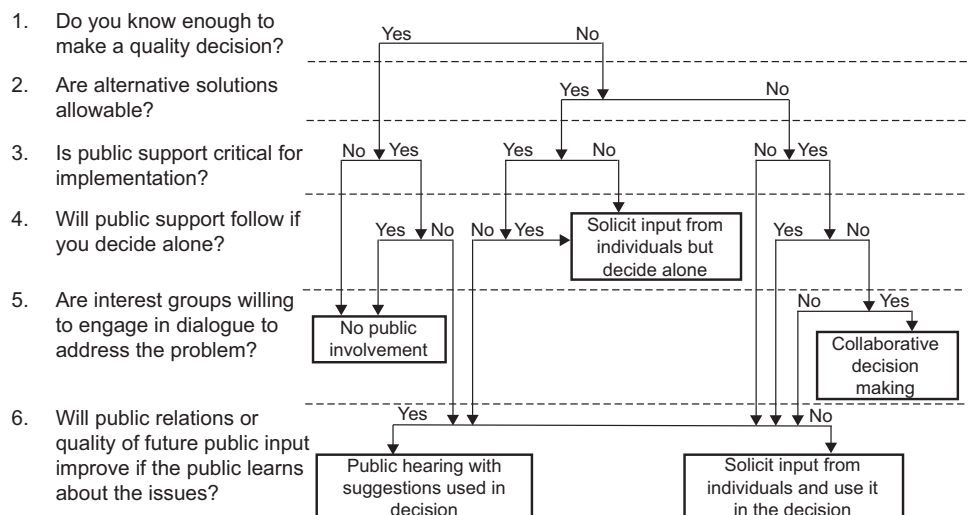

Being rooted in business, the model is based on efficiency and favors PI approaches that achieve goals in the most time-efficient manner. As one might guess, that equates to infrequent use of collaborative decision-making (see Fig. 23.3). Lawrence and Deagen (2001) use the Montana Department of Livestock's efforts to reduce risk associated with *Brucella abortus* transmission between bison (*Bison bison*) and cattle as a test case for their decision tree. They suggest social contexts dictate a decision based on input from a public meeting (see Fig. 23.3), but that if the meeting causes damage to public relations then the agency should shift to making decisions based on input solicited individually from stakeholders (see Fig. 23.3). Finally, they suggest that if the public meetings create an environment where stakeholders wish to engage in collaborative dialogue then collaborative decision-making should be employed (see Fig. 23.3). These specific

recommendations, however, emerge from multiple value judgments required while moving down the decision tree and demonstrate the danger of mechanistically using any decision-making tool. Someone familiar with acrimonious debate over bison management in the Greater Yellowstone area may find question 6 a problematic double-barreled question (see Fig. 23.3). Yes, public relations might improve if everyone learned more about the issue, but in this context, public meetings may simply reinforce polarized conceptions of the issues (Peterson et al. 2002).

The risk management approach for choosing when and how to include PI requires managers to answer either 1 or 2 questions: is the problem characterized as normal and, if not, is the problem characterized by complexity, uncertainty, or ambiguity (value conflicts; Klinke and Renn 2002)? Normal problems are characterized by low complexity, low uncertainty, and low ambiguity. They cannot exceed prespecified (by agencies) thresholds on 1 or more of 9 criteria for **risk characterization**: (1) extent of damage, (2) probability of occurrence, (3) incertitude, (4) ubiquity, (5) persistency, (6) irreversibility, (7) delay effect, (8) violation of equity, and (9) potential of public mobilization in response to the problem. Normal management entails routine operations of agency staff, and is conducted internally. For normal risks the probability times damage view of risk is compatible with public conceptions of threat, so risk-benefit analysis and other optimization strategies are the appropriate decision-making tools and PI is not needed (National Research Council Committee on Risk and Decision Making 1982). The ninth criterion, however, should be carefully considered before excluding PI because public concern and mobilization often have little to do with scientific risk (e.g., potential damage and probability of occurrence).

When risks exceed 1 or more of the thresholds for the 9 aforementioned criteria, 3 PI strategies should be considered based on whether the dominant characteristic associ-

Fig. 23.3. A decision tree for selecting public involvement methods for wildlife management decision-making. Adapted from Lawrence and Deagen (2001).

ated with management problem is complexity, uncertainty, or ambiguity. When high complexity characterizes the management context, PI should entail engaging external experts in the process of generating agreement on causal relationships and effective solutions, and regulating on the basis of their combined knowledge. Quantitative measures of risk and efficiency are appropriate tools for decision-making using this type of PI (National Research Council Committee on Risk and Decision Making 1982). Incorporating public concerns and values in resolving cognitive complexity usually makes little sense, further complicates decision-making, and underutilizes the abilities of scientists and experts (Klinke and Renn 2002). Simply put, people with knowledge and experience, who are using it to solve a particular suite of problems, can produce more cost-effective solutions to those problems than nonexperts.

When uncertainty dominates the management context, PI should engage the public in balancing the costs of overreacting versus the costs of underreacting. Research should focus on reducing uncertainty, thereby moving the risk back to the stage of handling complexity, but when knowledge acquisition is slow and immediate action is necessary, a precautionary approach is necessary (O'Riordan and Cameron 1994). Precautionary approaches, however, require stakeholders to use economic and social evaluations to strike the balance between being under- and over-cautious (Klinke and Renn 2002). Those bearing the burden of management (both its costs and the risks associated with failure) must be involved in the trade-off analysis. Recent wildlife diseases characterized by uncertainty include SARS and CWD.

When ambiguity dominates the management context, PI should focus on resolving or mediating value conflicts. Management contexts dominated by ambiguity must address what should be rather than identifying the facts, risks, and costs. Most PI in wildlife management fits in this category, and seeks to either identify the most socially acceptable solution or to create new win-win solutions not previously available. Neither knowledge- nor efficiency-based PI approaches should be used to address ambiguous risks because social and moral judgments dictate preferences (Yankelovich 1991). The conflicts surrounding management of bovine brucellosis in wild bison demonstrate relative unimportance of practical or scientific claims for managing ambiguous risks (Peterson 1997: 86–118).

Although most wildlife management contexts involve a mixture of complexity, uncertainty, and ambiguity, and require a mixture of PI strategies, the dominant characteristic should determine the dominant strategy. When multiple attributes play significant roles in management contexts, multiple PI strategies should be utilized simultaneously. Similarly, managers should be prepared to change PI strategies in a fluid manner. Risks are never fixed within one management context. A publicly visible rabies outbreak could change management context from normal to ambiguous, and man-

agement contexts associated with West Nile virus probably changed from uncertain to normal within a few years of the virus emerging in the United States.

Chase et al. (2002) developed a PI decision tree focused on manager objectives rather than management objectives. If managers do not want public input they should consider authoritative PI approaches including press releases or advertising, which many would not consider PI. If managers want public input, they must decide whether stakeholders should have influence. If managers do not want participants to help make decisions they should consider passive-receptive approaches (e.g., taking time to read unsolicited comments) or inquisitive approaches (e.g., conducting surveys, public hearings, focus groups). Finally if managers want help with decisions they must decide whether they want help implementing management actions. If they do not want help they should consider transactional approaches (e.g., citizen task forces), and if they want help they should consider comanagerial approaches where participants help implement the actions they recommend. This approach to choosing PI methods can be dangerous if managers do not want citizen input when it is needed, do not want decision-making help from citizens when it is needed, do not want to hear from citizens when citizen support is needed, or do not want help implementing management actions from citizens when it is needed. The model also uses several PI approaches (authoritative, passive-receptive, and inquisitive) that do not provide participants access, standing, and influence, so managers must exercise care when potential participants expect to have a voice.

Qualitative Approaches

Qualitative research offers great promise for addressing wildlife management challenges, but is underutilized. Qualitative studies typically use an emic perspective. An **emic perspective** views human behavior or beliefs in terms meaningful to actors, and comes from within the culture of the actors. Qualitative research methods share a tendency to focus on answering how and why questions with studies using small focused (but rarely random) samples (Denzin and Lincoln 2005). Diverse qualitative approaches include ethnomethodology, focus groups, narrative inquiry, and participatory action research (Denzin and Lincoln 2005). Emic focus and qualitative research are typically combined because researchers cannot understand actors' perspectives without sharing the same social context and spending time getting to know participants. The intuitive need to understand social issues from the perspective of people experiencing them has led to a resurgence of qualitative research in many social research fields (Denzin and Lincoln 2005). Most HDW approaches, however, provide accounts of social behavior and beliefs based on the **etic perspective** (neutral stance of researchers) instead of from the perspective of the social group in question.

Qualitative approaches dominated sociology until the 1930s (Converse 1987). During World War II funding and support for surveys and survey researchers created a shift toward quantitative research within sociology. Leaders of this movement (e.g., George Gallup, Paul Lazarsfeld, Rensis Likert, and Robert Merton) faced accusations from their peers of being “quantophrenics” (Converse 1987:253) and assertions that “those in the grip of methodological inhibition often refuse to say anything about modern society unless it has been through the fine little mill of statistical ritual” (Converse 1987:252). The latter assertion rings true in modern HDW research, where qualitative research is rarely used for anything but improving quantitative research, and few wildlife managers would dare make assertions about social relations (e.g., potential responses to regulation changes or opinions) unless the assertions were supported by a *P*-value or best model. For example, generalizing from focus-group studies is seen as both inappropriate and dangerous. Some qualitative researchers have responded to this skepticism by twisting qualitative methods to focus on counting and sorting phrases using computer software. Unfortunately such approaches tend to dilute the most powerful elements of emic research, a deep understanding of context and insider perspectives.

Fortunately **generalizability** is surprisingly similar in quantitative and qualitative research. The basic premise is: you can generalize to people who are similar to the ones you studied if those people are in similar social contexts. Quantitative studies use random sampling, nonresponse sampling, and statistical tests in an effort to ensure samples reflect the population of interest (Vaske 2008), while qualitative studies provide thick rich description of social context and allow managers to decide for themselves whether people and social contexts are similar enough for generalization (Denzin and Lincoln 2005). Accordingly generalizing from qualitative research is dangerous, but mainly because blame for faulty predictions falls on the interpreter instead of the researcher. The vast majority of useful social knowledge is based on generalizations from qualitative inquiry. One confidently gets out of bed, feeds their children, goes to work, walks on various surfaces, interacts with new people, and engages in a host of wildlife-related activities because generalizing from qualitative experiences (learning from what happened the first few times one tried the activities) works extremely well in most contexts.

Guba and Lincoln (1989) suggested several parallels for evaluating qualitative and quantitative research (Table 23.3). The different categories reflect paradigmatic differences rather than pragmatic differences. For instance, quantitative researchers might actually be more effective in wildlife conservation efforts if they focused on credibility and confirmability instead of validity and objectivity because they could legitimately engage in decision-making as active participants instead of working to perpetuate the illusion of objectivity (Peterson et al. 2007). The shift in perspective does not re-

quire methodological changes because quantitative research must be valid to be credible and qualitative research must be credible to be valid. Within qualitative research credibility is improved by (1) **triangulation** in data collection (e.g., field notes, document analysis, and interviews), (2) **informant validation** (e.g., designing clarification questions into the interview protocol, conducting multiple interviews with the same informant), (3) larger numbers of informants, (4) prolonged time in the field, and (5) documenting informants’ stories in their own words (Peterson et al. 2002). Reliability or dependability (Table 23.3) is a complex challenge because qualitative researchers are socially situated humans studying other socially situated humans and are neither value-neutral nor unresponsive to context (Peterson et al. 2002). Reflexivity (explicitly reflecting on how you impact and are impacted by the research) helps researchers to document potential biases. Qualitative researchers are the principal methodological instrument, and their interactions with informants become part of the research.

Wildlife managers face contexts where generalization or transfer of qualitative results is both possible and regularly beneficial when hunting and fishing regulations impact small towns, tribal or first-nation groups, or small subsets of hunting and fishing populations. As an example of the latter case, several states have struggled with the regulation of hunting with dogs. As states become progressively more urban, pressure to ban certain forms of hunting with dogs often emerges. If a state such as North Carolina wanted to assess how a ban on hunting deer with dogs would impact dog hunters in 3 rural counties, then focus groups or semi-structured interviews would answer the “how” question better than quantitative methods. Further, if the focus-group participants indicated a dog hunting ban would shatter their social networks, prove devastating to their unique culture, and elicit civil disobedience, then managers who understand the social context represented by focus-group participants should not need a survey based on a probability sample to generalize to other members of the dog hunting community. If qualitative methods are focused on “how” and “why” questions and inference is limited to the social context studied, then they may prove the most cost-effective and useful approach for answering small-scale wildlife management questions.

Table 23.3. A comparison of criteria used to evaluate qualitative and quantitative research

Criteria for evaluating qualitative research	Criteria for evaluating quantitative research
Internal validity	Credibility
External validity	Transferability
Reliability	Dependability
Objectivity	Confirmability

From Guba and Lincoln (1989).

Participatory action research (PAR) provides another example of underutilized qualitative research. PAR is the social science equivalent of adaptive management, and has been utilized since the 1930s (Denzin and Lincoln 2005). In PAR, researchers team with members of the public who want to tackle a management challenge and jointly design management interventions, assessments, and new interventions based on social response to the interventions. The PAR research approach also finds parallels in popular and cutting-edge wildlife management approaches (e.g., comanagement and adaptive impact management; Chase et al. 2000, Riley et al. 2002), yet the PAR research model is rarely used. Although qualitative research is frequently used to improve the rigor of quantitative research, innovative mixed-method studies using both perspectives to make major contributions are rare (Leong 2010).

SUMMARY

Being tasked with solving “people problems” may have seemed condescending to HDW luminaries in the 1970s when vocif-

erous stakeholders complaining about scientific decisions were treated as the people problem. Now a growing list of people problems dwarfs not only HDW, but wildlife management in general. Urban sprawl, water scarcity, energy development, climate change, and zoonotic disease cast a long shadow over the future of wildlife conservation. Human dimensions scholars have developed an impressive array of research tools to address these challenges and HDW will inform efforts to change people’s behaviors, but our discipline is simply far too small to be successful alone. Sustainable solutions for wildlife management in contexts of climate change, population growth, household proliferation, increasing energy consumption, and zoonotic disease outbreaks will require more than the oft-called-for integration of social and biological sciences; they will require partnerships with diverse groups including environmental engineers, environmental communication and advocacy experts, economists, and political scientists. Human dimensions of wildlife emerged to help wildlife managers cope with a diversifying constituency, and should be well-situated to facilitate future coalition building needed to address today’s wildlife conservation challenges.

Communications and Outreach

INTRODUCTION

THE **COMMUNICATION PROCESS** aims to understand and influence people's awareness, attitudes, and behaviors. Communications are important for soliciting people's involvement in sustainable wildlife management. Consider how effective communication has led to conservation:

- Tourists interacting with dolphins decreased inappropriate behaviors, such as touching dolphins, after exposure to a communication program (Orams and Hill 1998).
- Data collected and shared electronically by local birdwatchers helped to obtain US\$2.5 million in federal funding for habitat acquisition and restoration (Fitzpatrick and Gill 2002).
- Communications in parks have reduced threats to sea turtles and shorebirds (M. Whatley, National Park Service, personal communication), and influenced positive attitudes and beliefs about prescribed fire and forests (Bright et al. 1993).

"Wildlife management is comparatively easy; human management difficult" (Leopold 1966:197). Think of a challenging wildlife problem you have encountered—setting sustainable harvest limits, managing wetlands, or protecting endangered species. More than likely, people are part of the problem and communication will be part of the solution. Effective communication is essential for influencing conservation policy, changing people's behaviors, garnering funds, or recruiting volunteers. The fate of our wildlands and wildlife resources depends on successful communication with a variety of audiences—from anglers to zoo visitors, in a variety of places—from agricultural lands to the legislative floor.

This chapter describes the communication process. It provides a systematic plan for identifying communication goals, targeting specific audiences, selecting appropriate media and messages, and evaluating your results. The following guidelines will help ensure your effectiveness at using common communication techniques needed by wildlife professionals. Whether giving an interview or public presentation, designing a brochure or scientific poster, or working with groups and negotiating management decisions, follow a **GAME plan** for success.

WHY COMMUNICATE?

The public affects the success or failure of wildlife management efforts. Yaffee et al. (1996) found that public opposition was the major constraint to implementing eco-

system management plans. In the case of reintroduction of the gray wolf (*Canis lupus*) in Yellowstone National Park, biologists working with the recovery plan concluded that many recovery issues have more to do with people's deeply held personal values about the government and perceptions of nature rather than about wolves themselves (Fritts and Carbyn 1995). In essence, researchers could spend years designing plans or studying the biology of gray wolves, but wildlife goals may not be achieved without adequate public support. In such cases, failure to accurately assess and target public opinion can result in opposition to wildlife initiatives and costly political battles.

The need for improved communication about wildlife grows as more people use public lands and conflicts over natural resources increase (Fig. 24.1). The public is exposed to wildlife issues through print media, radio, television, and the Internet. Public opinion polls show interest and concern for wildlife. A 2007 Gallup poll found that 69% of U.S. citizens worried a fair amount or a great deal about the extinction of plants and animals (Gallup Poll 2007).

Communication skills of wildlife professionals must include the ability to promote a program's products—its mission, policies, services, and goods. Promotion entails sparking public interest by showing people how the objectives of wildlife management relate to their needs and wants. Communicating with and involving the public and decision-makers helps increase their long-term support and leads to sound wildlife conservation policy. One of The Wildlife Society's 4 principal objectives is to increase awareness and appreciation of wildlife values (Case 1989). Researchers have shown that appropriate communications can improve public support for and behavior toward wildlife, reduce vandalism and poaching, improve compliance with regulations, increase recreation carrying capacities, and influence policies and decisions that affect public lands and wildlife resources

Fig. 24.1. Human conflicts with wildlife range from concerns about diseases and safety to opportunities for ecotourism. Effective communication is needed to better manage wildlife and people. Photo by S. K. Jacobson.

(e.g., Knudson et al. 1995; Jacobson 1990, 2009). Can we afford not to communicate?

WHAT IS COMMUNICATION?

Communication is a process of exchanging ideas and imparting information. We do it all day long. It involves making yourself understood to others and understanding others in return. If you send a message—verbal, visual, or written—that the intended receiver does not understand, communication has not occurred. As such, the only way to make sure that the message has been received and properly understood is to incorporate feedback into the process. Consider a great public relations success story—the U.S. Forest Service's wildfire prevention campaign. Their message, "Only YOU can prevent forest fires" is unambiguous, on a poster with Smokey Bear dousing a campfire. They used a catchy slogan, a "charismatic spokesperson," and media targeting specific audiences to ensure that most U.S. citizens remember Smokey Bear and his message that we not only can, but should, prevent forest fires. In one public poll, 95% of those surveyed could recognize Smokey Bear, whereas only two-thirds could recognize the U.S. president (Jacobson 1999). The newer slogan—"Only YOU can prevent wildfires"—is attempting to rectify the impression that all fire is bad, and to spread our new understanding of fire-adapted ecosystems.

Communication involves both interpersonal and mass-media approaches. **Interpersonal techniques** use conversations, group interaction and decision-making processes, speeches, and participatory demonstrations. **Mass-media approaches** use newspapers, magazines, radio, television, billboards, mail, films, publications, the Internet, and other electronic techniques. The public receives much of its environmental information through mass-media channels. Although mass media are a primary source of information, interpersonal and hands-on activities can be more effective in influencing attitudes and behaviors. Selecting the appropriate communication medium based on your goals and audience is critical. Below, theories and approaches are described that apply to all forms of effective communication about wildlife.

Communication Theory

Communication theory borrows from the fields of psychology, education, and sociology. Models of communication include an encoding stage, in which the source (in this case, you, the wildlife professional) sends a message that is translated and conveyed via a medium (Cutlip et al. 1985). Your message is decoded by the receiver (your audience or stakeholder group), who possibly responds, thereby providing feedback (Fig. 24.2). Both encoding and decoding are critical stages in the communication process, no matter your media—interview, speech, brochure, scientific poster, Web site, or meeting.

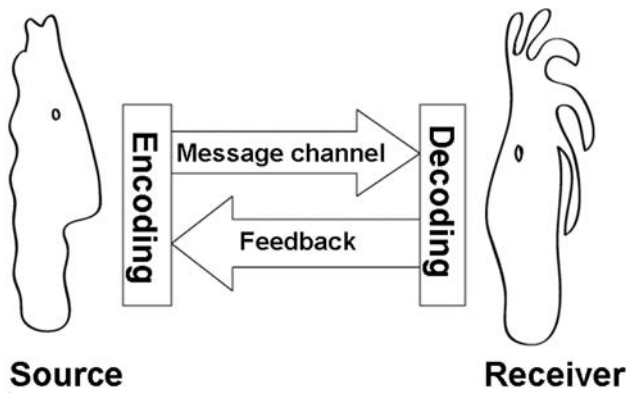

Fig. 24.2. A simplified model of the communication process.

Gatekeepers regulate the flow of information from source to receiver and can introduce additional changes or noise into the communication. Different media have different gatekeepers. For example, suppose you speak to a reporter about your organization's new project to save endangered beach mice (*Peromyscus polionotus*). The reporter encodes your message in the form of a newspaper article. A gatekeeper in the form of an editor must accept the story for publication. Perhaps the last 3 paragraphs will be cut due to a shortage of space. Perhaps the headline is misleading. Ultimately, the receiver—individuals perusing the paper over their morning coffee—will decode the article based on their own experience. Why should rodents interest them? If you do not catch their attention by addressing their interests or concern, they will not read it (Fig. 24.3).

Feedback from receivers allows the source to adjust the message; thus, receivers also are senders if their response is captured in some way. Sources must be listening or observing, however, to modify their communication on the basis of the receivers' feedback. For example, an agency that fails to respond to constituent anger about changes in a hunting policy will have more problems than an agency that listens and understands the needs of their constituents. Researchers in upstate New York found the communication process

Fig. 24.3. How can you interest your audience in an endangered beach mouse? Photo by Florida Fish and Wildlife Conservation Commission.

in itself—whether through individual conversations, group surveys, or a citizens' task force—improved satisfaction with the wildlife management agency, even when the management outcome was the same (Stout et al. 1997). Wildlife organizations fueled by tax dollars or private donations must understand and respond to their audiences' needs.

ELEMENTS OF COMMUNICATION

Understanding the vital organs of the communication system (source, message and medium, receiver, and feedback loop) can help you design effective wildlife communications. Failure of any one organ dooms the entire effort.

Source

The **source** of the message is the central person or organization doing the communicating. For example, an agency director gives a public speech on changes in hunting regulations to a hunt club, a scientist explains the release of endangered California condors (*Gymnogyps californianus*) to media representatives, an organization publishes a colorful, fund-raising brochure for members, or a manager facilitates a meeting of wildlife recreationists. The source knows how it wants the message to be received, yet it often cannot guarantee how the message is encoded or how it will be decoded by the receiver. During a speech, the speaker's body language, voice tone, and vocabulary influence how the audience receives the message. For environmental issues, source credibility is important. Most audiences will scrutinize a speech or advertisement by an oil company spokesperson regarding the status of oil development in the Arctic National Wildlife Refuge differently than an announcement by a government agency or environmental organization. It is important that your message is delivered by a source credible to the audience you are trying to reach. Credibility involves a perception of both trustworthiness and expertise.

Message and Medium

Once the source's ideas are encoded or translated, they are transmitted in the form of a **message**. The content of the message, its **medium**, and its source all influence the perception of the message. Simple messages are most easily understood.

"Can you hear me now?" asks a man on a cell phone wandering in a desert, in an advertisement demonstrating the clear range of a wireless network.

"A fed bear is a dead bear" is the blunt message of the New Hampshire Fish and Game Department, to discourage the public from feeding bears and creating potential conflicts.

"Lend a hand—care for the land" replaced the U.S. Forest Service's Woodsy Owl's original slogan: "Give a hoot, don't pollute" in the 1990s. Woodsy was directed at kids ages 5–8, when youngsters begin to form their views about the environment and how they should interact with it. Woodsy also

received a makeover with his new slogan. He now sports a backpack, hiking shoes, and field pants to appeal to modern children (Fig. 24.4).

Messages dealing with more complex issues may be harder to transmit to the public. The concept of prescribed fire as a management tool goes against many people's early indoctrination by Smokey Bear. In a survey of west Florida residents, only 12% knew that regular fires are a natural process maintaining their native pine forests (Jacobson and Marynowski 1997). Slogans to promote prescribed burning have been difficult to design. "Rx Fire: Prescription for Forest Health" is the title of a Division of Forestry's brochure in the southwestern United States. It seems to be more cumbersome than catchy. Personal experience with fire-adapted ecosystems or coverage of wildfires in mass media may stimulate public interest in prescribed burning and create a need for more information (Jacobson et al. 2001). Framing your message and strategically selecting media to reach your target audience is the key to successful communications.

How do you choose the medium that will effectively reach the target audience? Different channels offer different advantages (Box 24.1). For example, mass media has a powerful role in setting the public agenda and reinforcing opinions. However, more detailed publications or interpersonal methods are generally needed to change an audience's actions or shift their opinions. The adoption of new behaviors, such as recycling or composting, frequently occurs as a result of friends, family members, or colleagues introducing people to them (McKenzie-Mohr and Smith 1999). Communications that foster this type of social diffusion of the message provide opportunities to effectively reach your audience.

Fig. 24.4. Woodsy owl received a makeover by the U.S. Forest Service. Adapted from U.S. Forest Service.

BOX 24.1. A SAMPLE OF MEDIA CHANNELS USEFUL FOR REACHING AUDIENCES

- Personal dialogue
- Speech
- Public conference
- Advisory group meeting
- Demonstration
- Direct mail
- Workshop
- Telephone
- Magazine
- Newsletter
- Exhibit
- Guided program
- Web site
- Blog

Target audiences can be segmented by factors including age, education, occupation, recreation activities, geographic location, or environmental values. Using a variety of media may be the answer to sufficiently reach each audience. Different audience characteristics may call for techniques such as speeches and demonstrations or direct mailings and placement of messages in specialized newsletters. Knowing the media habits of your audience is one obvious way to target a message. For example, an article in the Washington Post may effectively reach policy-makers' eyes, but few farmers may ever read it. An article in an agricultural newsletter may better target rural farmers.

The use of more than one channel increases the likelihood of reaching a greater audience and reinforces the message. When selecting media to communicate about wildlife, one must evaluate such factors as potential impact, production and dissemination expense, and audience size (Box 24.2). Television ads may be beyond your budget, periodic newsletters may be too sluggish for your scheduling needs, or lack of staff may turn a special event into a nightmare. A realistic view of the resources and constraints of time, personnel, and money provides the foundation for a successful media strategy.

Receiver

The result of a communication varies. It may do nothing, or it may make the receiver aware of an issue, shift the receiver's attitude, or, more rarely, change the receiver's behavior. An understanding of the receiving audiences is vital in designing messages and selecting media to produce an effective program. Without knowledge of your audiences' needs and concerns, programs often are doomed. Wildlife communicators can be more effective by involving their audiences in the development of messages and dividing their audiences into segments according to their specific needs, interests, habits, or other characteristics. To succeed, messages must be directed to your target audience, whether it is hunters us-

BOX 24.2. FACTORS (AND ASSOCIATED QUESTIONS) THAT INFLUENCE DECISIONS REGARDING APPROPRIATE MESSAGES AND MEDIA

Factors	Questions to ask
Background and habits of the audience	What are the interests and media sources of your target audiences?
Attributes of the message	Does it require background knowledge, maps, graphics, color, or sound?
Urgency of the message	Do you need a response today or next month?
Complexity of the message	Is a 30-sec sound bite adequate for the message or is a lengthy educational publication necessary?
Frequency of the message	Is repetition needed regularly, seasonally, infrequently? Do new people keep joining the target audience?
Personnel required	Is staff time available for personal contact, developing materials, providing outreach activities, interfacing with media, or training volunteers?
Cost	How many in your target audience can be reached, for how long, with what detail, at what price?

ing the resource, homeowners living at the wildland interface, or wealthy urbanites who support your programs.

Audience research can help orient your wildlife communication program to meet your audiences' needs and to promote the products of your organization. Methods for identifying and targeting audiences include collecting data through public surveys, interviews, group meetings, direct observation, census reports, Internet sources, case studies, and networks with organizations that already serve the audience. Researchers in the field of human dimensions of wildlife use sociodemographic information, psychological profiles, consumer behaviors, geographic residence, and a host of other variables to help wildlife agencies tailor messages to audience needs. Audience research allows you to assess alternative strategies for communication channels and messages. It provides a foundation for building support for a program or influencing audience behaviors. Research also provides baseline information with which to evaluate the results of your wildlife communication efforts.

Natural resource managers at Eglin Air Force Base in Florida used their knowledge of their hunting constituents to craft messages regarding feral hog (*Sus scrofa*) control. The managers stressed the need to reduce hog populations to reduce competition with deer and other game species that the hunters valued. The importance of reducing hog damage to preserve endangered pitcher plant (*Sarracenia leucophylla*) bogs was not a compelling message for this audience (Jacobson 2009).

Thus, a wildlife organization or agency needs to be able to communicate with many audiences, each with its own beliefs, self-interests, and concerns. Communication theo-

ries portray information spreading through society from opinion leaders to informed people and finally to uninformed people, like ripples emanating from a rock thrown into a pond. Studies of how ideas diffuse through society show groups of early, average, and late adopters of information (Brown 1981). Knowledge of your target audience can facilitate diffusion of wildlife information to opinion leaders or critical members of your audience. This will improve the likelihood of obtaining the response you want from your audience.

Many wildlife agencies use **interactive techniques** to engage their audiences more directly and continuously, through Friends groups, stakeholder meetings, and citizen advisory boards. In some cases, stakeholder groups are involved in joint decision-making or undertake comanagement activities (Decker et al. 2001, Jacobson 2009). Knowing how to communicate with groups and effectively negotiate decisions is increasingly important for wildlife professionals.

Feedback

Was your message received? **Feedback** will help you evaluate whether you achieved objectives to increase your audience's awareness about a wildlife issue, shifted their attitudes, changed their behaviors, and resulted in a positive change in the environment. Feedback will help identify whether your program worked and how it can be improved. Feedback from local residents targeted in an environmental communication program in Senegal, Africa revealed they were *more* confused about conservation objectives of the government *after* the program. Not surprisingly, no conservation action occurred (International Institute for Environ-

ment and Development 1994). Without systematically obtaining feedback for evaluation, failed programs can be repeated, instead of improved.

Methods to **evaluate** your communication range from formal before-and-after surveys to direct observations of the target audience or their long-term impact on the environment. To measure the effectiveness of a communication program to conserve a rare wildlife species, you might count new members joining your organization or agency volunteer group, funds donated to purchase key habitat, legislators' votes to pass protective measures, increases in public awareness after your campaign, and ultimately, status of the wildlife population after a certain time period. Continuous assessment allows you to modify activities based on timely feedback and new information. Evaluation of products and outcomes tells whether your message and media strategy worked. It allows you to make decisions about the fate of the program—should it be continued, cut, or expanded?

Feedback and evaluation during program implementation allows you to change direction and chart a more productive course. The Florida Wildlife Federation avoided financial heartache by collecting feedback from their members about a new way of communicating with that audience. Before the Federation embarked on a new magazine for its members, they wisely collected information. They sent a sample of 240 members a trial magazine with a written survey. The survey asked members what they liked most and least about the publication and how much they might pay to receive such a magazine. Based on the negative responses to the survey and the high cost of the project, the Federation rejected the entire activity of publishing a magazine (M. Fuller, Director, Florida Wildlife Federation, personal communication).

GAME PLAN FOR COMMUNICATION PROGRAMS

Communication programs help wildlife organizations solve management problems or fulfill needs of their audiences. To succeed, organizations and agencies must understand and respond to their audiences' existing interests and behaviors. Some communication programs target a broad audience with a public awareness campaign, such as providing information about recycling to all homeowners in Colorado. Other programs directly involve groups practicing specific behaviors the organization wishes to change, such as working with hunters to develop new hunting regulations. To assess the nature of communication needs for a wildlife initiative, organizations must have a **G-A-M-E plan**. They must identify their **goals** and objectives, **audiences**, **message** and media strategy, and **evaluation** techniques (Fig. 24.5). This iterative process leads to a communication program that avoids common problems such as targeting the wrong audience or using an inappropriate message or medium.

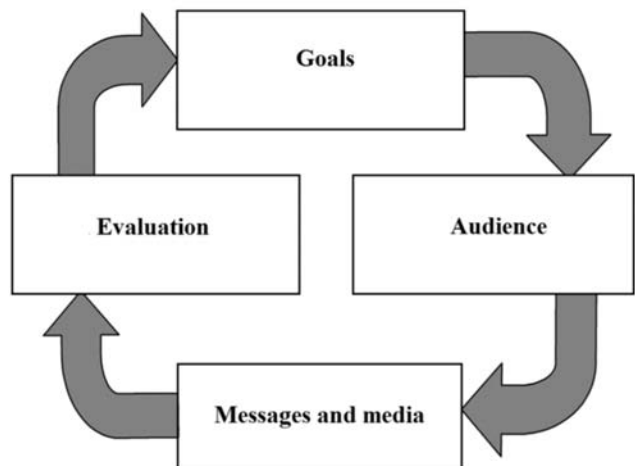

Fig. 24.5. A GAME plan to guide wildlife communications involves an iterative process to identify your **Goals** and objectives, **Audiences**, **Message** and media strategy, and **Evaluation** techniques.

Box 24.3 outlines a GAME plan for guiding just about any wildlife communications program. Most wildlife concerns are urgent. These guidelines help avoid wasting time on ineffective practices or programs. The first step in planning a communication program is determining the goals and objectives. Once the goals are established, objectives specific to target audiences can be identified and you are ready to plan an interview, public presentation, brochure, scientific poster, or public meeting to negotiate a conflict.

IDENTIFYING COMMUNICATION GOALS AND OBJECTIVES

Goals of wildlife agencies or organizations may be to protect endangered species, sustain game animals, conserve land, manage a reserve, or restore a forest. Communication goals generally address problems. Conversely, identifying problems is a good way to formulate goals. An analysis of the context and situation helps determine the specific conservation problem to be addressed. One of the Save the Manatee Club's goals, for example, is the recovery of manatees (*Trichechus manatus*) in the wild. The more clearly the problem is stated, the more targeted a goal will be. The problem, "Manatees are an endangered species" is less helpful for identifying potential communication-based solutions than, "Collisions with motorboats cause manatee deaths in Florida." This problem statement helps to identify a specific goal: "Reduce boat collisions with manatees." It also helps identify specific audiences, such as boat owners, marina operators, or water management district regulators. Now specific objectives can be identified for each audience (Fig. 24.6).

Communication objectives may be related to changing a target audience's knowledge, attitudes, or behaviors. Com-

BOX 24.3. PLANNING GUIDELINES FOR A COMMUNICATION PROGRAM

Goal: What is your goal?

Identify your wildlife problem or issue you want to address. Identify the specific objectives associated with your audiences.

Audience: What audiences or stakeholders are involved in the issues to be communicated? For each audience, what changes or actions are desired?

The audiences should be defined using socioeconomic, psychographic, or demographic analyses to gain insight into nature of the audience, their needs and interests, and their behaviors. Audience involvement is necessary to specify objectives regarding expected changes in knowledge, attitudes, or behaviors that will result from the communication program.

Message or media strategy: What messages must be sent? What channels will most efficiently result in the desired behaviors?

The interests, needs, and motivations of the stakeholder groups must be addressed, and media must be selected that will efficiently and effectively deliver the message to the audience.

Evaluation: How will you know if the strategy worked?

Changes in the environment or in audience knowledge levels, attitudes, or behaviors should be monitored and assessed.

mercial advertisers view objectives in the form of a staircase leading up to their goal of selling their product. The first step is building consumer awareness—the consumer’s ability to recognize and remember the product. The next step piques the consumer’s interest. This increases his or her desire to learn about some of the features of the product and to evaluate these attributes. The remaining steps lead to the consumer’s first purchase and, if all goes according to plan, the repeated purchase and continued use of the product.

This same process can be duplicated in wildlife communications, where each objective may focus on one or several steps. An initial message may try only to increase awareness about a wildlife issue or agency service. A further objective

may focus on increasing concern or shifting an attitude, and a final objective may encourage conservation action. However, increasing general awareness about a problem or product does not guarantee action.

To ascertain whether your communications objectives are met, they must be **measurable**. Often objectives specify the number of people that will display the desired concern or behavior and the dates by which these changes will be achieved (e.g., a 10% increase in visitors to a wildlife reserve per month or 100 new donors to a conservation organization in a year). All objectives should identify the audience, the media and message, desired effect, and timeframe for a communications strategy to be implemented and results attained. When objectives are specific, the program results can be compared with anticipated outcomes to judge success and make decisions about program continuation. Wildlife biologists may want to write objectives in terms of what they hope their intended audience will do. Consider the manatee example: “As a result of receiving a safe boating booklet in the mail, 90% of Tampa Bay boaters will obey voluntary speed zones by the end of the year.”

Goals to Shift Attitudes and Change Behaviors

Attitudes are predispositions to think in a specific way about a specific subject and are mediated by the situation. For example, a homeowner might enjoy watching woodpeckers and other cavity-nesting birds in his yard, but because he finds dead trees ugly, be unwilling to leave a snag standing to provide a nest site. People hold a positive, negative, or neutral attitude toward a particular issue, such as an endangered species. Most people (the silent majority!) are neutral or don’t care, and their attitudes may be shifted most easily (Seitel 1995). Social psychologists have noted that opinion is

Fig. 24.6. Managers of Abaco National Park in the Bahamas invited stakeholders to a participatory planning meeting to share ideas about zoning within the park. *Photo by L. Marks.*

affected by self-interest. A communication will affect public opinion primarily if its relevance to the audience member's interests is clear (Cantril 1972). A wildlife organization wishing to shift public opinion must ask, "What's in this for the individuals whose opinions we are trying to inform?"

People are motivated by various needs and desires. The psychologist Abraham Maslow (1954) developed a hierarchy of people's needs, or drives. His theory suggests that people first fulfill their physiological needs for food, health, safety, and security. Then they progress to fulfill personal drives for a sense of belonging, self-esteem, and, ultimately, self-fulfillment (Fig. 24.7). As people satisfy one level of needs, they move up the hierarchy. Maslow believed that fewer than 10% of people become self-actualized. Knowing where your target audience fits in this hierarchy, or appealing directly to these needs, can help you develop appropriate messages to influence their attitudes. For example, a wildlife refuge may offer recreational opportunities that appeal to hikers seeking to meet needs for esteem or fulfillment, while opportunities for hunting may appeal to desires for a sense of belonging or esteem in hunting clubs. Framing messages to appeal to people's specific needs can reinforce positive attitudes about your wildlife agenda (Box 24.4).

The **values** and **uses** to people of **ecosystem services** can be viewed according to Maslow's hierarchy of needs. These values are useful for communicators to use when trying to promote conservation of natural systems. People's basic physiological and security needs are fulfilled when natural systems provide material uses such as food, clothing, shelter, water, and medicine. Also basic are the life support or ecosystem services that natural systems provide such as clean water, degradation of wastes, and natural pest and pathogen control.

Nonmaterial uses of natural resources and ecological systems address people's higher needs for a sense of belong-

Box 24.4. EXAMPLE OF HUMOR USED IN MESSAGE-FRAMING

Humor or excitement appeals to the public by implying that a product or service is more fun than an alternative.

Humor can be used to lighten critical messages or to just catch an audience's attention. In an advertisement appearing in a January issue of their magazine, The Nature Conservancy presented a tongue-in-cheek list of suggested New Year's resolutions. The ad was displayed on a scrap of paper.

My New Year's Resolutions

1. Get in shape.
2. Take more hikes.
3. Eat more fruits and vegetables.
4. Include The Nature Conservancy in my will.

A Bequest to The Nature Conservancy will make you feel great, too!

ing, esteem, and fulfillment. These include the value of nature for religious beliefs and ceremonial uses, spiritual and aesthetic uses, scientific and educational uses, and physical and emotional recreation. For some people, preserving or delaying use of natural systems for future generations also may meet their need for fulfillment.

Although some argue that nature has values independent of human needs, most people find it difficult to relate to an

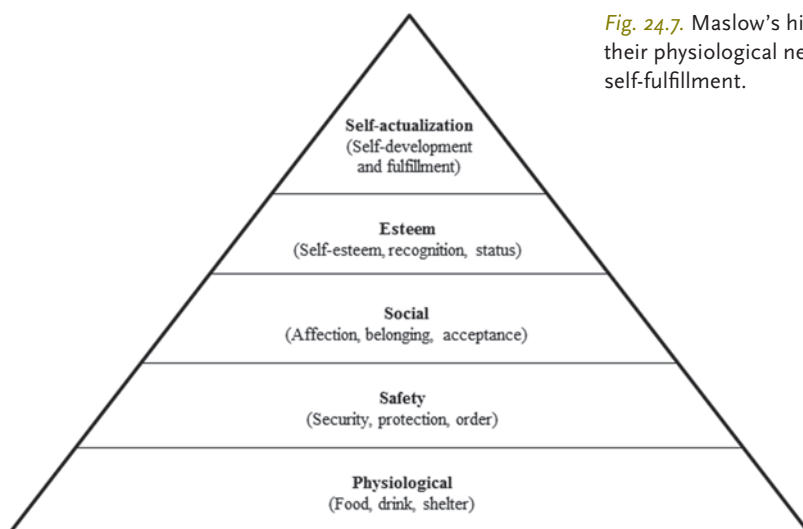

Fig. 24.7. Maslow's hierarchy of needs suggests people must first address their physiological needs before striving for self-esteem and, ultimately, self-fulfillment.

argument about the intrinsic value of natural systems. The belief that nonhuman species and ecosystems have values unrelated to human desires is rare, although perhaps more prevalent among readers of this book. Communicators must deal with the real needs and desires of their target audiences if they expect to achieve their wildlife management objectives.

The goal of many wildlife communications programs is to influence behavior—a difficult task. Increased awareness of a wildlife problem does not guarantee meaningful behavioral changes in support of wise management. The consequences of wildlife problems are often long term, and delayed or intangible benefits provide little incentive for people facing urgent day-to-day concerns. Many conservation problems seem national or global in scope, so individuals believe they can do little to help. Personal actions fail to have noticeable effects because of broader political and economic factors. People often misbehave despite knowledge of the environmentally correct thing to do. They poach wildlife; they do not carpool; they harvest trees unsustainably. Giving people new information will not necessarily change their behavior. People might be aware of the problem, but may not have the knowledge or skills to identify alternatives to their current behaviors or the motivation to comply.

Studies of **environmental behavior** reveal many factors affect conservation action. Educators focus on how environmental behavior depends on cognitive factors, such as an individual's knowledge of environmental issues and action strategies, and skills in performing conservation-oriented activities. Personality factors, such as the extent of responsibility and commitment felt toward the environment, attitudes toward the environment, and perception of the ability to effect change also influence an individual's intention to act in an environmentally responsible manner (Hines et al. 1986/87). Obviously, if someone does not believe they can make a difference, they are unlikely to act.

Marketing specialists use **psychological factors** to predict behavior change. They examine an individual's perception of benefits and barriers to practicing a new behavior (e.g., Smith 1995b, Byers 1996). Marketers believe you must offer people a benefit they want in exchange for their behavioral change. Thus, the benefits must outweigh any costs of engaging in a new behavior. Other researchers focus on social influences or norms regarding the new behavior. For example, whom does the individual care about and trust on this topic, and what do they think that person would want them to do? The **Theory of Reasoned Action** suggests that an individual's intention to behave in a certain way is mediated by how they think their family or friends might want them to respond, as well as an individual's beliefs and attitudes (Fishbein and Ajzen 1975, Decker et al. 2001). Communication researchers have found that resource managers often make the mistake of designing messages that contain only important **factual information** concerning the behavior they desire people to change, failing to consult the in-

tended recipients of the message to identify which of their beliefs really influence how they behave in a particular situation (Ham 1992). All of these factors influence a person's desire and ability to act in accordance with the objectives of your wildlife program.

Communication programs may follow a variety of strategies to achieve the goal of changing behaviors to conserve wildlife resources. Programs must influence not only their audience's knowledge about wildlife and the environment, but also attitudes and behaviors that can promote environmentally responsible actions in the future. It follows that techniques for wildlife communications must be multifaceted to influence knowledge, attitudes, and behaviors, and to involve your audiences in meaningful ways. Understanding the elements of communication and following a systematic GAME plan will help ensure your success.

Determining your goals is the first step in following a GAME plan. Successive steps include: audience identification, message and media strategy development, and evaluation. The following sections provide plans for developing specific types of communications for wildlife professionals. These include giving a news interview, presenting a public or scientific talk, developing a brochure or scientific poster, and negotiating with groups. For any activity, carefully identifying the goals, audiences, messages, and evaluation techniques—your game plan—will help ensure your success.

PLANNING SUCCESSFUL NEWS INTERVIEWS

Many wildlife professionals fear a close encounter with the press, perhaps envisioning a ruthless or ignorant reporter barging into their office. Yet, the consequences of not harnessing the power of **mass media**—newspapers, magazines, radio, television, and the Internet—are dire! What if you planned a special event and nobody came? What if you took a stand on a controversial wildlife issue or designated new hunting regulations without publicity?

Mass communication approaches can help you disseminate your wildlife message. Different types of media transmit messages of varying complexity to different audiences. Your situation and message will dictate the correct media approach for achieving your objectives. The GAME plan for preparing for news interviews follows the general framework that can be used for most mass communication approaches, from advertisements and public service announcements to press kits and news conferences. Following the GAME plan's 4 successive steps should help you put your best foot forward at an interview, rather than stumbling through it.

Defining Your Communication Goals and Objectives

Your overall goal may be to accomplish tasks associated with your organizational mission, such as gaining protection for a particular wildlife species or raising public awareness of an issue to influence legislative actions. Whatever the

medium for your interview—print or electronic—you must keep in mind your communication objectives. To be effective, your message must be interesting, informative, and persuasive. In advance, you must identify 1 or 2 specific messages that are most important for achieving your communication goal.

For example, your objective might be that a majority of the readers of a local newspaper understand your message: “Exotic air potato (*Dioscorea bulbifera*) vines are killing native plants.” A more ambitious objective would be to expect significant changes in behavior, for example, that 5% of the readers act on your message and pull air potato vines out of their yards or join a field day to assist you in removing the vines at your site (Fig. 24.8). Depending on your objective, you will need to carefully craft your message to achieve the desired result.

Identifying Audiences

Identify who is important to achieving your goals. Who are the **stakeholders**? You may need to research your audience to determine their relevant needs, concerns, and interests. What will motivate your audience to retain and accept your message or to shift their attitude or change their behavior? Before participating in an interview, ask in advance about the audience that listens to the station or reads the publication. Knowledge of the audience will guide your specific objectives for your presentation. It will allow you to put your story in a context relevant to the audience by emphasizing values and results that resonate with their lives. For a specialist audience, such as scientists, you obviously will describe your work or program with different words or visual props than for a general audience.

Mass media implies a diverse audience, but even mass-media channels have segmented audiences. For example, the audience of a top-40 radio show will be different from

the listeners of a classical music station. An understanding of the audience members’ backgrounds and common interests will improve your likelihood of a successful interview.

Developing Message and Media Strategies

Once you have identified your audience, develop and write your messages in advance to help organize your thoughts. Practice saying your key message 3 or 4 different ways—use action verbs, pithy phrases, and vivid images. During the interview, take every opportunity to make your point. Focus on components of the questions that allow you to deliver and repeat your message. You should be able to state your message in 1 or 2 sentences and deliver it in one breath. For example, Marjorie Stoneman Douglas, a venerated crusader for the Florida Everglades, is remembered for this sound bite: “The Everglades is a test. If we pass it, we get to keep the planet.”

Other examples of effective messages include: “If you care about clean drinking water, you’ll help us preserve the Jeffrey County Marsh.” Or, “Better protection of this rare wildlife species now will give you more land-use options in the future.” The Nature Conservancy reminds people: “A world that can sustain nature will be a healthier and happier place for our children and their grandchildren.” Note how these messages relate directly to people’s interests and lives.

Identify where your target audiences get their information. **Broadcast interviews** with you or other experts in your organization might complement messages transmitted through specialized newsletters for a specific audience. Ensure that your various media approaches enhance each other. In addition to understanding the audience, learn about the interview format and the background of the interviewer. If the interviewer has little knowledge of your subject, you can plan in advance the detail and explanations that you will provide. Before you give the interview, monitor the paper or show. Study the editorial style of the program in advance. Does the interviewer grill subjects or is he or she friendly? How long will you have? Will others with opposing viewpoints appear with you?

At times, an **interviewer** is looking for a response to some national or regional event (such as an oil spill), new policy (such as property rights legislation), or new study (such as data regarding declining animal populations). You may have 30 seconds to get your point across on an evening news broadcast or 30 minutes on a radio talk-show interview. You can prepare for the interview by anticipating the kinds of questions that might be asked (Box 24.5). Most reporters ask the 5 “W”s: who, what, where, when, and why. Be prepared to briefly answer these questions about your organization or wildlife issue. Always remember your communication objectives—the 1 or 2 messages you want to deliver about your project or position, whether asked about them or not. To help advance your message, be prepared to give specific data. Do not be vague. For example, the answer: “250 land-

Fig. 24.8. Families participate in the “Great Air Potato Round-up,” sponsored by the Nature Operations Division in Gainesville, Florida. Photo by M. Spalding.

BOX 24.5. TYPICAL QUESTIONS ASKED IN A FEATURE INTERVIEW

- What are you trying to achieve?
- What is the purpose of your program?
- What problems have you had?
- What obstacles do you still face?
- How have you handled past (and future) problems?
- When did your program start?
- Who started it?
- How did you get interested in it?

owners signed the petition” is better than “Lots of people support us.”

Interviewers for print and broadcast media have varying time constraints and deadlines. News broadcasts are brief. Public relations experts suggest anticipating questions you may be asked and imagining a 15-second reply in the form of a newspaper headline. Use each question as a launching pad for your key messages. If the interview will be taped and edited, your replies must be self-contained statements that can be aired without any of your preceding or following replies.

For longer interviews, it is necessary not only to decide your message and to repeat it, but also to support your message with data and examples. You can supply written background material to the reporter in advance of the interview. This could include fact sheets about the program or issue and background documents about your organization. Not all interviewers will have the time or interest to take advantage of it, but background material will help them prepare for an effective interview based on your agenda.

Interviewers will probe to discover your program goals, obstacles you have faced, solutions found, and the roots of your activities. Make your point with data and information that support what you have to say. Use a few good examples or anecdotes to vividly dramatize your point. Stories are an effective method for ensuring your message is remembered. Politicians litter their campaign speeches with personal stories to help the audience relate to their message; you should, too.

Evaluating and Monitoring Your Performance

Using mass communication successfully requires an understanding of what makes your activities or events newsworthy. Your organization is newsworthy when you do things that are socially useful, fill a public need, or are just plain interesting (Fig. 24.9). To be newsworthy, a story must appeal to people’s concerns and desires. **Monitoring** can help you evaluate whether you have reached your audience and addressed their interests. Monitoring allows you to modify

Fig. 24.9. Unusual wildlife like this albino alligator attracts public curiosity. Photo by S. K. Jacobson.

your program as you go along. You can assess the outcomes of your communications activity—press coverage, audience members contacted, and impact on natural resources—to identify what did and did not work. Without monitoring, you risk duplicating failure rather than success.

People will read or watch only what interests them. Your topic must concern or touch the audience in some way. Capitalizing on the audience’s self-interest (a quality called *relevance*), will increase the audience’s attention. Whether you are conducting and publishing a wildlife study or protecting an endangered species or parcel of land, you must convey the relevance of your work to your audience.

Monitoring techniques to measure the impact of your interview can range from informal feedback from colleagues to tallies of additional press coverage or specific actions taken by members of your audience, such as votes generated, numbers of participants in an activity, and funds garnered. Regular monitoring helps you assess whether you are achieving your objectives.

Few people are natural stars. Following a GAME plan reminds you to identify your audience, develop your message, and learn exactly what the reporter wants and the format for the interview. This will go a long way toward a successful encounter.

PLANNING A PUBLIC TALK

Some people are more afraid of speaking in public than dying, according to psychologists. Yet, much of daily life revolves around oral communication. You greet people. You give and receive information. Your voice, tone, body language, and appearance combine to communicate information to others. This is also true of speaking to the public. **Public presentations** are delivered in a variety of settings such as auditoriums, outdoor theatres, classrooms, extension program sites, campfire circles, park trams, zoos, and almost anywhere visitors or organized groups can gather. Unlike a media interview, you usually have more control over the con-

tent and duration of your presentation. The principles of effective public talks, not surprisingly, follow the GAME plan for all effective communication. Once you've established your goals, you must identify your audience members and address their needs and interest. By following your plan, you can be an effective public speaker, whether talking to small groups of people or giving scientific presentations to large audiences. Like any successful communication, a good presentation is interesting, targeted to the audience, and organized around your main idea or theme (Box 24.6).

In planning your talk, first clarify in your mind exactly what you hope to accomplish. If your goal is to inform the audience, what are the major themes and points you want them to learn? Do you want to change the way your audience thinks or behaves? What specific actions do you want them to take?

When preparing a talk, think about the content and organization of the subject matter. But don't just think about the major points you want to make—think about what your listeners want to hear and to what they will pay attention.

Professional public speakers, like politicians, never recite only dry facts and figures to an audience. Their secret is to transform the information into a story. They make their major points through stories and follow each story with a punchy statement of fact or opinion. Translating abstract facts and data into stories or relevant life situations makes them matter to people. Try it!

Introduction

The **introduction** provides a succinct explanation of your presentation and defines the purpose of your talk for the audience. It reveals your theme, or main message, and the reason your subject is important. Audiences that are given the theme at the beginning of a talk will have better recall of it later (Thorndyke 1977). Your introduction presents a road map to help your audience follow the talk. It presents the organization of the talk and any ground rules, such as: "Please hold your questions until the end of the show." In the introduction, you can enhance your rapport with the audience by describing what you share in common. You also may wish to

BOX 24.6. TIPS FOR EFFECTIVE TALKS

- Practice ahead of time. As Mark Twain said, "It takes three weeks to prepare a good ad-lib speech."
- Make sure your talk is the proper length of time. Thirty to forty-five minutes is the maximum length for an auditorium program. Orientation presentations should be only 5–15 minutes long.
- Adapt your talk to your audience's background and interests. Simplify things and do not give unneeded detail. Stick to your theme.
- Talk to the audience. Do not hide behind a podium. Stand where the audience can see you and talk directly to them. If you need to write on the board, or point at a slide, stop talking while your back is turned. Then continue.
- Make eye contact with the audience. Some speakers like to pick out a few people in the audience in different areas of the room to focus on during their talk.
- Talk at a rate of about 125 words/minute. Talk clearly; do not mutter. Vary the pitch and tone of your voice.
- Avoid saying "uhmm," and other filler words. Use a microphone if it is provided.
- Use hand gestures and body language to help tell your story and keep the audience's attention. Put your whole body into your presentation. Facial expressions and body movements can show pleasure, enthusiasm, pain, and sorrow. Gesture with your hands and arms to show shape and location or to emphasize an important point.
- Record or videotape your practice talk to evaluate how you do. Watch politicians as they deliver speeches, and see how gestures may work for you.
- Use visual aids to complement your talk. If your props are small, like a rock or leaf, have several specimens that you can quickly pass around the audience. Use your props actively—move them around, have people touch or smell them.
- Use slides, PowerPoint or overhead projections and other visual cues. Use birdcalls, music, or other audio cues to make presentations more interesting and memorable.
- Make sure charts and graphs are simple and clear if you use them, and make sure the entire audience can see or hear the aids you use.
- Do not worry if you are nervous. Most people feel a sense of anxiety before a talk. This can make you seem enthusiastic and help you stay focused on the presentation. Your own interest in, and enthusiasm for, the subject will be contagious.
- End on time.
- Leave time for questions or discussion.

establish your credibility by letting your audience know the reason you are qualified to talk about the subject.

The introduction should create a supportive atmosphere for learning and capture the audience's attention by describing how your subject relates to the audience's needs. Acknowledge your audience and grab their attention with questions, a quotation, an illustration, a story, a picture, or an attention-getting generalization. Why should the audience listen? Tell them something that affects them directly, for example, "We all drink water from Blues Reservoir, but do you know where the water originates?" Or give an illustration that relates the subject to your audience. A provocative statement beginning your talk may help convince the audience to stay. "Picture yourself in a situation where the only food you can eat must be gathered from the forest. . . ." Or grab audience attention with a startling fact: "These golden toads (*Bufo perigrines*) may now be extinct" (Fig. 24.10).

Body

The **body** of the talk presents the factual support for your theme. As the theme is developed, key points are made in a logical sequence and the audience follows along as you elaborate. People only make sense of 5 to 9 new ideas at one time (Miller 1956). Limiting your talk to 5 or fewer main points that illustrate or support your message will help ensure that people will remember them. The amount of information you include in the body depends on the amount of time you have. The use of stories and anecdotes can illustrate your meaning and keep the audience's attention.

Conclusion

The **conclusion** of your speech is the climax. Reemphasize your theme or take home messages and tie the conclusion back to the opening of your talk. The conclusion should suggest what you want the audience to do—how to learn more about the topic and/or take action on the issue. You might want to finish the talk in a memorable way with an anecdote, poem, visual image, or quote. When you finish your talk, don't fade away. Conclude!

Transitions

Do not forget to use smooth **transitions** between the opening, body, and conclusion of the speech. Transitions provide continuity and make the talk easy to understand. Transitions also are needed between each main point you are making. A good transition should summarize the preceding idea, establish the relationship between the preceding and following ideas, and preview the next idea (Lewis 1980). For example: "Now that we know how frogs reproduce, let's see what happens to their eggs."

Visual Props

Once you have identified your goals and audiences and developed your talk, think about **visual props** to illustrate your points. Visual aids can increase audience understanding and

Fig. 24.10. Grab the audience's attention with a startling fact and an interesting photograph. Photo by S. K. Jacobson.

Fig. 24.11. An interpreter at the Monterey Bay Aquarium demonstrates jellyfish anatomy using a plastic model. Photo by S. K. Jacobson.

retention of information by 50–200% (Bunnell and Mock 1990). Many wildlife talks occur outdoors or in settings where a variety of visual props can enhance the presentations. Props can be actual artifacts, such as plant parts, live animals or animal specimens, soil samples, rocks, scientific equipment, or other objects that you want the audience to see. Props also can be 3-dimensional models that illustrate things that are barely visible or difficult to witness. For example, you can show an enormous model grasshopper with clearly visible chewing mouthparts. Staff members at the Monterey Bay Aquarium show their audience a model of a jellyfish to explain its unusual biology (Fig. 24.11). Then, they

hold up a clear plastic bag and let the audience see for themselves the reason that sea turtles mistake plastic trash for their jellyfish prey. The audience clearly sees how their litter endangers sea turtles.

Evaluation

Once your talk is over, breathe a sigh of relief. But don't forget the last step in your GAME plan: **evaluation**. The best way to improve your presentation skills is to carefully evaluate them. Before the actual performance, you can make a videotape of your practice talk and review it, or ask your colleagues to provide feedback (Box 24.7). Feedback from your audience, solicited via comment forms or other methods, will provide direct evidence of the success of your talk and will help improve your next one. Informal feedback from the audience, such as people looking alert during the talk, asking questions, coming up to you at the end of the talk, or contacting your organization at a later date, also is valuable. For many audiences, particularly children, asking

questions about the presentation content or their behavioral intentions after the talk will let you know whether your main points were retained and well received.

PLANNING A SCIENTIFIC PRESENTATION

The GAME plan for most **scientific presentations** is obvious. The goal is to convey scientific information and the audience is generally other scientists. A good presentation can help you accomplish a variety of objectives, such as making professional contacts, establishing your reputation in the field, exchanging information about research findings with similar researchers, and promoting your department or agency. Typical media used for scientific presentations include computer graphic programs and slide-shows. These easily illustrate a scientific subject with a succession of pictures, graphs, tables, and text. Not surprisingly, all of the guidelines outlined for public presentations also apply to scientific talks.

Most scientific presentations fall into 2 categories, 1-hour research seminars for job interviews or departmental colloquia and 15–20-minute presentations at scientific meetings. Generally, leaving the last 15 minutes of an hour-long presentation and 3 minutes of a 15-minute presentation to answer questions and interact with the audience is standard. Ironically, the shorter the talk, the more preparation is required to ensure you make your main points. Similar to public talks, use of slides, PowerPoint or other electronic media, and other visual images should help you introduce your study, explain your methods and results, and discuss the findings. The sequence of visual images and accompanying narration should have a cohesive introduction, body, and conclusion to help you weave a unified story.

Knowing the composition of your audience (students, faculty, researchers, administrators, and/or field practitioners) and the number expected to attend is helpful to design a GAME plan for your presentation. It will help dictate how much time you need to spend introducing the scientific context of your presentation or the details of your methods.

Generally, the **introduction** of a scientific talk lets you set the stage by describing the theoretical or applied context for your research question and the main topics you will cover in the rest of your talk. This focuses the audience on your subject and allows them to understand the logical structure of what they are about to hear. An introductory slide listing the main topics you will cover should adequately orient your listeners. The aphorism for giving talks—"Tell 'em what you're going to say; say it; tell 'em what you said"—is good advice, because you introduce your talk at the beginning, present your information, and reiterate your key findings at the end.

The **body** of your talk will briefly explain your study site, subjects, and methods. It will focus on your results and the implications of your findings. Planning the body of the talk depends on the time available. In a 10-minute presenta-

BOX 24.7. AN EVALUATION CHECKLIST FOR YOUR PUBLIC PRESENTATION

Voice and body

- Suitable voice volume
- Understandable speaking rate
- Varied vocal pitch
- Pleasant voice tone
- Clear articulation
- Language appropriate for audience
- Expressive body language
- Appropriate dress
- Confident manner (your audience will think you are confident if you *appear* confident)
- Good eye contact with audience

Content

- Addressed audience's needs and interests
- Attention-getting beginning
- Organized, logical flow of ideas
- Points supported by examples
- Effective transitions between points
- Effective conclusion
- Clear message
- Precise words
- Vivid mental images
- Good use of illustrations and/or anecdotes
- Visual aids enhance message and points
- Visual aids clear and easily seen

tion, details must be jettisoned and only your most important results described. For longer talks, a more complete discussion of the results and their ramifications is in order. Although this is a “scientific” talk, you are still obligated to present information clearly, in an interesting manner, and to make your findings relevant to the audience. This is just as important for an audience of scientists as for any other audience.

The **conclusion** of a scientific presentation reviews the key findings and ends with your take-home message. The outline for your talk should be built by putting flesh and muscle around the backbone of your take-home message. Your conclusion should logically follow from the introduction and body. The conclusion also can stimulate further interest in the subject by suggesting unanswered questions raised by the results or future lines of research.

It is easy to lull an audience to sleep with an electronic presentation: just dim the lights, speak in a monotonous tone, and show graphics that are hard to see, out of focus, repetitive, or irrelevant to your main topic. Too much text per image and too many images for your allotted time also will lose the attention of your audience.

Tips

To ensure a quality scientific presentation

- arrive early. Arrange in advance for someone to operate the lights and projector and to troubleshoot problems so that you can remain in front of the audience. If no one is available, familiarize yourself with the equipment before your talk; test your computer files. Of course, you will have discussed computer compatibility issues with your host in advance.
- establish rapport with the audience prior to showing slides; talk to the audience before plunging the room in darkness or hiding behind your computer monitor. During the presentation, face your audience (not the image). Stand to the side of the screen and don't block it.
- always preview your graphics. Make sure they show clearly in the darkened room. Make sure computer images are legible and colors contrast well for easy viewing.
- organize your images in sequences to develop a single idea. For example, if your point is to describe forest growth, a wide view of a pine forest will orient the audience. Follow this by closer shots of pine trees, pine cones, and finally pine seedlings. Slide sequences and groups of images are especially good at showing before and after conditions and cause and effect images.
- use sequences of images to reveal the complex nature of a specific topic, such as adding more details to a diagram or additional items to a list. Revealing information progressively also adds an air of mystery and interest to your talk.
- use high-quality images: clear, focused subjects with good composition and color. Include people in some

of your images, where appropriate, such as the researcher collecting data at a field site. People like to look at other people.

- use symbols and bullets to minimize the number of words on text slides. Use simple fonts and large lettering. Choose colors that have good contrast: light text on a dark background is easily seen. Let the colors help emphasize the organization of the talk. Keep a consistent format and color scheme throughout, and select one that is easy to decipher.
- avoid crowding too much information on a slide. Leave spaces between lines and use indentations to help your audience follow along. Graphs, like bar graphs and pie charts, are easier to read than tables or text (Fig. 24.12). Don't frustrate your audience by showing a riot of material they cannot read or comprehend.
- vary the length of time you leave each image illuminated, from a few seconds to a minute or more, depending on the text or image. On average, plan to show images at a rate of 1 slide/15 seconds. This may vary greatly depending on your topic, style, audience, and objectives. Once the image no longer pertains to your narration, change it. Don't let the audience contemplate the image for longer than is necessary to illustrate your particular point.
- do not introduce each image, for example, “This is a giant panda (*Ailuropoda melanoleuca*).” Instead, make your point: “The giant panda is one of the world's most imperiled mammals.” The image should enhance your narration.
- change your voice inflection to keep the audience's attention. If you are showing slides, they cannot see your enthusiastic hand gestures in the dark.

Fig. 24.12. The top slide (graph) depicts results visually and avoids displaying extraneous information. Data from Organ and Ellingwood (2000).

- make your narration anticipate the next image and provide a smooth transition to it, in advance of flashing it on the screen.
- make your talk more interesting and entertaining by adding sound, video, or animation to your PowerPoint presentation.
- practice your talk in front of sympathetic colleagues to get feedback on the content, transitions, clarity, graphics, timing, and delivery. Then, practice your talk. Again!
- end on time, reiterating your take-home message and let everyone know you have concluded. You might want to finish your conclusion with the room lights on to reestablish rapport with the audience.
- allow enough time for questions. Don't be alarmed if it takes the audience a few seconds to blink and muster some questions. Repeat questions before answering if the acoustics are poor. Answer questions briefly and directly. If you don't know an answer, say so. If time permits, you can sidestep a question and remark, "That's a good question, does anyone have a response to that?" Deflect the question to your audience and stimulate some discussion.

Evaluation

Few scientists start out as gifted public speakers. **Feedback** from your friends during practice talks is helpful for improving your presentation. Just like a rehearsal before a theatre production, trying out your talk on colleagues allows you to fine-tune your performance. Ask them for feedback using the checklist for successful talks provided in Box 24.7.

Observing other peoples' presentations also helps. What delivery styles do you like? What annoying behaviors—repeating "uhhm," jingling pocket change, clicking a ball-point pen, not speaking into the microphone—can you avoid? The ultimate evaluation for your scientific presentation is whether you're offered a job, asked to submit your work for publication, provided with additional funding for your study, and the many other beneficial kinds of feedback you can reap from being a good communicator.

PLANNING PRINT COMMUNICATIONS— DEVELOPING A BROCHURE

Wildlife professionals create a mountain of **print and electronic communications** over a lifetime. It starts with your first research proposal as a student and, with luck, expands into a thesis, research reports, professional papers, books, newsletter articles and editorials, presentation abstracts, and scientific posters.

Wildlife professionals also commonly use print media for reaching audiences that visit their refuges or for offsite audiences ranging from legislators to school groups. Brochures, booklets, magazines, guidebooks, Web sites, Blogs, and other electronic media can provide your target audience with a lot

of information, ideas, and illustrations. Publications are easy to disseminate to target audiences, and can be used how and when the audience desires. Printed materials also are relatively easy to produce and revise.

The GAME plan for creating effective print materials follows similar guidelines for any effective communication. This section explores the design of a brochure for popular audiences. The next section describes the development of a professional poster for a scientific meeting. Although the goals and audiences for these 2 types of print media differ, most of the concepts for effective print communication are similar. If you make your material attractive, brief, clear, and dynamic—the A, B, C, Ds of print communication—you will be successful (Ham 1992, Jacobson 1999). Some tips for writing briefly and clearly are provided in Box 24.8. Good writing is a prerequisite for accomplishing communication goals using print media.

Design Elements

Brochures are the most commonly used written format for interpretation at parks and refuges. They are used for many purposes and disseminated as handouts at sites, exhibits, and trails, mailed to groups planning a site visit, and used for fund-raising or membership drives. Brochures also are

BOX 24.8. TIPS FOR EFFECTIVE WRITING

- Write with nouns and verbs. Adjectives and adverbs seldom add vigor to a story. For example, "Bob yelled" is more compelling than, "Bob said loudly."
- Use active, not passive, voice (e.g., Good: "Biologist Bob darted the grizzly." Bad: "The grizzly was darted by biologist Bob.").
- Write simple, ordinary English. Avoid jargon and elaborate words (e.g., write "use" not "utilize" and "now" not "at the present time").
- Avoid using qualifiers, such as "very," "rather," and "little." They sap strength from your statements.
- Be clear. As Mark Twain admonished, "Choose the right word, not its second cousin."
- Relay your message using elements of interest to the reader.
- Be specific and provide details; do not be vague.
- Be concise. Use short sentences and paragraphs; they are easier to read.
- Rewrite, rewrite, rewrite. Particularly when you are starting out, the wastebasket or delete button is your best friend.

dispensed at nearby hotels and at other public lands or agencies. For much of the lay public audience, if the cover of a brochure does not look inviting, few will make the effort to delve into the text, no matter how scintillating the writing.

Following a GAME plan, your communication goal and specific audience will dictate the design and content for your brochure. Think about the main goal of the brochure and what you want your readers to know or do. To attract most audiences, a brochure should have a catchy title, bright colors, and an inviting layout (e.g., Brigham 1991, Fazio and Gilbert 2000). Brochures for a general audience are written for an eighth-grade reading level. If your audience speaks English as a second language or is not familiar with your subject, visual images may relay your message better than text. Collect and study brochures that catch your eye from other organizations before deciding on a design for your brochure. Your budget and the number of copies you need will limit some choices, such as glossy paper or full-color graphics. An attractive brochure does not have to be expensive.

Catchy Covers

Keep the title brief and thematic. Short titles of 10 words get read more. For example, “*Insects—We Can’t Live without Them*” or “*Water—Lifeblood of the Everglades*” give a snappy overview of the theme of the brochure. Keep your target audience in mind. If the brochure is for hikers, hunters, boaters, or other specific audiences, mention them in the title. For example: “*Insect Ecology for Successful Fly Fishing*” or “*Boater’s Guide to Seeing and Protecting Manatees*.” Draw readers in with an emphasis on their personal interest.

A single photograph or illustration on the **cover** is usually more effective than multiple visuals (Fig. 24.13). Make the visual interesting by showing something happening. Ac-

tion shots of a bear eating berries or people hiking through a forest have more appeal than an inactive bear or a forest setting. Use bright colors or a high-contrast design to attract people. Select colors that help emphasize your theme, such as red for a brochure on prescribed fire or blue for marine ecology. Resist the urge to fill the cover with your agency logo. This identifying mark should not distract from the main message and illustration.

Body and Content

The **body** of the brochure should make use of subtitles, photographs, and other graphics to break up the writing. Many people will only read the headlines, so you need to make it obvious why the reader should continue. Some tips for ease of reading are below.

- Use wide margins and extra white space (empty areas) around the headlines and between sections to make the brochure look casual and easy to read. Empty areas attract the reader’s attention.
- Use a simple font to make the page look inviting. Try a bold, sans serif font (e.g., Helvetica or Futura) for the headings and subheadings and a serif font (e.g., this print), which is easier to read, for the text.
- Consider using direct quotes or question-and-answer approaches. These often entice people to continue reading.
- Use bullets or check-boxes to add interest and help organize the text.
- Use simple graphics, maps, and charts. Your photographs or illustrations should be sharp and compelling.
- Put captions (in a different size or font from the text) under photos and graphics. People often read captions, second only to headlines.

Fig. 24.13. A brief title and single, interesting image attracts readers to these brochures.

- Ensure that your layout, colors, text, font, type size, and visual images all reinforce your overall message. The headings, captions, and images should create a visual order so the audience can easily follow the information in a logical sequence.
- Follow the tips for effective writing (see Box 24.8). You need relevant and interesting content to hold attention and accomplish your communication goal.

Evaluation

All communications benefit from **evaluation**. Have members of your target audience evaluate your brochure before you invest in publication. Ask a dozen members of your audience, as well as other experts in your field, to review the draft brochure. Have several versions of the theme, content, and design from which they can make a selection. Their feedback can help you avoid the common mistakes in brochure design that reduce readership, such as the following:

- The page is too jammed with information.
- The type is hard to read.
- Organization is poor and the reader cannot follow the flow of the text.
- The page lacks white spaces and does not provide breathing space for the reader.
- Nothing in the brochure stands out; it looks like a page of gray.
- Headings are too small or columns are too wide.
- Paragraphs and sentences are too long or complex.
- Pictures or items of visual interest are lacking.

Once you have received feedback, you are ready to revise your brochure. Get more feedback if revisions are extensive. If not, you are ready to go to press.

PLANNING A SCIENTIFIC POSTER

The advancement of scientific knowledge depends on effective communication of research findings to the scientific community as well as the wider public. **Poster sessions** are an important form of communication at many scientific meetings. Poster sessions allow you to highlight the main message—your research findings. Viewers can study your poster at their own pace and discuss the results with you in an informal and interactive setting. Poster sessions of the annual meetings of The Wildlife Society, the Society for Conservation Biology, and the Ecological Society of America have hundreds of scientific posters on display.

The GAME plan for a poster follows the usual guidelines of identifying your **goal**, **audience**, **message**, and **evaluation** process. The goal of a poster is to convey scientific information in a visual format to an audience, primarily comprised of other scientists. Similar to a good oral presentation, an effective poster can help you make professional contacts, exchange information about research findings with other re-

searchers, and promote your organization. With some planning and preparation you can create an effective poster presentation and a great impression.

Attracting Viewers

How do you attract viewers to your poster? The type of meeting you are attending allows you to determine your probable audience. You'll be competing with scores of other posters and often a concurrent social gathering. The same principles for designing an effective brochure apply to posters. Qualities of attractiveness, brevity, clarity, and dynamism are crucial to hook your audience. The audience will want to briskly scan the important points of your poster to see how it relates to them. An inviting title, attractive graphics, and clear layout will entice your audience to give your poster a closer look. Study other scientific posters that catch your eye before deciding on a design for your poster.

Content

The conference organizers will often dictate the format of a poster. Posters may be required to include a title, authors and authors' affiliations, abstract, introduction, methods, results, discussion, conclusions, and literature cited. A good poster is organized around an introduction, body, and conclusion, similar to an oral presentation. The title should concisely communicate your main message. It should catch the attention of the audience and arouse their interest in your subject.

The introduction should briefly indicate the reason the topic is important, placing it in the context of other scientific literature. It should state the hypotheses and objectives of your study and briefly explain your methods. A photograph of your study organism or site helps illustrate this section. If a separate methods section is needed, you can briefly describe your experimental equipment, techniques, and statistical analysis. Often a flow chart or brief table can be used to illustrate the research design.

You should **illustrate** the most important results, visually, if possible, using graphs, photos, and other illustrations. Describe briefly whether the study supported your hypothesis and whether the experiment worked. The figures illustrating your results should have legends that concisely state your major findings. This may be all many viewers read. The main conclusions and implications should be discussed. This section should summarize the hypothesis and results, and tell everyone the reason they are noteworthy relative to other studies and to the real world. Literature citations can be placed at the bottom of the poster because only the most dedicated will want to peruse them.

Keep in mind that most people will spend about 10 seconds gazing at your poster, so you must catch their interest with your title and graphics. Few will spend more than a few minutes. This limits the amount of text. It is important

to curb the urge to tell the viewer everything about your study. Instead, you must be satisfied if your main messages are successfully communicated. Colleagues who are involved in related research will no doubt spend time chatting with you at the poster session—then you can tell them the details. It's a good idea to have your business card or an abstract of your study available next to the poster for viewers who want to request more information later.

Layout

Your poster is made up of 3 components: text, graphics, and empty space. A rule of thumb is to have equal parts of these 3 elements. Just as in the brochure design, the empty space helps make the poster look inviting and easy to read. Visual material, such as photographs, drawings, diagrams, charts, graphs, and tables will make the poster attractive and emphasize your main points. Charts and graphs are usually easier to absorb at a glance than tables. These should be simplified to enable the reader to understand the main points quickly. To create more empty space, avoid extraneous text and distracting graphics. Colors, graphics, and text should work together to make the poster easy to read. The size of the text and the colors selected for text and graphics help orient the reader and emphasize the main points. Larger text for headings and subheadings will indicate the organization of the poster and can be used to emphasize important points. Choosing a light, unifying color for the background and 2 or 3 dark, contrasting colors for your various-sized text and graphics will make your poster stand out and can highlight your photographs and other visual materials. Color can be used to associate related text and graphics and to separate various sections. However, too many colors can confuse the viewer.

Conference organizers will usually specify the size of the posters. A vertical format that is about 120 cm high \times 100 cm wide is common. The poster title should have lettering large enough to be read from 4 m away to reel in prospective viewers. Poster text should be legible from a distance of 2 m. This requires font sizes of 90–110 point for the title, 48–72 point for section headings, and 24–36 point for the text. Some scientific posters use a minimum text font size of 18 point, but see what **you** can read from a 2-m distance from the poster. If you can't read it, no one else can. Only the least important information should be printed in smaller fonts. The headings and subheadings form different levels to emphasize your main points and lead the reader to the conclusion.

The layout should follow how people usually view material. English speakers are used to reading from left to right and from top to bottom. Their first glance at your poster will be at the center. Attract them with your succinct title and effective graphics. Then, don't confuse them. Your overall format should proceed from left to right and from top to bottom. If the allowable poster size is large, think carefully

before you fill all the space. Few people will squat to read your conclusions if they are printed at knee height.

Many of the design elements for posters are common sense if you keep the audience in mind. Posters often display text and graphics in 3 vertical columns because of the size of the text font and the number of words (about 11) that fit across each column and make it easy to read. Lowercase print is more legible than all capital letters. Using all capitals reduces reading comprehension by 25% and reduces speed by 14% (Tinker 1963, Ham 1992). This means capitalize only the first letters in your title and headings to maximize ease of reading. Bulleted lists are easier to read than full sentences or numbered items. A clear graph or chart is more succinct than a lengthy table.

Evaluation

Similar to other communication materials, it is imperative to pilot-test your poster with members of the target audience. Feedback is critical. Before you print your poster, make a small mock-up and ask your colleagues to critique it. Are they confused? Can some verbiage be eliminated? Do they understand your main points? Are your graphics clear? Fix it before you waste time and money printing your final poster. Once you are at your meeting, observe viewers as they pass your poster to see if they read any or all of it, react to the information, talk to each other about the information, ask you questions about it, and ask for any follow-up information (Fig. 24.14). You also should ask colleagues and experts in your field for additional feedback about your poster—what could be changed or improved in future posters. Also, take advantage of the opportunity to study other posters that attract many viewers. Can you identify common elements that are interesting or stimulating? Similar to all forms of communication, if people don't read or can't understand your message, have you really communicated?

Fig. 24.14. A graduate student explains her study at a conference poster session.

WORKING WITH STAKEHOLDER GROUPS

Successful wildlife agencies and organizations do not operate alone. **Collaborations** with community groups, partnerships with other organizations or businesses, establishment of friends groups and volunteer programs all can multiply conservation success and help organizations achieve their conservation goals. Strengthening existing institutions or forging new partnerships involves communication skills from start to finish. Working effectively with groups of supporters and even opponents is necessary for your long-term survival. Working with a diversity of people and groups also requires skill in facilitating group discussion and decision-making activities as well as in the art and science of negotiation. Developing and following a GAME plan for your work with groups is also necessary for success. Understanding a variety of ways to work with groups can help ensure that wildlife management goals and objectives can be achieved. Here are some key factors to consider in working with groups to make difficult management decisions and solve problems.

Many wildlife stakeholder groups depend on informal or formal discussion to achieve their objectives. Specialized discussion groups are found in different settings, ranging from informal roundtable discussions to more formal panels, seminars, and specialized conferences. The members of more formal decision-making groups usually volunteer or are assigned to the group based on their interests and expertise. More formal groups generally have designated rules for communicating. Members are expected to follow agreed-upon rules for communication that dictate who can say what to whom in what way. These sorts of formal rules and restrictions result in group members exchanging information by following an agenda, Robert's Rules, or a specific conference format. A successful meeting is efficiently run and achieves the stated objectives. Being part of a clear, democratic process allows people to enjoy participating in an effective group. Allowing time before or after the meeting, particularly with refreshments, can further social interaction and the development of long-term relationships and trust.

Working with groups is not easy. Members may have radically different personality types, cultural backgrounds, experiences, and interests from yours. That is the point. You can gain new perspectives, creative ideas and solutions, and broader bases of support because of these differences. Working in groups also helps to share the workload. It can even be fun. Box 24.9 offers some general tips for working successfully with groups. From active listening to setting realistic goals, communication skills are needed. How will you know if you are successful?

Negotiation and Conflict Resolution Activities

Many agencies are involved in collaborations and negotiations with a variety of audiences, such as hunters, hikers, or landowners. Conflicts over natural resources seem to be inevitable. This is because there is a complicated network of

BOX 24.9. GUIDELINES FOR EFFECTIVE COMMUNICATION IN GROUPS

Working on relationships:

- Allow time for introductions.
- Acknowledge that all members have needs and sensitive feelings.
- Understand and respect the background and cultural norms of group members. This is especially important if they differ from your own.
- Make accommodations for differences (e.g., language interpreters for multicultural groups or logistical support to meet needs of people with disabilities).
- Listen actively and nonjudgmentally to what each person is saying.
- Accept that there may be more uncertainty and, perhaps, anxiety in the meeting process when many types of people are involved.
- Beware of your own biases; do not stereotype people.
- Be honest.
- Be humble.
- Show enthusiasm.

Working on the meeting:

- Set realistic and shared goals.
- Determine time and resource constraints.
- Agree on leadership and on a means to reach decisions (voting, consensus, etc.).
- Agree on how, and with whom, group participation happens.
- Agree on a system for delegating tasks.
- Deal with conflict as it arises.
- Welcome creativity and innovation.
- Establish a schedule and benchmarks for action.
- Ensure the meeting accomplishes something.
- Evaluate the results and learn from them.

stakeholders—many groups are affected by environmental regulations, land development, watershed protection, and other issues facing many communities. Conservation professionals play a key role in building support for sound environmental policy and actions. Some conflict can be helpful. It can foster new perspectives and practices. **Consensus-building processes** can be used to foster dialogue among stakeholders, improve the information on which a decision is based, and resolve controversial issues in ways that all parties find acceptable. Communications may involve informal interactions to promote participation by affected stake-

holders to build a broad base of support for an issue. More formal negotiation or mediation processes may be necessary to resolve more intractable conflicts. Although trained mediators may be necessary, it is important for wildlife professionals to understand the steps of negotiation.

Negotiation is a (2-way) communication designed to reach an agreement when you and the other side have some interests that are shared and others that are opposed. Natural resource conflicts are particularly difficult for a number of reasons. Stakeholder groups have different levels of expertise and resources; strongly held values are often in conflict; issues are complex, and existing regulations may inhibit flexibility and options. Environmental disputes are sometimes resolved by trying to determine who is “correct” or who is more powerful. However, better decisions are made when people focus on reconciling their interests. “Flight or fight” is not the appropriate response to conflict. Principled negotiation is.

If effective negotiations do not take place, conflicts may spiral as positions harden and stakeholders take “sides.” Communication stops and crises emerge. If bargaining focuses on the differences among positions, unwise agreements can be produced. Inefficient and dragged-out bargaining occurs, damaging relationships among stakeholder groups. Residual anger and distrust will contribute to future problems.

Many books and resources are available to help guide negotiation practices. Business and policy curricula offer entire courses in negotiation. *The Conservation Professional's Guide to Working with People* (Bonar 2007), provides in-depth guidelines for resolving conflicts among stakeholder groups involved in environmental management conflicts. The following 4-step summary for a GAME plan is from the well-tested guide, *Getting to Yes: Negotiating Agreement without Giving In* (Fisher and Ury 1991). The authors have helped to negotiate everything from Middle East peace settlements to international reductions in nuclear risks. They provide a GAME plan for being effective, principled negotiators.

The goals of any negotiation are to make sure everyone's interests are acknowledged, to maintain cordial relations with your stakeholders, to creatively investigate options to try to meet people's diverse interests, and to base decisions on transparent and objective criteria. The audience is your stakeholders (groups that have an interest, or stake, in a wildlife issue or management concern). The media channel is generally face-to-face meetings but also may include electronic communications. A key requirement of negotiation is the time and effort for building relationships within the group to foster trust and effective decision-making. Evaluation of a negotiation is centered on assessing how well you achieved your goals in order to attain the best solutions possible. One outcome of the negotiation should be that group members will be satisfied with the process and will want to continue to communicate and interact in the future. Implementation of your GAME plan for a successful negotiation will depend on following 4 steps:

Step 1. Focus on Interests, Not Positions

It is tempting to keep rehashing your position over and over until you are so entrenched you reach an impasse. It is better to acknowledge that you are stuck and take a step back to try to focus on your actual interests. Do you know where you agree and disagree? Negotiations often break down because the parties focus on areas of disagreement. Behind opposed positions lie shared and compatible interests, as well as conflicting ones. Ask “Why?” and “Why not?” to help identify interests. As discussed in Chapter 2, Maslow identified many powerful interests—our basic human needs, such as security, economic well-being, a sense of belonging, and recognition. Make sure everyone's interests in relation to the problem are clearly identified and acknowledged. Do not just dwell on areas of disagreement. Try shifting the focus of your discussion to areas of agreement and shared goals. Focusing on a shared goal may highlight a trail to lead you to a wise solution and acknowledging your areas of agreement may ease the hike up that trail.

Step 2. Separate People from the Problem

It is important to build a good working relationship with all sides in a conflict. This is most easily done *before* there is a conflict. Some of the activities described previously, such as developing partnerships or establishing stakeholder advisory groups, can help nurture relations among different groups. Every negotiation ideally maintains a good relationship between contending sides while focusing on the substance of the problem. The groups should view themselves as partners in a joint search for a fair agreement advantageous to each. By dealing directly with the people and communicating that you understand their interests, you can help separate emotions and egos from the substance of the negotiation. This, of course, is easier said than done. It helps to practice the basic tenets of emotional intelligence, such as identifying how people are feeling and understanding the consequences of their emotions and yours.

Step 3. Generate a Variety of Options

Negotiations sour because the parties keep repeating their positions without adding anything new. By identifying the shared and unique interests among the parties, you can begin to look for ways in which everyone can gain. Try brainstorming ideas to overcome obstacles. Ask specifically what would make people change their minds or support broader interests. Don't assume a “fixed pie”; instead, find ways to broaden the pie to begin to address the interests of everyone and solve their individual problems.

Step 4. Base the Result on Objective Criteria

People like to be treated fairly. It is important that the results of your negotiation are based on objective and clear criteria. If you were negotiating your salary for a new job, you would want to know what others with your background and doing the same work were being paid. Do the

same sort of research to bring in objective information to any negotiation. Frame each issue or problem as a joint search for objective criteria. This means you need to keep an open mind and actually want to identify fair standards and procedures for resolving conflicting interests. Joint problem-solving can help build better relationships.

Like all communication processes, it is important to define and keep in mind your objectives to ensure you make wise decisions, including the decision to try pursuing another avenue. Sometimes it is helpful to bring in a mediator or third party to ensure an open discussion of interests. They can provide an impartial view and help separate the discussion of options from the actual decision-making.

The 4 steps are useful to practice whether you are negotiating with wildlife stakeholders about management options or even with your partner over what movie to see: “What type of movie do you feel like?” (Define interests) “What movies are playing?” (Identify options) “You choose this time, I’ll choose next.” (Use fair standards) And so on!

Like any group activity, the negotiation process has inherent constraints as well as much value. Some of the criticisms of environmental dispute resolution include the potential lack of focus on scientific information. Sometimes negotiations resolved at local levels address issues that should involve a national dialogue, and groups such as urban environmental organizations are left out. Other critics argue that the process may include groups with unequal resources such as time, money, information, and negotiation training (O’Leary and Bingham 2003).

It is important that negotiation processes are as transparent and inclusive as possible to ensure that good and satisfactory decisions are made. Recommendations for environmental negotiation include the following best practices. These criteria can be used to evaluate the success of your negotiation. Of course the long-term impact should be the wise management of wildlife resources and the continued positive relationships with your stakeholders.

- All interests are represented.
- The process is driven by a purpose that is shared by all sides.
- Participation is voluntary.
- Participants share responsibility for the process and the outcome.
- High-quality information is incorporated.
- Participants are encouraged to challenge assumptions, learn, and find creative solutions.
- All participants are able to participate effectively.
- The outcome should be just.
- The outcome should serve the common good and contribute to the sustainability of natural and social systems (O’Leary and Bingham 2003).

SUMMARY

Effective communications are essential for influencing conservation policy, changing people’s behaviors, garnering funds, sharing scientific advances, and negotiating conflicts. The fate of our wildlands and wildlife resources depends on effective communications with a variety of audiences in a variety of places. This chapter described the communications process and provided guidelines for several common communication channels used by wildlife professionals, including interpersonal approaches such as interviews, public talks, and group negotiation; and the design of print media such as brochures and scientific posters. Following a GAME plan that includes identifying goals and objectives, analyzing audiences, selecting media and message strategies, and evaluating your impact will help ensure your communication success. As the National Outreach Strategy drafted in 1997 by the U.S. Fish and Wildlife Service stated: “It is our job to speak up for the wild creatures that cannot speak for themselves” (<http://www.fws.gov/policy/NationalOutreachStrategy.html>:1). By following a systematic plan, all communications by wildlife professionals should be effective and efficient.

Adaptive Management in Wildlife Conservation

JOHN F. ORGAN,
DANIEL J. DECKER,
SHAWN J. RILEY,
JOHN E. MCDONALD, JR.,
AND SHANE P. MAHONEY

INTRODUCTION

ADAPTIVE MANAGEMENT in wildlife conservation emerged from the wildlife profession's search for better solutions to increasingly complex conservation challenges. This search for solutions and better management practices arose from a deeply felt, if poorly defined, sense of vacancy in our conservation delivery mechanisms. Lancia et al. (1996) articulated the philosophical premise for the reason that ecological science and wildlife management should link together within an adaptive management framework. Riley et al. (2003b) expanded the concept to integrate social and ecological science, and incorporate stakeholders in the wildlife management enterprise. Today, the term "adaptive management" is used widely in wildlife conservation, although it often is used to describe practices that, at best, merely approximate true adaptive management. The term itself connotes flexibility and responsiveness, traits many people find admirable. The attractiveness of this concept has led wildlife managers, in most cases, to be more adaptable; a few have actually pursued adaptive management.

The **primary principle** underlying adaptive management is the following: decision-makers should learn from their management interventions and apply that knowledge to development of more effective management interventions in the future (Holling 1978, Enck et al. 2006, Williams et al. 2009). Simply stated, this means "learning by doing," but true adaptive management is a rigorous **stepwise process** designed to achieve learning from the management experience. "**Adaptive**" should not be confused with the term **adaptable** in the case of wildlife management. The latter term refers to an ability to change oneself or a management system in adjusting to occurring changes. In ecology, adaptability often is used to describe the ability of ecosystems, or components of ecosystems such as a wildlife population, to cope with unexpected disturbances in the environment. To be adaptable is a desirable trait in managers, but nonetheless means something quite different than managing adaptively. The latter is a rigorous and disciplined process of conscious application; the former often one of reactive technique gradually emergent from experiential learning (Box 25.1).

Each step described in this chapter must be executed for the process to be legitimately called adaptive management. Skipping or inadequately addressing any step compromises the integrity of the process, impairs our ability to learn from management actions (White 2001), and degrades our capacity to effectively apply new insights in a timely and appropriate manner. Thus, adaptive management necessitates a commitment of time and resources above what is required for "**normal**

BOX 25.1. DEPARTMENT OF THE INTERIOR DEFINITION OF ADAPTIVE MANAGEMENT

Adaptive management (is a decision process that) promotes flexible decision-making that can be adjusted in the face of uncertainties as outcomes from management actions and other events become better understood. Careful monitoring of these outcomes both advances scientific understanding and helps adjust policies or operations as part of an iterative learning process. Adaptive management also recognizes the importance of natural variability in contributing to ecological resilience and productivity. It is not a “trial and error” process, but rather emphasizes learning while doing. Adaptive management does not represent an end in itself, but rather a means to more effective decisions and enhanced benefits. Its true measure is in how well it helps meet environmental, social, and economic goals, increases scientific knowledge, and reduces tensions among stakeholders.

From Williams et al. (2009).

management” and is not essential for all wildlife management situations. However, executed properly, adaptive management is an investment in the long-term durability and success of a wildlife management enterprise (Lancia et al. 1996).

Wildlife management typically involves making decisions under circumstances where uncertainty may exist about almost every aspect of the management environment. Estimates of an animal population’s size or demographic features may lack reliability (Williams et al. 2002, Skalski et al. 2005), or even be unknown. The relative importance of different habitat features to a population’s viability may not be well understood (Morrison et al. 1998). The most important positive and negative outcomes of interactions people have with wildlife or their habitat (referred to as **impacts**), and the consequences of these, may not be adequately described, nor the significant stakeholders identified or already engaged (Riley et al. 2002).

Contributing further to overall uncertainty are the dynamic natures of the coupled social–ecological systems managers work with in wildlife management. Change is an inherent part of natural processes and ecosystems. Change also is an inherent trait of human social systems. In addition, anthropogenic forces are influencing change in natural processes in diverse ways and at unprecedented rates; changes that, in turn, influence human emotional and cultural responses.

These multiple influences on an organic system coupled with variable rates of change among them make for a management environment with high degrees of uncertainty. It is a complicated business.

Adaptive management has been described as a way to embrace such change and uncertainty (Riley et al. 2003b, Williams et al. 2009). Holling (1978) and Walters (1986) established techniques for applying adaptive management principles to environmental assessment, drawing from systems dynamics (Forrester 1968) and industrial operations theory (Ackoff 1970). The promise of adaptive management for addressing complex, uncertain, and dynamic systems then led to its adoption in wildlife management (Johnson et al. 1993, Williams and Johnson 1995, Lancia et al. 1996, Williams 1997, Riley et al. 2003b). In many respects, however, adaptive management has been more significant as a concept than a management practice (Lee 1999). Its conceptual power lies in its encouragement of managers to evaluate the effects of their management actions, to learn and adapt, all within a coordinated and iterative process. In fact, it is the circularity of its conceptual dynamic, foraging, and fertilizing within a specific problem landscape, that gives adaptive management its traction in evolving states of knowledge.

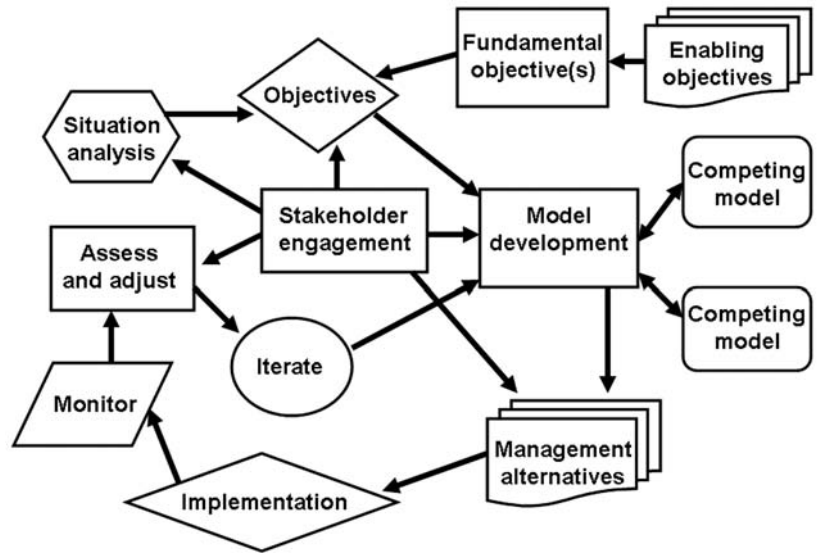

THE ADAPTIVE MANAGEMENT PROCESS

Adaptive management taken simply is **an iterative stepwise process** beginning with an analysis of the situation requiring management, then working through several steps: engagement of stakeholders in defining management objectives, model(s) development based on hypotheses about the system to be managed, identification of management alternatives, implementation of management interventions and monitoring of the system’s response, making adjustments to the model(s) based on system responses, refining the management alternatives and then implementing refined interventions, and so on (Fig. 25.1). An adaptive management process builds on itself such that continuous learning from management actions and rapid reapplication become integral components of the wildlife manager’s job. Capturing the learning and packaging this for reentry into the process emerges as the critical factor, requiring disciplined ongoing analysis of new insights and probabilities.

Situation Analysis

Wildlife management typically occurs within a complex system where ecological, social, political, and economic factors interact. Identification of these factors, their effects on each other, and their relative importance helps to frame the management situation and the likely scope of management decisions. This framing process is termed **situation analysis**, but also may be called context analysis, problem definition, or problem scoping. Whatever it is called, this process is best conducted in 2 phases. Phase I is when the wildlife man-

Fig. 25.1. A diagram of the adaptive management process.

ager and team develop an initial assessment of the management challenge and the social–ecological context. This is akin to getting one’s house in order. The scope and complexity of the situation will dictate the scale of effort and to what extent the management team will require practitioners from multiple disciplines. It also will inform the range and identity of stakeholders who need to be engaged.

Let us examine a real case study. In insular Newfoundland, Canada, a dramatic decline in woodland caribou (*Rangifer tarandus caribou*) has alarmed the hunting outfitter industry and other citizens, who contend that predation on calves by black bears (*Ursus americanus*), coyotes (*Canis latrans*), and Canada lynx (*Lynx canadensis*) is responsible for the decline (Mahoney and Weir 2009; Fig. 25.2). Others have

suggested that land-use impacts (largely induced by extractive resource industries such as oil, gas, mineral, and timber) are the major drivers for the decline, either through direct energetic effects on disturbed animals or indirectly through displacement of animals from preferred foraging and predator-escape terrain. Still others suggest climate change effects on habitat have a significant role to play.

Using an intensive review of existing knowledge, the Province’s wildlife managers have scoped out the available intelligence, initiated new inquiries to address knowledge gaps, and are using this understanding to generate a conceptual management system that illustrates the presumed interaction of climatic, ecological, biophysical, socioeconomic, and political factors. Each of these categories is sufficiently

Fig. 25.2. Adaptive management is being applied toward reversing the decline of woodland caribou in insular Newfoundland, Canada. One suspected cause of decline is predation on calves by black bear, coyote, and Canada lynx. Photo of caribou, black bear, and coyote by Sustainable Development and Strategic Science Branch, Government of Newfoundland and Labrador, Canada; photo of caribou calf mortality by J. F. Organ, U.S. Fish and Wildlife Service; photo of Canada lynx by J. H. Vashon, Maine Department of Inland Fisheries and Wildlife.

complex to be viewed as a subsystem unto itself (Fig. 25.3). This initial analysis will reveal the key stakeholders, the context within which decisions will be framed, and the limits, constraints, scope, and opportunities for management. In this particular example, the wildlife managers determined they needed to enlist expertise in population dynamics, resource economics, sociology, and landscape ecology as part of the management team now formed. We refer to the product of this initial phase of situation analysis as a manager's model (Decker et al. 2009; Box 25.2).

Phase II of situation analysis involves engagement of stakeholders. A **stakeholder**, in the context of adaptive management, is any person who affects, or is affected by, the wildlife issue or wildlife management approach under consideration (Organ et al. 2006). The latter half of the 20th century saw a shift in how wildlife management agencies perceived the public and vice versa. Historically, **wildlife managers** were the experts who determined what was best for the public as far as wildlife was concerned. This expert authority model derives from the Prussian forestry roots of wildlife management (Gill 1996). Public acceptance of this expert authority approach waned as broader segments of society sought to exert influence over wildlife management programs and policies.

Recent trends have been toward an increase in participatory decision-making (Decker et al. 1996; Jacobson et al. 2010). The purpose of stakeholder engagement in situation analysis is to affirm the management need (i.e., to accurately identify impacts-based management objectives) and apply local knowledge to refine or validate the management system. Of greater importance, potentially, is to foster public trust and ownership in the management process by ensuring transparency and participatory engagement throughout the decision-making process. Stakeholder engagement is an art and discipline unto itself. Depending on the scale of the issue or the risks at stake, enlisting a professional to manage the stakeholder engagement process may be war-

BOX 25.2. THE PRODUCT OF THE INITIAL PHASE OF SITUATION ANALYSIS IS A MANAGER'S MODEL

A manager's model is:

- A portrayal of desired conditions, actual conditions, factors that influence conditions, and considerations to be made before taking actions.
- A broad view of what needs to be managed to achieve objectives, with respect to a particular resource.
- Adaptable in that, as one learns more about the management system, the model should be modified.

A manager's model is not a plan, per se. It is a situation analysis.

From Decker et al. (2009:1).

ranted (Fig. 25.4). Stakeholder engagement is most effective when it is attuned to the spatial, temporal, and social scale of the management situation (Chase et al. 1999). Determining the relevant scales and appropriate stakeholders are part of the art of wildlife management (Lee 1993b). In our Newfoundland caribou case study, deliberating on the scale of problem and the scale of management response led to a variety of critical questions, such as the following:

- Is the issue unique or limited to specific human and/or biological communities, or will management intervention affect other communities?

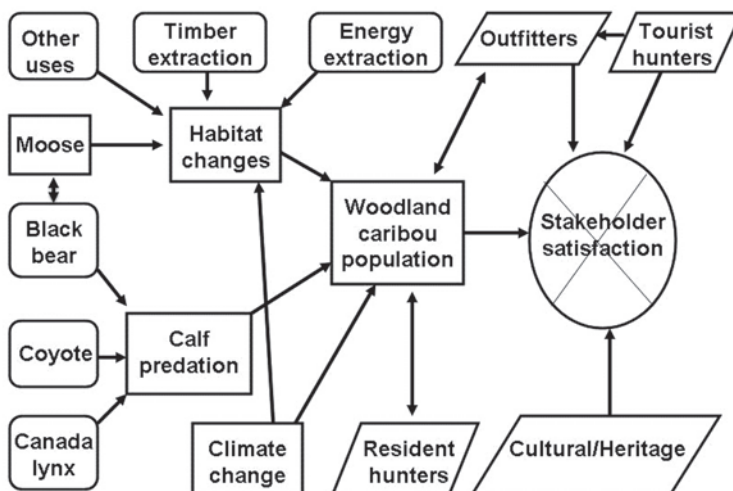

Fig. 25.3. A Conceptual Manager's Model of causes and effects of a decline in woodland caribou in insular Newfoundland, Canada.

Fig. 25.4. Stakeholder engagement is an important part of the adaptive management process and should be matched to the geographic, temporal, and social scale of the issue. *Photos courtesy of U.S. Fish and Wildlife Service.*

- Is there potential for collateral effects on species other than those that are of concern?
- Will potential effects of management for caribou habitats impact other land uses?
- Will management actions that lead to improvement of caribou hunting inadvertently diminish opportunities for other forms of wildlife enjoyment (i.e., adversely affect other stakeholders)?

These are some of the questions that managers need to address when determining the appropriate stakeholders to engage in situation analysis and management decision-making. Having too broad a suite of stakeholders for the scope of the issue only confounds the process, reducing efficiency and possibly diverting it from the core management issue. Having too narrow a stakeholder base ultimately results in decisions that may not be durable, because affected interests not engaged may believe their concerns were not addressed. Many wildlife management issues involve conflict between different stakeholder interests. Engagement of competing stakeholders may slow the situation analysis process and make objective identification difficult (Wondolleck and Yaffee 2000), but the alternative of dealing with excluded stakeholders (i.e., their political and litigation activities) is even more time-consuming and counterproductive. Conflict resolution may be required early on (Lee 1999) and, depending on the scale and severity of the conflict, may require professional intervention.

In the woodland caribou example, the stakeholder base is broader geographically than is the caribou population itself. Stakeholders were drawn from the hunting outfitter community, the recreational and rural community interest groups, natural resource industries, tourism agencies, conservation organizations, the scientific community, and even

nonresident and foreign hunters. This diverse constellation reflects the managers' efforts to consider all angles of this complex situation when identifying the appropriate stakeholders. For example, if reduction of predator populations is a likely management intervention, are there particular stakeholders unique to those species? Should representatives of the extractive industries be included as stakeholders? Although this process of articulating the managers' model initially reveals who the appropriate stakeholders are, others may be identified as the management process proceeds. Indeed, the founder stakeholder group may itself recommend additional members, thus linking stakeholder membership to the evolving and organic nature of the much larger management process.

Effective stakeholder engagement processes are open and transparent. Deliberating as a group avoids managers needing to explain the values of one group to another, which can lead to them being perceived as preferring a particular interest. When eliciting information from stakeholders, expect different perspectives to arise with respect to how the system operates. This can lead ultimately to the development of competing models, an acceptable outcome so long as all steps in the adaptive management process are followed (particularly monitoring the effects of alternative management interventions). Identifying responses of the system to different management actions sheds light on which model(s) best represent it.

Objective Setting

One of the most challenging aspects of wildlife management is establishing objectives that are clearly defined, achievable, and measurable within a specific timeframe. Too often objectives are presented that merely describe an action as op-

The importance of having both model levels operational in the adaptive management process is they provide (1) better structure to guide and communicate thinking (Walters 1986), (2) increased decision-making capacity (Forrester 1968), and (3) increased rates of learning (Senge and Sterman 1994, Riley et al. 2003b). The reduction of a complex state of affairs to more simplified components has a proven track record of problem solving in science, and is of relevance to successful adaptive management approaches. Managers should recognize that adaptive management, while inclusive, does not imply dissociation from science, or any diminished application of it.

Of course, it is unlikely that stakeholders will have (at the outset, especially) a common understanding or vision of the system. However, model development, when conducted as a group exercise, does help participants focus and organize their thoughts and information onto a common template. This exercise reveals biases and assumptions, as well as information available and required. If done well, the process fosters appreciation among the stakeholders for the complexity of the system and the management challenges, as well as for one another's viewpoints. It also exposes where uncertainties exist in the management system. Additionally, models typically illustrate the linkages of ecological and human dimensions in the coupled social-ecological systems in which wildlife management occurs (Riley et al. 2003b).

Despite shared knowledge, competing models may still arise as a result of differing beliefs or uncertainty over how the system operates and what its underlying mechanisms are (e.g., compensatory versus additive harvest mortality). Regardless of the ongoing dialogue, some stakeholders will still see habitat issues as driving the woodland caribou decline while others will continue to espouse predator reduction as the only meaningful management response. This does not imply, however, the various stakeholders have not "learned" in the process, or they do not appreciate the complexities involved. Enabling objectives should be assessed in the context of the models to determine their relevance, achievability, and overall acceptability within the larger political and social dynamic. Burnham and Anderson (2002) provide a solid overview of model development and testing.

Identification and Selection of Alternatives

Alternative approaches to accomplishing enabling objectives are developed as a series of management interventions. Stakeholder involvement in identifying alternatives is important because it can reveal any important differences in social acceptability of alternatives. (Some of the most controversial wildlife management issues are about management actions, not about desired outcomes.) Experience also has shown that stakeholders often contribute creative ideas (Gregory 2000). Wildlife managers tend to rely on traditional approaches (Russo and Schoemaker 1989, Riley et al. 2003b), but stakeholder engagement fosters consideration

of a larger suite of options. It is essential that management interventions are measurable as responses in the context of the system model. In the woodland caribou example, a potential management intervention is to reduce the black bear population (enabling objective) through increased hunter harvest of bears (management action). How to measure its efficacy has been an ongoing dialogue by managers, independent scientists, and public stakeholders.

Clearly, the hunting intervention needs to be implemented and monitored with attention to several questions if it is to contribute to adaptive management purposes. For example: Can the effect of harvest on the black bear population be measured? What is the effect level necessary to detect a change in calf survivorship? How many bears need to be removed to achieve that effect level? Can this level of removal itself be achieved? How do you know with certainty that the reduction in bears was responsible for any change detected in calf survivorship? Clearly, for each management intervention, a **monitoring plan** must be developed to assess whether the enabling objective was accomplished, and if not, why not.

Monitoring

Monitoring is critical to the adaptive management process. White (2001) identified the lack of rigorous evaluation of management interventions as the most common failure in attempts to implement adaptive management. Adaptive management is about learning from management and using that knowledge to improve, which is a good definition of evaluation. Adaptive management treats each intervention as an experiment, and the results of those experiments must be measured, applied to the models, and then used to improve the models, refine management (i.e., enabling objectives and related actions), and ultimately achieve the fundamental objectives. Monitoring provides improved information on the status of species populations, habitats, and satisfaction of stakeholders. In an adaptive management context, field research, surveys, habitat manipulation, and public education efforts are all directed toward contributing information that ultimately leads to improved decision-making.

In the woodland caribou example, the monitoring plan for determining whether an increased harvest of black bears could yield greater calf survival involves several independent yet related efforts (Fig. 25.6). A study of the black bear population was initiated ≥ 2 years prior to any reduction for purposes of developing baseline estimates of (1) the population size, (2) variation in movements related to the calving grounds and individual behavior associated with calf predation, and (3) the number of bears that would need to be removed to permit detection of a reduction in the population of $x\%$ over n years. Harvest of bears will need to be quantified to determine whether the population reduction level was achieved.

Concurrently, caribou calves are being radiomonitored from birth to document predation and mortality rates. In

Fig. 25.6. Monitoring is a critical component of the adaptive management process. Adaptive management of woodland caribou in insular Newfoundland, Canada includes monitoring spatial movement and population responses of predators and caribou to management interventions. Photos by Sustainable Development and Strategic Science Branch, Government of Newfoundland and Labrador, Canada.

addition, herd composition surveys are being conducted to see if the intervention yields increased calf recruitment. Social science studies are assessing public acceptance of increased bear harvests, and hunter interest in participation and increased effort is being engaged through public workshops and information sessions. Whether the public observes changes in either the numbers of bears or caribou, their overall satisfaction with the management program also can be assessed through this process. Without such monitoring effort, managers would not have the ability to determine whether the interventions were achieving the desired results. Wildlife managers simply cannot afford to expend time and resources on prescribed interventions without acquiring knowledge of the system's response to those efforts.

Implementation

After following the steps of situation analysis, objective setting, model development, identification and selection of alternatives, and establishing monitoring plans, decisions can be made as to which management actions are implemented. Depending on the scale of the management system and magnitude of the issue, the decisions could rest with the managers and their stakeholder advising group or be vested in a policy-making body, such as a commission, administration, or legislature. Regardless of the form of governance in place, the initial recommendations will be formulated within the stakeholder group as facilitated by the wildlife managers.

Obviously, the **decision-making process** should incorporate both scientifically derived knowledge and experience-

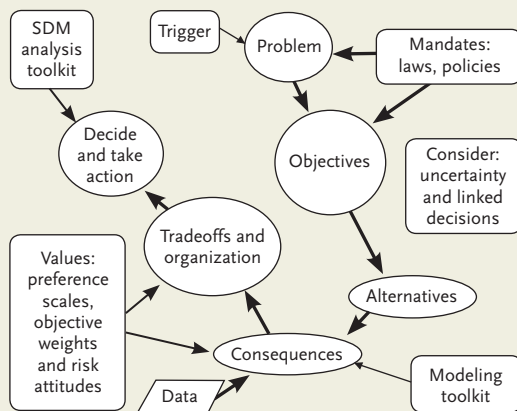

based insights regarding which interventions among the set of potential alternatives should be selected and implemented. The process can be informal and driven by reasoning and consensus, or be highly structured (Box 25.3). In any case, social acceptability of the alternative should be a key selection criterion. Ultimately, however, the long-term sustainability of the wildlife resource must not be compromised. Managers must recognize that, despite the urgency of a prevailing management challenge, certain actions can have implications for wildlife that may be irreversible in their effects. An important part of the stakeholder engagement process is the role of the wildlife manager in advising stakeholders what the limits of management are as defined in law (Organ et al. 2006). Typically, this provides for the long-term sustainability of wildlife.

Assess and Adjust

Within the adaptive management framework, information derived from monitoring the management interventions is used to compare model predictions with actual responses. This process fosters learning, the core purpose of adaptive management, by assessing the effectiveness of the management approach in achieving desired outcomes. Information on the system itself also may be gained, and the system model may need to be adjusted to reflect this new knowledge. Assumptions about system dynamics used to develop the enabling objectives may now be refined or modified, leading to alteration of management prescriptions. Where competing models have been developed, the model that

BOX 25.3. A MODEL OF STRUCTURED DECISION-MAKING

Structured decision-making (SDM) is a term used to describe a process to carefully organize analysis of problems in order to reach decisions focused clearly on achieving fundamental objectives. Based on decision theory and risk analysis, SDM encompasses a simple set of concepts and useful steps, rather than a rigid, inflexible approach. SDM is about making decisions based on clearly articulated fundamental objectives, dealing explicitly with uncertainty, and responding openly to legal mandates and stakeholder preferences or values in decision-making. SDM integrates science and policy. Each decision contains key components—management objectives, decision alternatives, and prediction of outcomes for each alternative. Analysis of each component discretely within a comprehensive framework improves overall decision-making.

An adaptive impact management diagram. From U.S. Fish and Wildlife Service (2008b).

most realistically simulates the actual response may be identified as the “best” model to describe the system components and their relationships.

In this sense, the monitoring process and knowledge gained also are used to assess whether the fundamental objectives have been achieved, not just the efficacy of enabling objectives. If the results fall short, adaptations to management interventions (enabling objectives and actions) based on this new knowledge can be developed, and the process can be repeated iteratively. It is important to engage stakeholders continuously in this process. They need to under-

stand the outcomes, see the measures used as credible, and have input into the adjustments for future iterations. It is important to recognize that, in some instances, the results may warrant major alteration of the model or the development of an entirely new one. Such reevaluations and subsequent changes in approach should be viewed as positive outcomes of the process, rather than emphasized as weaknesses in original thinking.

Iteration

The **iterative process** in adaptive management involves a constant cycling back to implementation, involving stakeholders in decision-making about which management interventions to conduct next, in what manner they should be implemented, and what outcomes to expect. Monitoring, assessment, and adjustment, along with economic considerations, determine whether this cycle should continue. Managers normally terminate the process with a final management action informed by assessment of data collected in the previous iteration. This may, due to economic considerations or the unlikely prospect that ecological and social learning is complete, lead to a nonadaptive wildlife management approach (Williams et al. 2009). At that point, management carries on while outcomes inherent to the original fundamental objectives may continue to emerge, facilitated by inertial properties now expressed within the system being managed. This may require some lower intensity supportive measures or, in some cases, just monitoring (the system now being capable of producing desirable outcomes without active intervention).

PASSIVE OR ACTIVE ADAPTIVE MANAGEMENT

Two types of adaptive management are recognized: passive and active. Passive and active adaptive management approaches are distinguished primarily by the degree to which they emphasize the reduction of uncertainty. In practice, this means a different amount of emphasis is placed on learning in the objectives used to guide decision-making (Walters 1986; B. K. Williams, U.S. Geological Survey, personal communication). **Active adaptive management** pursues the reduction of uncertainty (learning) through management interventions, while **passive adaptive management** pursues a particular resource-related objective(s), with learning a useful by-product of decision-making. Passive adaptive management has been criticized at times for not being rigorous enough, but a true passive approach should have adequate rigor and differ from active adaptive management primarily in terms of how explicitly learning is incorporated as an objective. Both passive and active adaptive management incorporate competing hypotheses about how a system works. Passive approaches may (but do not always) base decision-making on only one model deemed most appropri-

ate from among several potential models. Results from management actions are used to update the model. Trial-and-error types of management—in which evaluation of management actions is missing, sporadic, or weak—should not be mistaken for passive adaptive management.

In comparison, active adaptive management uses management actions to elicit a learning response. The objectives used to guide decisions on management actions explicitly incorporate uncertainty and potential for learning. Active adaptive management obviously requires a greater commitment of time, money, intellectual rigor, and other human resources, along with a willingness to take risks with management. The promise of an active approach is that learning will occur more rapidly than in a passive approach. Those benefits must be weighed against the costs and abilities to conduct active adaptive management (Table 25.1).

EXAMPLES OF ADAPTIVE MANAGEMENT APPROACHES

Adaptive Resource Management

Adaptive resource management (ARM) uses the act of managing a system to learn about that system; it is likely the concept that most wildlifers have in mind when they hear the term “adaptive management” (Enck et al. 2006). In ARM, a resource management goal is set; for example, to

maximize the harvest of a certain species or group of species or to maintain some amount of habitat in a certain condition within a management unit. A management prescription (a set of harvest regulations or a prescribed burning regime) is then described that is expected to lead to realization of the goal. Thus, managers are required to make explicit predictions of the results of their selected actions (the prescription) based on their existing knowledge of the system as derived through research and modeling. Simply put, ARM requires managers to say aloud, and preferably document on paper, “If we do X then we expect the result to be Y.” They are then responsible to implement a monitoring scheme sufficiently robust to detect those expected results. The data collected during the monitoring lead to review of the outcomes relative to the a priori predictions. Finally, the process is repeated, with a new prescription and set of predictions put in place based on the knowledge gained in the previous iteration. Thus, “learning is not simply a by-product, but is formally acknowledged as an integral objective of the management process” (Lancia et al. 1996:439).

Inherent in ARM is the realization that management decisions must be made in the face of uncertainty and that the system changes through the act of management (Williams and Johnson 1995). Thus, ARM provides a framework for managers to reduce that uncertainty through a rigorous approach to the selection and evaluation of management ac-

Table 25.1. Criteria proposed by Gregory et al. (2006) for assessing appropriateness of adaptive management (AM) applied to 4 hypothetical wildlife management cases

Adaptive management criteria	Grassland–bird habitat-management experiments	Suburban deer overabundance	Wolf reintroduction	Land-use plan or climate change
Temporal and spatial scale

^aNot a major barrier to proceeding with an active, experimental, AM approach.

^bChallenge that must be addressed in order to successfully proceed with an active, experimental, AM approach. Passive approach may be more applicable.

^cSignificant challenge; active, experimental AM infeasible unless resolved. Likewise, passive approach must be resolved in order to be feasible.

tions that will lead to improved understanding of the system in question and ultimately better decision-making in the future (Williams et al. 2002). The actions available to the managers must be sufficiently diverse and intense such that their application to the system would be expected to produce a detectable change in the resource, either consistent with the predicted response such as to increase the confidence in that prediction or inconsistent with the prediction, but consistent with the expectations of an alternate hypothesis about the nature of the system.

Adaptive Harvest Management

In wildlife conservation, adaptive management has been most commonly applied to the process of regulating the harvest of game species, especially waterfowl (Johnson et al. 1993, Williams and Johnson 1995, Williams et al. 1996). **Adaptive harvest management** (AHM) is a special case of ARM because the management prescriptions and assumptions that drive the allocation and regulation of harvest can be expressed quantitatively and the predictions can be measured in the resulting population levels and demographics of the harvested species. Consequently, AHM presents a logical and very clear application of adaptive management theory.

The application of AHM to real world problems requires the specification of models of the population processes of the species in question and clear statements of the assumptions underlying those models. As applied to waterfowl management in North America, Williams et al. (2002) identified 4 key elements that characterize the process: (1) the existence of a suite of regulatory options available to managers that span a range of management (i.e., harvest) intensity, (2) the existence of an objective function by which to evaluate the regulatory options (e.g., harvest over time), (3) competing models of waterfowl population processes that would lead to meaningful predictions of the results of different harvest intensities, and (4) some measures of the reliability of these models that can be used to incorporate uncertainty into the evaluation process.

Specific to the application of AHM to mallard (*Anas platyrhynchos*) populations, Johnson (2001) described 2 competing hypotheses of additive and compensatory mortality in regards to harvest and 2 competing hypotheses regarding the effects of mallard abundance on per capita reproductive rate (i.e., density-dependent reproduction). These hypotheses allowed for predictions of the results of various harvest regulations that could then be used to evaluate their effectiveness in meeting the agreed population goals.

In practice, AHM involves developing an algorithm that is used to determine the appropriate regulatory options in light of the management goals and the likelihoods of the competing models (i.e., hypotheses) to explain population responses to management efforts. Information must be gathered on the population status, realized harvest, harvest rates, hunter effort, and other ecological variables that the manag-

ers and researchers believe are necessary to predict the population response to management. Regarding the latter, environmental variables such as previous year's rainfall or current year's number of ponds on the breeding grounds may be useful to understand population-level reproductive rates in waterfowl; alternatively, for white-tailed deer (*Odocoileus virginianus*), especially in northern environments, winter severity may be a key factor explaining population response to a range of management options. Regardless of the species in question, after monitoring and analyzing the relevant variables, model likelihoods require annual updates to drive the regulation setting process anew (Williams et al. 2002).

One of the fortuitous consequences of adopting AHM (or ARM) as a decision-making process is that it requires managers, researchers, and administrators to work together to identify a course of action and the criteria for evaluating those actions relative to an agreed-on set of goals. It requires that all parties acknowledge that decisions are made in the face of uncertainty and that the results of the management actions and their short- and long-term effects on the harvested population cannot be predicted with absolute certainty (Johnson 2001); indeed, if that were not the case, there would be no need for an adaptive decision-making process. Thus, all parties involved in the process have some ownership and cannot deny responsibility or shift blame if a set of predictions is incorrect and the management actions do not meet the goals.

Adaptive Impact Management

Adaptive impact management (AIM) builds off the concept of adaptive resource management (ARM). AIM explicitly incorporates the philosophy of value-based decision-making in wildlife management (Hammond et al. 1999). The main *difference* between AIM and ARM also is the main way in which they *complement* each other (Enck et al. 2006). AIM seeks to define fundamental objectives in terms of stakeholder-defined impacts, which may or may not be related to the status of the resource (Riley et al. 2003b). ARM seeks to identify fundamental objectives in terms of the status of the resource, incorporating stakeholder input as to what that status should be.

A focus on impacts and stakeholder involvement leads to management that "really matters" to society (Riley et al. 2003b). This improves societal support for the experimental aspects of adaptive management, support that is often lacking. A focus on impacts and stakeholder involvement also improves shared learning among scientists, managers, and *stakeholders*. This attribute of AIM is important to the credibility of wildlife managers and the agencies or organizations for which they work. In our woodland caribou case study this has been manifested in numerous ways, most particularly in how often a majority, though certainly nonunanimous, position is achieved on critical issues by the stakeholder group.

Definition of impacts and associated management objectives requires stakeholder involvement (Shindler and Cheek

1999). The kind of stakeholder involvement, and perhaps even collaboration, depends on the scale of impacts to be addressed, the level of stakeholder interest, and the number of jurisdictions (i.e., other agencies) that are involved. Stakeholder involvement can take several forms, and often must to capture input from all the relevant stakeholders and sustain engagement of key stakeholders. Often wildlife managers, or people they hire and oversee (staff or consultants), guide the flow of interactions with and among stakeholders and the analyses that are required to define objectives.

SUMMARY

Adaptive management is an effective process for wildlife managers to employ to (1) deal with uncertainty in the management system, (2) learn from their management actions, and (3) achieve desired results. Being adaptable or flexible in your management approach is not the same as managing adaptively or conducting adaptive management. Adaptive management requires adhering to a stepwise process and fully executing each step. A critical step is rigorous monitoring and assessment of management interventions. Without this, wildlife managers cannot achieve the essence of adaptive management, which is the explicit goal of learning more about the management system after each management action.

Stakeholder engagement is essential to adaptive management. Stakeholders help define the management system and the issues that are prompting management interven-

tion. Their engagement throughout the adaptive management and decision-making process will foster ownership of the resulting actions and decisions, and will aid greatly in the learning process. Developing both fundamental and enabling objectives will help wildlife managers treat management interventions as experiments, and monitor and evaluate them against desired outcomes.

Different approaches toward adaptive management have been employed in wildlife management. Adaptive resource management is a process where wildlife managers predict a system response (typically an enabling objective) to a management intervention based on a model and then test the observed response against the model. Adaptive harvest management is a special application of ARM applied primarily to waterfowl and other game-harvest management scenarios that uses explicit quantitative models. Adaptive impact management explicitly incorporates the philosophy of value-based decision-making in wildlife management and complements ARM. AIM seeks to define fundamental objectives in terms of stakeholder-defined impacts, whereas ARM focuses on enabling objectives and the best methods for achieving them. In considering the initiation of an adaptive management approach, wildlife managers should carefully evaluate whether it is appropriate for the management challenge at hand. To further understand the concepts presented in this chapter, we recommend the following articles: Lancia et al. (1996), Johnson (2001), Riley et al. (2002), Riley et al. (2003b), Enck et al. (2006), Organ et al. (2006), and Williams et al. (2009).

Managing Forests for Wildlife

INTRODUCTION

Forest Definition and Types

A FOREST MAY be defined as a group of trees in a prescribed area; and what represents a forest can vary markedly, depending on geography and human perceptions. For instance, an urban woodlot in a metropolitan area, an old-growth stand in the Pacific Northwest, a Midwestern shelterbelt, an eastern state forest, or a southern pine (*Pinus* spp.) plantation can each be viewed as forests by people from different regions of the United States. Although these forests vary in characteristics (e.g., extent of naturalness or size); each has aesthetic, wildlife habitat, economic, recreational, and other values (Yahner 2000).

Forestland in the lower 48 states can be divided into **coniferous forest** in the West and **deciduous forest** in the East, separated by a nonforested landscape of extensive farmland, grassland, remnant prairie in the Midwest (U.S. Forest Service [USFS] 1968, Patton 1992, Yahner 2000). The western coniferous forest includes 3 regions: **Pacific Coast and Interior** (dominated by Douglas-fir [*Pseudotsuga menziesii*], ponderosa pine [*Pinus ponderosa*], and redwood [*Sequoia sempervirens*]), **Northern Rocky Mountains** (dominated by lodgepole pine [*P. contorta*], Douglas-fir, and larch [*Larix* spp.]), and **Southern Rocky Mountains** (dominated by pinyon [*Pinus* spp.]–juniper [*Juniperus* spp.], ponderosa pine, and fir [*Abies* spp.]–spruce [*Picea* spp.]). The eastern deciduous forest also has 3 regions: **Lake States and Northeast** (dominated by aspen [*Populus* spp.]–birch [*Betula* spp.] and maple [*Acer* spp.]–beech [*Fagus* spp.]–birch), **Central Mountains and Plateaus** (dominated by oak [*Quercus* spp.]–hickory [*Carya* spp.] and oak–pine, and **Southern States** (dominated by loblolly pine [*P. taeda*]–shortleaf pine [*P. echinata*] and longleaf pine [*P. palustris*]–slash pine [*P. elliotii*]).

History of Forests

The pre-European forest once covered about two-thirds of North America (Cutter et al. 1991). In the lower 48 states in the 17th century, approximately 50% of the landscape was forested, with 75% in the eastern states (Harrington 1991, MacCleery 1992). In the pre-European era, **disturbances** in the forest resulted from natural events (e.g., wildfires and wind throws) or were created (e.g., prescribed fires and clearings) by Native Americans for agriculture, fuel-wood harvesting, wildlife habitat, and village establishment (e.g., Day 1953, Spurr and Barnes 1980, Delcourt and Delcourt 1997).

From the early 17th century and continuing into the 21st century, the **original forest** in the United States was reduced by human activities (reviewed by Yahner [2000]). Early on, timber was harvested extensively in the East and exported to other countries for shipbuilding and sugar-producing industries (Perlin 1989, MacCleery 1992). Wood was used extensively in the United States for building farm fences, fuel wood to heat homes, and fuel for iron production and railroad engines (Spurr and Barnes 1980, MacCleery 1992). Distribution and abundance of certain species, such as eastern hemlock (*Tsuga canadensis*) and American chestnut (*Castanea dentata*), were markedly reduced by the tanning industry and disease, respectively (Spurr and Barnes 1980, Duffield 1990, Patton 1990, Yahner 2000). An estimated 47 million ha of forest in the eastern United States was cleared for agriculture by the mid-19th century (Clawson 1979, Williams 1989). As a result of historical land uses, the 400 million ha of forestland present in the lower 48 states in the 1500s were reduced to about 188 million ha (53% decline) by the early 20th century (Harrington 1991).

Early successional forest reverted to **second-growth forest** with regeneration, fire suppression, and abandonment of many farms in the initial decades of the 20th century (Cutter et al. 1991, Pimm and Askins 1995, Trani et al. 2001). The composition of the forest changed, as red maple (*Acer rubrum*) replaced oak stands in some areas of the East (Abrams 1992). These changes (habitat loss or change in species composition) in the forest landscape in the lower 48 states had negative effects on forest wildlife populations, some of which were well documented (e.g., those of American beaver [*Castor canadensis*] and white-tailed deer [*Odocoileus virginianus*]) or strongly suspected of occurring despite a lack of data on historical population trends (e.g., those of forest and early successional bird species; Perlin 1989, MacCleery 1992, Litvaitis 1993, Yahner 2000, Trani et al. 2001).

Increased urbanization and suburban sprawl influenced the amount of forest in the United States (e.g., Robbins et al. 1989). About 3–5% of the original old-growth forest remains in the lower 48 states, with most in the Pacific Northwest (Miller 1992). Most of today's forest is second-growth, with 54% and 81% in the Mid-Atlantic and New England States, respectively (Trani et al. 2001). Moreover, relatively low amounts of early successional forest remain in the eastern United States (e.g., 15–16% of total forestland).

Forests of Today and Their Management

Today's forestlands are classified from a timber-management perspective into commercial forestland, reserved timberland, or noncommercial forestland (Hagenstein 1990, Cutter et al. 1991). **Commercial forestland** in the lower 48 states (66%) is most common, but its extent differs from East (95% of the total forestland) to West (50%; Hagenstein 1990). **Private-forest landowners** own the majority of commercial forestland (57%) in the United States; public agencies and forest industries control a smaller amount (28% and 15%,

respectively; Martin and Bliss 1990, Cutter et al. 1991). Amount of commercial forestland in the United States has increased 5% from the mid-1940s to the mid-1970s, whereas amount of noncommercial forestland has increased 102% from the 1930s through the 1970s (Williams 1992).

Forestlands should be managed for other values, including their value as wildlife habitat (e.g., Gullion 1990, Yahner 2000). Forested habitats are used by 80–90% of the vertebrate species in North America (Flather and Hoekstra 1989), making management of forestlands one of the most important challenges facing wildlife biologists and natural resource managers. However, effective management of forestlands for wildlife is contingent on a number of factors (e.g., land ownership and public opinion). Ownership of forestland, which totals approximately 296 million ha in the United States, has remained relatively stable since at least the middle of the 20th century (Society of American Foresters 1981, Hagenstein 1990). Private landowners control nearly 46% of the total forestland; the remaining forest (41%) consists of public lands (federal, state, and county owned) or forest-industry lands (13%; Society of American Foresters 1981).

Forestland ownership patterns vary substantially among regions in the United States, with private ownership predominating in the East and **federal ownership** (e.g., USFS, Bureau of Land Management) in the West (Mannan et al. 1996, Yahner 2000). About 84 million ha of forestland is managed by the USFS, 190 million ha (most of this land is rangeland) by the Bureau of Land Management, 32 million ha by the National Park Service, and 49 million ha by other governmental agencies (U.S. Fish and Wildlife Service, U.S. Army Corps of Engineers, and U.S. Department of Energy; Bureau of Land Management 2001). Individual state governments and nongovernmental organizations (e.g., The Nature Conservancy and a variety of land trusts) own public-accessible forests. There is no adequate system to coordinate large-scale, comprehensive management activities on privately owned forests; therefore, successful management of these forests for wildlife biodiversity can pose challenges from sociopolitical perspectives.

Management of forestlands requires an understanding of changing land uses plus public support. For example, with a reduction in area affected by agriculture and timber harvesting in recent decades, slightly more timber is being grown today than is being harvested (USFS 1982, Cutter et al. 1991). The public may view this increase in total forestland (e.g., second-growth forest) as wise use of a resource, thereby leading to conflicting opinions regarding some forest-management practices (Askins 2001).

LEGISLATION RELATED TO FOREST MANAGEMENT

With the passage of the **Forest Reserve Act** in 1891, executive authority created the first forest reserves in Wyoming and Colorado in response to nonregulated and exploitative

logging (Bolen and Robinson 1995). The Act of 1897, also known as the **Organic Act**, established the **National Forest Service**, which originally was under the jurisdiction of the Department of Interior, but was transferred to the U.S. Department of Agriculture. Under the leadership of Gifford Pinchot and President Theodore Roosevelt at the turn of the 20th century, 4 million ha of western forestlands were transferred into federal ownership (Miller 1992). The passage of the **Weeks Law** in 1911 permitted states to cooperate with federal assistance to acquire land for forest and water conservation. Throughout the early 20th century, management of federally and state-owned forests focused on sustained yields of timber, but changed to a multiple-use approach after World War II (Bolen and Robinson 1995).

The **Multiple Use and Sustained Yield Act** of 1960, and subsequent amendments, mandated that national forests be managed for outdoor recreation, rangeland and timber productivity, watershed integrity, and maintenance of wildlife and fisheries. This act marked the first time the federal government formally acknowledged the importance of national forests for wildlife conservation. Passage of the **Wilderness Act** in 1964 further recognized the importance of national forestlands for uses other than timber production. Currently, wilderness designation applies to approximately 2% of all federally owned lands (Bolen and Robinson 1995).

In 1969, the federal government passed the **National Environmental Policy Act** (NEPA), which required federal agencies to consult with each other and systematically review and evaluate activities occurring on federally owned lands (Gilbert and Dodds 1992). Specifically, NEPA requires a detailed Environmental Impact Statement (EIS) about the effects of proposed activities on environment and natural resources, including wildlife (Truett et al. 2004).

With the passage of the **Forest and Rangeland Renewable Resources Planning Act** and the **Forest and Rangeland Renewable Resources Research Act** in 1974 and 1978, respectively, the federal government began the coordination of multiple-use and sustained-yield opportunities between federal and private lands. These acts called for assessment, comprehensive inventories, coordinated research, and development of land-management plans to meet specific management objectives for conservation of natural resources, including wildlife. The **Sikes Act** of 1974 more specifically promoted planning, development, maintenance, and coordination of wildlife conservation and rehabilitation on public lands by federal and state agencies (Mannan et al. 1996).

The **National Forest Management Act** of 1976 formalized governmental sale of timber on federal lands and required public comment and an EIS. Implementation of this act also required that forest management maintain viable populations of existing native vertebrate species. This act also established the **Salvage Timber Fund**, which encouraged removal of insect-infested, dead, damaged, or downed timber for purposes of stand improvement and fire suppres-

sion. A portion of the purchase of salvaged timber was designated to fund road construction and maintenance necessary for timber harvesting and other multiple-use purposes. The **Emergency Salvage Timber Act** of 1995 permitted expedited reviews of requests to salvage timber to further decrease risk of fire in national forests.

In recent years, however, salvage timber sales have come under increased scrutiny, criticism, and controversy. For example, in 2002, a federal court denied a salvage timber purchase in Montana's Bitterroot National Forest because of opposition by environmental organizations (Sierra Club 2002). The controversy stems from lack of evidence that removal of salvage timber reduces fire risk. Furthermore, road building associated with salvage timber operations may cause environmental degradation of streams, and equipment necessary to remove salvaged timber may impede forest regeneration by causing compressed soils and erosion.

In 1978, 2 acts were passed that promoted and enhanced forest management of private lands for conservation of natural resources. These were the **Renewable Resources Extension Act**, which funded research and educational assistance directed at private-forest landowners, and the **Cooperative Forestry Assistance Act**, which provided cooperative forestry assistance for private landowners interested in managing their lands for timber, wildlife, and other renewable resources. The Cooperative Forestry Assistance Act specifically mentioned threatened and endangered species as resources in need of protection and management.

The **Forest Resources Conservation and Shortage Relief Act** of 1990 also identified threatened and endangered species as important resources. Under this act, the federal government set aside millions of hectares of otherwise harvestable timber in national forests for the sole purpose of conservation of natural resources pursuant to the objectives of the **Endangered Species Act** (1973) and the **National Forest Management Act** (1976). In addition, the **Forest Resources Conservation and Shortage Relief Act** restricted exports of unprocessed timber from federal lands. This act has been met with much controversy, especially in western states where logging was prohibited on millions of hectares of national forestlands.

Another controversial policy was signed into effect in 1999, when President William J. Clinton directed the USFS to protect roadless areas in national forests (Strittholt and DellaSala 2001). Under this **directive**, the USFS released a proposed EIS that included a rule-making process on roadless areas, prompting >1 million public responses both for and against protecting roadless areas. Although road construction is permitted and often encouraged in national forests under the **Forest Roads and Trails Act** of 1964, it is controversial because research indicates that roads contribute to forest fragmentation, spread of exotic species, and restriction of wildlife movements (Andrews 1990, Forman 2000). A recent study of the importance of roadless areas in bio-

diversity conservation was conducted in the Klamath–Siskiyou Ecoregion of the United States; this study indicated that roadless areas contained important ecological elements, including at-risk species, key watersheds for aquatic biodiversity, and landscape connectivity (Strittholt and DellaSala 2001).

FOREST AND WILDLIFE SUCCESSION

Successful forest management is directly linked with **forest succession** of both plants and animals and is critical to understanding patterns of forest biota (Yahner 2000; Fig. 26.1). Plant succession may be classified as primary or secondary (Spurr and Barnes 1980, Aber 1990). **Primary succession** occurs after a catastrophic disturbance (e.g., a volcanic eruption on Mount St. Helens in 1980 that left areas of bare earth and ash; Frenzen 1992). **Secondary succession** proceeds from the plant community that remains after a less severe disturbance, such as that created by fire or timber harvest.

Shade-intolerant species of plants (e.g., aspen and grasses) predominated in the initial decades of the 20th century in early successional habitats, which were replaced over time with **shade-tolerant**, longer lived and more competitive plant species (e.g., sugar maple [*Acer saccharum*] and hemlock [*Tsuga* spp.]; Spurr and Barnes 1980, Patton 1992). As plant succession changes the composition and structure of a forest stand, the associated animal community also changes (Yahner 2000). For instance, bird species characteristic of early successional habitat (e.g., common yellowthroat [*Geothlypis trichas*] and chestnut-sided warbler [*Dendroica pensylvanica*]), are replaced by species adapted to more mature forests (e.g., red-eyed vireo [*Vireo olivaceus*] and ovenbird [*Seiurus aurocapilla*]; Probst et al. 1992; Yahner 1997, 2008; King et al. 2001).

A forested landscape is dynamic and subject to natural and human-induced perturbations; therefore, a major challenge for wildlife biologists and land managers is to provide **successional stages** for disturbance-dependent species while balancing the needs of other species that rely on relatively undisturbed mature forests (Thompson and DeGraaf 2001). **Early successional stages** resulting from recurring disturbances (e.g., fire, timber harvest, and storms, must be an integral component of the ecology in a forested landscape;

The Wildlife Society 1993, Franklin 1997, Trani et al. 2001). Absence or scarcity of early successional stages in some areas contributes to regional declines in many species of wildlife (e.g., a variety of songbirds [Askins 1993, 2001; Brawn et al. 2001], American woodcock [*Scolopax minor*; McAuley and Clugston 1998], and New England cottontail [*Sylvilagus transitionalis*; Litvaitis 1993, 2001]).

The wildlife profession is beginning to appreciate that ecological disturbances are fundamental to conservation of forest wildlife (e.g., Askins 2001, Brawn et al. 2001). For instance, forest birds comprise 60–89% of the breeding bird species in the eastern deciduous forest (Yahner 2000), and those adapted to early successional stands show dramatic population declines compared to those typical of more mature forest stands (Askins 1993; Yahner 1995, 2008; Brawn et al. 2001; Hunter et al. 2001). Hence, conservation efforts in forests need to maintain a variety of stands in different stages of plant succession with variable disturbance frequency to enhance diversity (Anglestrom 1998, Brawn et al. 2001, Hunter et al. 2001, Trani et al. 2001). Two major **anthropogenic disturbances** or management tools that can help wildlife biologists and forest managers create a mosaic of forest stands in various successional stages are **fire and silvicultural practices** (Yahner 2000, Brawn et al. 2001).

FIRE AND WILDLIFE RESPONSE

Wildfires have been a major natural anthropogenic factor affecting forests well before European settlement, but fire-suppression efforts after the 19th century have decreased number and size of fires and increased intervals between wildfires (Oliver and Larson 1996, Yahner 2000). Historically, wildfires probably occurred every 50–100 years in some areas of eastern North America, but now occur every 100–400 years (Lorimer 1990b, Cutter et al. 1991).

Fires are important to the successful regeneration of species (e.g., aspen and oak [Schier 1975, Lorimer 1990a]; Fig. 26.2). Some fire-adapted tree species (e.g., *Quercus* spp., *Pinus* spp.) often have thick bark or **serotinous cones**, and fires create favorable seedbeds for their regeneration (Lorimer 1985). Conversely, fires act to control species that compete

Fig. 26.1. Plant community succession in a hypothetical forest stand. From Mannan et al. (1996:692).

Fig. 26.2. A low-intensity forest fire in a northern pin oak (*Quercus palustris*) stand in northern Wisconsin. Photo by Marc D. Abrams, School of Forest Resources, Pennsylvania State University; from Yahner (2000:80).

with fire-adapted species (Van Lear and Waldrop 1989). Lack of fires may contribute to decline of oak in some regions, thereby resulting in greater regeneration of other species (e.g., maple), which have relatively lower resistance to fire (Abrams 1992, Abrams and Ruffner 1995). Loss of oak can, in turn, negatively impact wildlife communities (Rodewald 2003a, Yahner 2003, McShea et al. 2007). For example, diversity and abundance of bird communities was greater in oak compared to maple-dominated stands (Rodewald and Abrams 2002).

Prescribed fire has been a controversial, but useful, tool in managing vegetation in certain ecosystems (Jacobson et al. 2001; e.g., serpentine barrens in eastern North America [Arabas 1997]). Fires also have been deliberately set by foresters as a means of removing excess woody debris after a timber harvest or preparing a seedbed prior to tree planting (Lorimer 1990a). Prescribed fire can be used to prepare a site for planting trees or enhance natural regeneration (Mannan et al. 1996). Moreover, prescribed fires traditionally have been used to manage habitat for a variety of wildlife species (e.g., northern bobwhite [*Colinus virginianus*; Stoddard 1931], ruffed grouse [*Bonasa umbellus*; Gullion 1972], Kirtland's warbler [*Dendroica kirtlandii*; Probst and Weinrich 1993], white-tailed deer, and elk [*Cervus canadensis*; Thomas et al. 1979b, Masters 1991]).

The role of prescribed fires in restoring or maintaining biodiversity of songbird communities in coniferous and boreal forests of the western United States and southern Canada, oak savannas of the midwestern United States, and pine savannas of the southeastern United States has been reviewed extensively by Brawn et al. (2001). For instance, abundance of 15 bird species increased appreciably in western coniferous forests that were recently (within 1–3 yr) burned (Hutto 1995). Early successional bird species (e.g., field sparrow [*Spizella pusilla*]) and woodpeckers were quite

abundant in midwestern oak forests altered by fire; these burned forests were characterized by variable densities of understory vegetation, high densities of snags, and fewer trees compared to unburned oak forests (Davis et al. 2000). Habitat management using fires for a species of concern (e.g., the red-cockaded woodpecker [*Picoides borealis*]) occupying southern pine forests can have direct benefits to other bird species adapted to early successional habitats (Krementz and Christie 1999). In contrast, fires can have negative effects on canopy-feeding birds (e.g., red-eyed vireo; Davis et al. 2000).

Alteration of vegetative structure of forests by fires also can have indirect effects on other communities, such as herpetofauna in southeastern forests (Russell et al. 1999). For instance, certain amphibian and reptilian species in Florida pine forests are benefited by the mosaic of habitats created by frequent fires in the landscape (Campbell and Christman 1982, Mushinsky 1985). Availability of browse as food for white-tailed deer and elk can be increased by prescribed burning at regular (3-yr) intervals (Masters 1991). These studies show that fire can have profound effects on biodiversity of biotic communities in forested habitats (Brawn et al. 2001). Hence, natural resource and wildlife managers need a better understanding of the effects of fire as a management tool for wildlife communities and ecosystems (Russell et al. 1999). These professionals must inform the public about the historical role of fires in shaping structure and composition of past and current forests and the potential role of fire as a management tool.

CHEMICAL TREATMENTS

In addition to prescribed fire, chemicals have been used to prepare a site prior to tree planting or to enhance natural regeneration (Gullion 1990, Mannan et al. 1996). Although controversial, **herbicide applications** have little or no direct toxic effect on wildlife, but the negative effects of **pesticides** on wildlife are well documented (Ratcliffe 1967). Herbicide application in combination with certain mechanical treatments on wooded rights-of-ways, for example, provides ideal conditions for wildlife associated with early successional habitats (e.g., Bramble et al. 1999, Yahner et al. 2002). However, reductions in abundance of several bird species have been observed after herbicides were applied to clearcut forest stands (Savidge 1978, Morrison and Meslow 1984, Santillo et al. 1989).

FOREST MANAGEMENT AND WILDLIFE RESPONSE

Forest management consists of planting, growing, and tending a stand of trees, as well as the economics associated with growing trees (Society of American Foresters 1981). Forest management can be divided into 2 general systems:

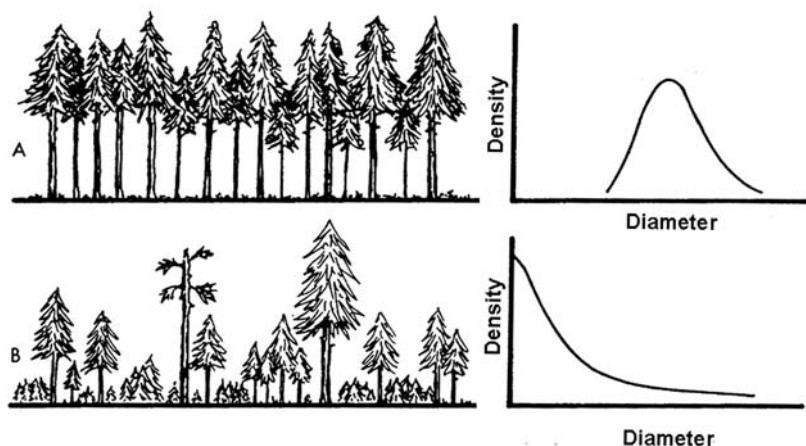

Fig. 26.3. Distribution of tree sizes in an even-aged (A) and an uneven-aged (B) forest stand. From Mannan et al. (1996:694).

uneven-aged and even-aged (Society of American Foresters 1981, Lorimer 1990b; Fig. 26.3).

Uneven-Aged versus Even-Aged Management

Uneven-aged management retains trees of different age via selective cutting of single or small groups of trees at frequent (e.g., 5–10-yr) intervals (Yahner 2000, Thompson and DeGraaf 2001). **Selective cutting** involves the removal of either individual trees to promote growth of preferred trees or of small groups (0.1 ha) of trees to enhance growth of shade-intolerant species (Leak and Filip 1977, Mannan et al. 1996). Stands treated with uneven-aged techniques retain many overstory trees; therefore, shade-tolerant tree species (like maple and beech) regenerate best in these stands (Society of American Foresters 1981). Uneven-aged management may be a good strategy on small parcels of forest if landowners want both timber and wildlife benefits. In contrast, **even-aged management** is the infrequent removal of all trees of a desired age at the same time to create regenerating stands, often ranging in size from 0.5 ha to 20 ha (Hunter 1990, Lorimer 1990b, Yahner 2000, Thompson and DeGraaf 2001). Examples are **clearcuts** (all trees removed), **seed-tree cuts** (a few trees are left standing to serve as sources of seeds for regeneration), and **shelterwood cuts** (more trees are left to provide shelter to regenerating trees). These methods work best when trying to regenerate trees that are not shade tolerant, such as oak. Choosing not to harvest also can be a good option in some situations, as when managing for **late-successional** wildlife species.

Even-aged and uneven-aged management approaches affect wildlife differentially by creating either early or late-successional stands. From a wildlife perspective, the “best” approach depends on availability of nearby habitat, sensitive wildlife species in the area, and management goals. Clearcuts will attract species, such as eastern cottontail (*Sylvilagus floridanus*) and chestnut-sided warbler, which use shrubs and saplings, but will not be regularly used by species that require mature forests. Harvesting methods that retain large

numbers of overstory trees provide suitable habitat for a variety of mid- to late-successional forest animals and tend not to dramatically affect composition or structure of plant and wildlife communities.

Selective cutting is generally an acceptable method of forest management for private landowners who wish to obtain income from timber sales without dramatically changing structure of plant and wildlife communities. For instance, creation of small (0.4-ha) openings in northern temperate deciduous forests had little effect on incidences of predation or parasitism of avian nests (Robinson and Robinson 2001). Similarly, selective cutting had no impact on survival or densities of adult gray (*Sciurus carolinensis*) or fox squirrel (*S. niger*) populations (Nixon et al. 1980), but if large oak and hickory trees are selectively cut, it potentially can be detrimental to squirrels and other wildlife species that rely on mast for food (Yahner 2000). Compared to even-aged management, single- or group-tree selection can provide favorable, short-term habitat for a variety of forest bird species, such as white-breasted nuthatch (*Sitta carolinensis*), red-eyed vireo, hooded warbler (*Wilsonia citrina*), and ovenbird (Crawford et al. 1981, Annand and Thompson 1997, Rodewald and Smith 1998).

Thinning

Thinning is the selective removal of trees in advance of a scheduled, extensive harvest (Patton 1992). As many as 10–50% of the trees in a stand may be removed, thereby increasing growth rate of the remaining trees and resulting in a stand with relatively evenly spaced trees (Crawford and Titterton 1979). This type of removal is termed a **commercial thinning** if trees are removed as timber or termed a **salvage cut** if unusable trees (e.g., no commercial value because of damage by insects, fire, etc.) are removed. Thinning can benefit certain species adapted to more open forested areas (e.g., hooded warblers; Crawford et al. 1981, Carey and Wilson 2001). Conversely, retention of large dying trees can have benefits to wildlife that use these substrates as

nesting and foraging sites (e.g., Yahner 1987, Stribling et al. 1990), such as pileated woodpecker (*Dryocopus pileatus*; McClelland and McClelland 1999). **Selectively removing** or thinning only the highest quality trees from a stand (sometimes termed **high-grading**) also can have detrimental effects on flora and fauna, as well as on future timber production from the stand.

EVEN-AGED REGENERATION METHODS

Clearcutting Method of Regeneration

Clearcutting is a method of regenerating an even-aged forest stand whereby all trees in a prescribed area are harvested, and seedlings become established to produce a stand with trees of similar age and size (Society of American Foresters 1981). This has been the most common method of even-aged forest regeneration, often accounting for about two-thirds of the timber harvested in the United States in the past (Gullion 1990, Miller 1992). The term clearcut refers to stands during the time between clearcutting and the formation of a closed-canopy sapling forest (mean stem diameter >2.5 cm). Clearcuts provide quality early successional wildlife habitat that generally persists from 5 years to 20 years following cutting, depending on site quality and growth rate of seedlings. Yet despite the widespread use of clearcutting, it has been controversial, especially as applied to relatively large stands (>100 ha) on steep slopes and adjacent to highways, resulting in soil erosion and negative public reaction (Harlow et al. 1997).

The value of clearcuts to wildlife is species-specific and can vary with size and age of the stands (reviewed by Harlow et al. 1997, Yahner 2000, Thompson and DeGraaf 2001). For instance, small (e.g., 10-ha) clearcuts are habitat for gray catbird (*Dumetella carolinensis*), ruffed grouse, snowshoe hare (*Lepus americanus*), and white-tailed deer (Scott and Yahner 1989, Hughes and Fahey 1991, Yahner 1997). Larger clearcuts provide habitat for populations of other early successional species (e.g., field sparrow, yellow-breasted chat [*Icteria virens*]; Crawford et al. 1981), but are not used by species requiring older forests (e.g., ovenbird, red-cockaded woodpecker; Thompson et al. 1992, Irwin and Wigley 1993). Some studies have shown that species richness and abundance of certain breeding birds is greater in larger than in smaller clearcuts (Rudnicki and Hunter 1993b, Yohn 2002, Lehnen and Rodewald 2009; but see Kremenetz and Christie 2000).

Younger (e.g., 5 yr since harvest) clearcuts generally have lower numbers of vertebrate species than do older clearcuts (e.g., Yahner 1988b, 1993). A major factor affecting suitability of younger clearcuts for wildlife is the absence of key features (e.g., snags, overstory trees, and certain types of food resources; Yahner 2000). For example, in the first 2 years after clearcutting, aspen and mixed-oak clearcuts in Pennsylvania were virtually devoid of bird species, including early successional species, because of a lack of under-

story vegetation for nesting and foraging (Yahner 1993). Reduced understory vegetation and leaf-litter moisture in relatively young clearcuts result in lower abundance of other vertebrates (e.g., terrestrial salamanders) compared to abundance in mature forests (Ash 1997, Rodewald and Yahner 1999, Grialou et al. 2000, Yahner et al. 2001a). Gray squirrels are typically absent from clearcuts because of the lack of overstory mast-producing trees (Nixon et al. 1980). The absence of snags in clearcuts reduces the suitability of these areas for cavity-nesting species (e.g., woodpeckers or small mammals; Yahner 1988b, Stribling et al. 1990, Renken and Wiggers 1993, Shackelford and Conner 1997). Certain species rely on snags as perch sites while hunting in clearcuts (e.g., red-tailed hawk [*Buteo jamaicensis*]). Use of perch sites by birds can be an important means of seed dispersal via the excretion of ingested seeds by birds while they are perched on these substrates (McClanahan and Wolfe 1993).

Populations of wildlife (such as black bear [*Ursus americanus*], white-tailed deer, moose [*Alces alces*], ruffed grouse, and American woodcock), and assemblages of breeding birds, require early successional stages of forest development, such as those created by clearcutting, in conjunction with features provided by proximal forest stands of differing ages, to meet their annual resource needs (Gullion 1976, 1990; McDonald et al. 1994; Dessecker and McAuley 2001; Hunter et al. 2001; Litvaitis 2001). Recent work indicates that early successional stands are heavily used by many bird species that breed in mature forests, including ovenbird, scarlet tanager (*Piranga olivacea*), wood thrush (*Hylocichla mustelina*), and worm-eating warbler (*Helminthos vermivorum*; Vitz and Rodewald 2006). This necessitates a mosaic of different-aged stands in the landscape (Fig. 26.4). Other species, like snowshoe hare and New England cottontail, require early successional habitats spaced relatively close to one another (e.g., 0.5 km) to sustain populations in the long term (Scott and Yahner 1989, Litvaitis 1993).

Fig. 26.4. An aerial photo of a mosaic of clearcuts in the Allegheny National Forest, Pennsylvania. Photo by J. Timothy Kimmel, School of Forest Resources, Pennsylvania State University; from Yahner (2000:89).

The traditional method of clearcutting has been modified by other silvicultural methods that retain a certain number of trees in a forest stand after harvest (Society of American Foresters 1981, Lorimer 1990b, Yahner 2000). Retention of trees in harvested stands increases aesthetics and improves their value to wildlife adapted to early successional habitats (Thompson and DeGraaf 2001).

Seed-Tree Method

The **seed-tree method** is another even-aged regeneration technique that removes the old stand in one cutting, except for a small number of seed trees (5–10 trees/ha) left singly or in small groups, and seed trees then are harvested once new trees become established in the stand (Society of American Foresters 1981, Smith et al. 1997). This method has been used extensively in management of southern pine stands. Trees retained by the seed-tree method can provide cavities for nesting birds (e.g., eastern bluebird [*Sialia sialis*]; Crawford et al. 1981). Somewhat similar to the seed-tree method, retention of 15–20 trees scattered within small (1-ha), even-aged oak stands in Pennsylvania creates perch sites for bird species, like cedar waxwing (*Bombycilla cedrorum*) and Baltimore oriole (*Icterus galbula*; Yahner 1993, 1997). Clusters of about 15 residual trees in even-aged aspen stands in Minnesota are used extensively by ovenbird, black-throated green warbler (*Dendroica virens*), and other forest species (Merrill et al. 1998).

In addition to density of residual trees retained in even-aged stands, wildlife biologists and forest managers need to consider size of residual trees (Hunter and Bond 2001). As an example, 5 trees/ha of Douglas-fir or redwood with a **diameter at breast height** (dbh) of ≥ 91 cm or ≥ 122 cm, respectively, have been recommended for retention in even-aged stands of the Pacific Northwest.

Shelterwood Method

In contrast to other methods of even-aged forest management, the **shelterwood method** involves a series (3) of cuts spanning about 10 years (Lorimer 1990b). Roughly 30–50% of the trees are harvested in the first cut to permit light penetration and increase vigor of seedlings and seed production in the remaining trees; many of the trees removed may be diseased (Society of American Foresters 1981, Patton 1992). After seedlings become established, another 25% of the nonharvested trees are removed followed by a final cut that removes all nonharvested trees, allowing seedlings to grow to maturity and creating an even-aged stand. Depending on the wildlife species, the shelterwood method may have contrasting effects on population abundance (e.g., Sullivan et al. 1999). For instance, populations of white-footed mice (*Peromyscus leucopus*) may remain the same, whereas those of southern red-backed voles (*Clethrionomys gapperi*) can increase immediately after treatment of stands by the shelterwood method (Sullivan et al. 1999). Shelterwood cuts

retain moderate canopy cover; therefore, over the short term they continue to provide habitat for canopy species of birds (Lanham et al. 2002, Wang et al. 2006).

ALTERNATIVES TO CLEARCUTTING METHOD

Two-Age Method

A recent alternative to clearcutting is the **2-age method or deferment cutting** (Smith et al. 1989a, Miller et al. 1997). This method involves retention of 30–49 trees/ha; after 40–80 years of sufficient regeneration, residual trees then are harvested. Bird species nesting or foraging in low-lying vegetation were more abundant in 2-age cuts after the first cutting cycle compared to those in clearcuts in West Virginia (Duguay 1997, Duguay et al. 2001). Differences in bird communities persisted even 10 years after harvest, with both early and late-successional species occupying 2-age cuts (McDermott and Wood 2009). Salamander abundance was similar in 2-age cuts and clearcuts, but was lower than in mature forests (Duguay and Wood 2002).

Variable-Retention or Partial-Harvest Systems

Variable-retention or partial-harvest systems retain trees, snags, or small patches of trees within harvests, and these systems are increasingly popular in North America (Franklin et al. 1997). These systems attempt to achieve harvest goals while enhancing local biodiversity. An excellent example of such a system, termed even-aged reproduction stands with guidelines, was adopted in Pennsylvania (Boardman and Yahner 1999). At least 12 trees and shrubs/ha were retained in these stands to provide vertical stratification of vegetation, enhance floral diversity, and increase aesthetics; often >100 trees/ha were retained in these stands (Rodewald and Yahner 2000). Trees retained were used by bird obligates of mature forests (e.g., eastern wood pewee [*Contopus virens*] and scarlet tanager), while the stands simultaneously provided breeding habitat for a variety of early successional birds (Boardman and Yahner 1999, Talbott 1999, Rodewald and Yahner 2000, Talbott and Yahner 2003). These stands were most beneficial in enhancing avian diversity when 10–40 ha in size (Boardman and Yahner 1999). However, because abundances of forest-breeding birds decreased and brown-headed cowbirds (*Molothrus ater*) increased with size of the harvest, managers should consider limiting size to 20 ha (Rodewald and Yahner 2000). Despite the presence of residual trees, harvests in these areas failed to provide habitat for woodland salamanders (Rodewald and Yahner 1999).

RECOMMENDATIONS FOR WILDLIFE-SENSITIVE HARVESTING

Although it is difficult to generalize about the effects of forest management on wildlife, several practices can improve

the suitability of harvested stands for forest wildlife. These include **protection, retention, and management efforts.**

Protection of Unique and Important Habitat Features

Tree removal proximal to unique habitat features such as rocky outcrops, small ponds, temporary pools (vernal pools), and seeps can destroy valuable wildlife habitat. Rocky outcrops in forested landscapes of the Northeast, for instance, are critical habitat for conservation of the threatened Allegheny woodrat (*Neotoma magister*; Balcom and Yahner 1996). Vernal ponds also are required by many forest amphibians and should be protected from harvesting operations whenever possible.

Enhancement of the Vertical Diversity of Forests

Vertical diversity (or vertical structure) refers to the different layers of vegetation within a habitat (e.g., ground, understory, subcanopy, and canopy). Ecologists have long recognized that species richness tends to increase with vertical diversity of forest stands (MacArthur and MacArthur 1961, James 1971, James and Wamer 1982). Although forest animals may specialize on particular “layers” of the forest, some species may use different strata during specific periods of the annual cycle. For example, juvenile canopy-nesting birds (e.g., cerulean warbler, *Dendroica cerulea*) regularly use shrubs during the postbreeding period (Bakermans 2008).

Retention of Buffers along Forest Streams

Riparian zones are important to a rich diversity of flora and fauna (Naiman and Decamps 1997). Tree removal near streams not only destroys habitat for terrestrial wildlife, but also harms aquatic organisms by increasing water temperature and sedimentation (Brown and Krygier 1967, Society of American Foresters 1981, Mitsch and Gosselink 1993). Depending on slope and other site characteristics, **buffer zones** of 30–75 m should remain unharvested near streams and other riparian zones to reduce effects of tree removal on aquatic fauna and flora (Brazier and Brown 1973, Society of American Foresters 1981). Logging roads and skid trails also should be kept away from water, and number of stream crossings for roads should be minimized.

Retention of Overstory Trees in Harvested Areas

Live **overstory trees** (trees at top of canopy), when retained both individually and in small groups of different species and sizes, provide perching, nesting, and foraging opportunities for wildlife (Duguay 1997, Merrill et al. 1998, Boardman and Yahner 1999, Rodewald and Yahner 2000). Efforts should be made to retain trees that produce mast (e.g., fruits, nuts, and seeds), such as that of beech, oak, cherry (*Prunus* spp.), and dogwood (*Cornus* spp.), which provide important food resources to many species of forest wildlife. Small groups of conifers (like spruce and hemlock) also can provide important cover from snow and cold temperatures during winter.

Retention of Decaying and Dead Trees (Snags)

Tree cavities provide shelter, dens, nests, and foraging sites for many wildlife species (Fig. 26.5). At least 85 bird species in North America use tree cavities (Scott et al. 1977). Thus, retention of standing trees and limbs of all sizes is a good management practice; in particular, large snags and large decadent trees (e.g., live trees with dead or broken tops) are valuable for cavity-nesting and cavity-roosting species that cannot use smaller cavities (Thomas et al. 1979a, Bonar 2000, Aubry and Raley 2002). Some trees should be as large as 46-cm dbh for larger cavity-dependent species (e.g., wood duck [*Aix sponsa*] and pileated woodpecker). Some damaged young trees should be reserved to provide future cavity trees. Fungal conks, dead branches, old scars, and soft or decaying wood (especially heart-rot) are good indicators of trees with cavity potential. Thomas et al. (1979a) have recommended retention estimates for densities of trees with cavity potential.

Retention of Woody Debris

Many animals, especially salamanders and small mammals, use logs, slash, and other woody debris for cover, dens, nests, foraging sites, and as places for courtship displays (e.g., Maser et al. 1979a, Yahner 1986, Petranka et al. 1993; but see Rodewald and Yahner 1999). If possible, leave large logs, which persist longer than small logs, as potential wildlife habitat; ≥ 5 large logs/ha (>12 cm diameter, >2 m long) should

Fig. 26.5. A snag containing a cavity that potentially could be used by wildlife species. Photo by R. H. Yahner; from Yahner (2000:92).

be retained (Maser et al. 1979a). Woody debris on the forest floor also mitigates soil erosion, increases moisture on the forest floor, and stores energy and nutrients (Spurr and Barnes 1980). Woody debris often impedes movements by deer, thereby improving opportunities for seedlings to regenerate in managed stands (Grisez 1960).

Creation of Feathered and Meandering Edges

An **edge** is the interface between 2 types of landscape elements, such as the juncture of a forest stand and a crop field (e.g., Yahner 2000). Edges can be **abrupt**, as with the interface of a forest and a farm field, or **feathered**, as with a gradual transition along a gradient from forest to old field to grassland (Fig. 26.6). Some wildlife, such as salamanders and certain forest birds, avoid using abrupt edges, and those that use them may experience high rates of predation and brood parasitism (Gates and Gysel 1978, Brittingham and Temple 1983, Wilcove 1985, Hoover et al. 1995). Edges are often associated with higher amounts of nest predation, fewer food resources for some species, warmer air and soil temperatures, drier conditions, and more wind than interior forest (Yahner 1988a). Type and severity of edge effects is highly dependent upon landscape context, with edges in forested landscapes generally being associated with fewer negative consequences to breeding birds (Donovan et al. 1997, Hartley and Hunter 1998, Rodewald 2002). Abrupt and highly contrasting edges generally have more negative “**edge effects**” than gradual, low-contrast edges (Suarez et al. 1997, Yahner et al. 2000). Gradual, low-contrast edges can be made by allowing shrubs, saplings, and some overstory trees to remain along the harvest boundary.

Maximizing Forest Interior

Forest interior is unbroken forest ≥ 100 m from edges and usually is positively related to size of a patch of forest, assuming the patch is more circular than linear (i.e., the larger the patch size, the greater amount of forest interior; For-

man and Godron 1986). Some wildlife species occur only in forests containing adequate amounts of interior forest (e.g., Forman et al. 1976, Ambuel and Temple 1983, Blake and Karr 1987, Robbins et al. 1989). Large tracts of mature timber, for instance, are recommended as roosting habitat for forest bats (e.g., red bat [*Lasiurus borealis*]; Hutchinson and Lacki 2000), and for many Neotropical migratory birds (e.g., wood thrush, ovenbird, and scarlet tanager; Robbins et al. 1989). Amount of interior forest can be increased by leaving a large patch of uncut forest. Harvesting, if necessary, should be confined to the borders, rather than the interior (where it would fragment the intact forest), of the forest.

Retention of Old Forest Stands

In the 1500s, about 400 million ha of forest spanned the 48 contiguous states (Harrington 1991). Since European settlement, only about 3–5% of the **original or old forest** remains today. Old forests (>110 yr old) differ from managed, younger stands in structure, composition, and function (Thomas et al. 1988). Many old forests are maintained by internally driven gap-phase dynamics (Bormann and Likens 1979) and can persist in the landscape for centuries. These older forests usually have high structural and floristic complexity and contain features such as multilayered canopy, widely spaced large trees, canopy gaps, and snags and logs (Davis 1996, Oliver and Larson 1996). Canopy heterogeneity, in particular, is increasingly recognized as an important component of habitat for some species. For example, canopy openness was positively related to density and nesting success of cerulean warblers, a songbird species with a rapidly declining population, which breeds in eastern deciduous forest (Bakermans 2008). Today, managed forests cannot be expected to contain the same plant and animal communities as pristine, old forests (Yahner 2000). Examples of wildlife species characteristic of old forests are northern spotted owl (*Strix occidentalis caurina*), red-cockaded woodpecker, and fisher (*Martes pennanti*; Thomas et al. 1988, Mannan et al. 1996).

Old forests are relatively rare in the United States; therefore, contiguous blocks of forest of $\geq 1,000$ ha should be maintained for species sensitive to human-induced disturbances (e.g., Robbins 1979). Moreover, state and federal agencies, which serve as stewards of public lands, should ensure that a proportion of forestlands (e.g., 10%) be set aside in large tracts (>100 ha) for establishment of old forests of the future (Yahner 2000).

FOREST FRAGMENTATION AND LANDSCAPE CONSIDERATIONS

Habitat fragmentation is one of the greatest threats to ecological communities throughout the world (Wilcox and Murphy 1985). Fragmentation is associated with several changes to a landscape, and each change can strongly affect

Fig. 26.6. Forest clearcutting creates edges for use by wildlife. Photo by R. H. Yahner; from Yahner (2000:124).

wildlife communities (Andrén 1994). Fragmentation (e.g., that created by timber harvesting or urbanization) can result in habitat loss of varying permanency in a forested landscape (McIntyre and Barrett 1992, Yahner 1996). Because of the direct impact of habitat loss on native flora and fauna, fragmentation has been implicated in population declines of more species than any other human-induced influence (e.g., Terborgh 1989).

As amount of **forest cover** declines in the landscape, remaining forest patches generally are reduced in size and become increasingly isolated (Harris and Silva-Lopez 1992, Knight and Landres 2002). For this reason, area and isolation add to the effects of habitat loss and exacerbate negative effects on forest-dependent, area-sensitive species in fragmented landscapes (Andrén 1994). As landscapes are fragmented, presence of new land uses (like agriculture or urban development) increases, and these land uses can vary markedly in their effects on adjacent habitats (Friesen et al. 1995; Rodewald and Yahner 2001a, b; Rodewald and Bakermans 2006). In some respects, the extent of fragmentation falls along a continuum, with small perforations of disturbance in a relatively continuous matrix of habitat occurring at low levels of fragmentation, and greater shrinkage of remaining habitat patches within an extensive disturbed matrix at high levels of fragmentation (Forman 1995a; Fig. 26.7).

Fragmentation and Edge Effects

Fragmentation often is related to edge because small forest patches have greater edge-to-interior ratios than large patches (Forman and Godron 1986). Edges can affect ecosystems and within-patch ecological functions through abiotic effects (e.g., alter fluxes of radiation, wind, and water), direct biological effects (e.g., promote plant growth near edges), and indirect biological effects (e.g., alter species interactions; reviewed by Yahner [1988b] and Murcia [1995]). These edge effects may extend up to 600 m from an edge into the interior of an adjacent forest stand (Wilcove et al. 1986). In most studies, edge effects have been largely attributed to indirect biological effects (e.g., higher rates of nest predation and brood parasitism [Fig. 26.8] nearer to, rather than farther from, edges; Gates and Gysel 1978, Brittingham and Temple 1983, Wilcove 1985, Hoover et al. 1995, Brand and George 2000; but see Ratti and Reese 1988, Rudnicki and Hunter 1993a, Yahner et al. 1993, Chalfoun et al. 2002). Although edge sensitivity or avoidance is frequently perceived to be limited to late-successional forest wildlife, a growing body of literature suggests that many early successional species, especially shrubland birds (e.g., yellow-breasted chat and prairie warbler [*Dendroica discolor*], also may avoid edges; Rodewald and Vitz 2005, Schlossberg and King 2008). Edges in conjunction with other landscape features (e.g., in prox-

Fig. 26.7. Fragmentation of forests (shaded areas) in Cadiz Township, Wisconsin, from 1831 to 1950. From Mannan et al. (1996:705).

imity to agricultural fields and streams) are preferred habitats for some wildlife species, like common raccoon [*Procyon lotor*]; Dijk and Thompson 2000).

Despite decades of study, generalizing about the consequences of edge to wildlife remains a challenge. Abrupt or permanent edges are widely thought to have more severe effects than gradual edges (Suarez et al. 1997), though studies conducted in forested landscapes have shown no difference between gradual and abrupt or permanent edges (Ratti and Reese 1988, Yahner et al. 1989, Chalfoun et al. 2002). Studies of nest predation along edges created by silviculture have detected greater rates near edges (Small and Hunter 1988; King et al. 1996, 1998; Tittler and Hannon 2000), whereas others have failed to detect differences (Yahner and Wright 1985, Ratti and Reese 1988, Rudnický and Hunter 1993a, Hanski et al. 1996, Morse and Robinson 1999, Yahner et al. 2001b, Rodewald 2002). Most (88%) studies of edge-related nest predation in forested landscapes have failed to detect edge effects (Andr n 1995). These conflicting results may be partly explained by the role of landscape characteristics (e.g., amount of fragmentation [Donovan et al. 1997, Hartley and Hunter 1998] and type of land uses within fragmented landscapes [Askins 1995, Bayne and Hobson 1997, Rodewald 2002]). A meta-analysis of multiple studies indicated that elevated predation rates near edges were detected less often in highly forested than in fragmented landscapes (Hartley and Hunter 1998). Ries and Sisk (2004) developed a predictive model for edge effects based on how species perceive habitats. If a species perceives that resources at edges are complementary to those in the patch (i.e., bordering patches contain different resources and the edge allows access both), then that species should respond positively to edges. In contrast, a species that perceives resources at edges as supplementary (i.e., they contain same resources present within the habitat patch) or as not containing any usable re-

source will derive no clear benefit from edges, and is expected to show a neutral or negative response to edge.

Area and Isolation Effects

The importance of **patch** (e.g., forest stand) area and **isolation** (distance to other patches) to faunal communities became widely recognized with the development of island-biogeography theory (MacArthur and Wilson 1967), which predicted that species richness increased with increasing island size and decreasing distance to the mainland (source habitat). In the decades since, numerous studies have demonstrated that certain populations may be more abundant or communities may be more diverse (particularly vertebrates) in larger patches of habitat than in smaller ones and in less isolated patches than more isolated ones (Forman et al. 1976, Ambuel and Temple 1983, Blake and Karr 1987, Robbins et al. 1989, Keller 2001, Crooks 2002; but see Fleishman and MacNally 2002; Fig. 26.9). Despite problems with applying island-biogeography theory to terrestrial habitat patches (e.g., habitat patches are usually surrounded by a matrix that allows some dispersal), these species-area patterns have been detected across many forest ecosystems, especially in the eastern United States.

Wildlife biologists and forest managers recognize that some taxonomic groups (e.g., many forest bird species) are area-sensitive and require large tracts of habitat to live and reproduce successfully (Whitcomb et al. 1981, Robbins et al. 1989). Although classic examples of area-sensitive wildlife breed in older forests and are Neotropical migratory birds (e.g., scarlet tanager, ovenbird, and wood thrush; Ambuel

Fig. 26.9. A hypothetical species-area relationship in isolated versus less isolated habitats. From Yahner (2000:106).

and Temple 1983, Robbins et al. 1989) certain early successional birds (e.g., yellow-breasted chat) also may prefer large patches of shrubby regenerating forest (Rudnicki and Hunter 1993b, King and DeGraaf 2004, Lehen and Rodewald 2009).

Several factors have been proposed to explain area sensitivity in forest birds. Small habitat patches may not be sufficiently large enough to accommodate a territory or provide sufficient resources for individuals (Whitcomb et al. 1981). Also, reduced habitat size can decrease probability of occurrence of large carnivores with appreciable home ranges (e.g., mountain lion [*Puma concolor*] and bobcat [*Lynx rufus*]), whereas the exotic domestic cat (*Felis catus*) is more apt to occur in smaller fragments than larger ones (Crooks 2002). A reduction in patch size also may reduce habitat heterogeneity (Freemark and Merriam 1986), making a species less likely to find specific habitat requirements in smaller patches. A frequently invoked explanation for area sensitivity of some bird species is that rates of nest predation and brood parasitism are much higher in small patches or fragmented landscapes than in large patches or in forested landscapes (Lynch and Whigham 1984, Wilcove 1985, Wilcove and Robinson 1990, Hoover et al. 1995, Van Horn et al. 1995). In this respect, small fragments may be viewed as “ecological traps” (Gates and Gysel 1978), where birds nest in areas that are unlikely to allow successful breeding.

Extent of isolation among patches is an important landscape consideration because it can affect the ability of organisms to successfully disperse among habitat patches (Lynch and Whigham 1984). For example, movements of eastern chipmunk (*Tamias striatus*) and eastern cottontail are restricted in intensively farmed landscapes that lack woody corridors connecting woodlots (Swihart and Yahner 1982). As a habitat patch becomes more isolated with increased fragmentation, it becomes less likely to contain large carnivores (e.g., mountain lion and bobcat; Crooks 2002). The scarlet tanager is a species that appears to be sensitive to isolation in the Appalachian region. As forest patches become increasingly isolated, the probability of occurrence of scarlet tanagers decreases from 100% in small patches within 100 m of large forest blocks, to 49% if separated by 1.6 km, to 20% in patches separated by >6 km (Rosenberg et al. 1999; Fig. 26.10). Furthermore, effects of isolation are not necessarily a function of only juxtaposition of patches, but also a function of dispersal capabilities of organisms and characteristics of the landscape matrix. A matrix containing residential developments may be more difficult and risky for a wide-ranging, yearling mountain lion to traverse during dispersal compared to a matrix comprised of agricultural pasture and cropland.

Maintenance or creation of **habitat corridors** connecting patches is frequently proposed as a solution to mitigate isolation effects on wildlife (Noss 1987, Simberloff and Cox 1987, Vos et al. 2002) because corridors should facilitate movement among patches (MacClintock et al. 1977, Harris

and Gallagher 1989, Vos et al. 2002) and enhance gene flow (Britten and Baker 2002). For instance, American robin (*Turdus migratorius*) and brown thrasher (*Toxostoma rufum*) in agricultural landscapes moved more often between wooded patches connected by wooded corridors than between isolated wooded habitats (Haas 1995). A wooded corridor also may provide additional suitable habitat for home ranges of some wildlife species (Hodges and Kremenetz 1996, Yahner 1997, Hein et al. 2009), depending on width and landscape context (Beier and Loe 1992). On the other hand, some ecologists contend that corridors negatively influence some wildlife by facilitating spread of disease, exotic species, or disturbances (Noss 1987, Simberloff and Cox 1987, Hess 1994). For decades relatively few empirical data were available to evaluate usefulness of corridors in fragmented landscapes (Harrison 1992, Morrison et al. 1992, Vos et al. 2002), with most examinations being small-scale or confounding habitat area with presence of corridors. However, a recent large-scale experimental study provided compelling evidence that corridors promote movement of plants and animals among patches and facilitate seed dispersal (Tewksbury et al. 2002, Levey et al. 2005, Damschen et al. 2006). At present, potential benefits of corridors seem to outweigh possible negative effects.

Evidence also suggests that sensitivity to area and isolation is tied to landscape context, and area requirements may change dramatically depending on landscape characteristics. In landscapes containing >30% remaining suitable habitat, the primary consequence of fragmentation is habitat loss, rather than area and isolation effects (Andrén 1994). Only in highly fragmented landscapes, do area and isolation effects exacerbate the negative effects of habitat loss on area-sensitive species (Andrén 1994). For example, Rosenberg et al. (1999) found that area requirements of scarlet tanager varied by order of magnitude depending on the amount of fragmentation in the landscape. In a 1,000-ha landscape with >70% forest, only 27 ha are required for “high” suitability, whereas in a landscape with 40% forest, 250 ha are needed (Rosenberg et al. 1999). Similarly, minimum area required for high habitat suitability for the veery (*Catharus fuscescens*) ranged from 51 ha in forested landscapes (90%) to >406 ha in less forested landscapes (Rosenberg et al. 2003). This suggests that managers working in heavily forested landscapes may do better to concentrate efforts on increasing the amount of habitat within the landscape rather than focusing specifically on increasing patch size or reducing isolation.

Landscape Matrices and Land Uses

A **landscape matrix** is the “background” within which habitat patches and corridors are embedded. The matrix can alter movements of individuals, serve as sources of species and individuals invading patches and corridors, and can determine severity of edge, area, and isolation effects on wildlife (Donovan et al. 1997, Hartley and Hunter 1998, Gascon

et al. 1999). Both amount and type of disturbance or land use within the matrix can affect flora and fauna within adjacent habitat patches and corridors.

Land uses within landscapes can vary structurally and temporally and, hence, differ in their impact on associated wildlife (McIntyre and Barrett 1992; Yahner 1996; Rodewald and Yahner 2001a, b; Rodewald 2003b). For example, conversion of forest to residential developments or agriculture generally can be regarded as permanent loss to wildlife, whereas silvicultural treatments may change the forest from one developmental stage to another. Furthermore, silvicultural disturbances tend to be more structurally heterogeneous than agricultural areas and may provide more habitat structure than other types of disturbances.

Residential or urban development adjacent to woodlots, in particular, can have pronounced effects on wildlife (Friesen et al. 1995). Presence of residential homes within 100 m of woodlots, for example, decreased diversity and abundance of breeding birds, irrespective of woodlot size. Similarly, amount of urban development surrounding **riparian forests** (forests along waterways) in the Midwest was more important to bird communities than width of the forest corridor, with Neotropical migratory birds (e.g., Acadian flycatcher [*Empidonax virens*]) being negatively correlated with urban matrices (Rodewald and Bakermans 2006, Rodewald and Shustack 2008).

Characteristics of a given matrix can have profound influences on wildlife movements. Small clearcuts (0.5–22.3 ha) in northern hardwood forests, ranging from 1 year to 13 years since cutting, can impede movements of southern flying squirrels (*Glaucomys volans*; Bendel and Gates 1987, Healy and Brooks 1988). Forests within a landscape matrix disturbed by small amounts of agricultural land uses (e.g., pasture, cropland) had fewer forest-dependent and long-distance migratory bird species, but higher abundance of nest predators, than forests within landscapes disturbed by similar amounts of silvicultural land uses (e.g., even-aged forest stands; Rodewald and Yahner 2001). Although studies have shown that fragmented agricultural landscapes have greater abundances of generalist predators than silvicultural landscapes (Andrén 1992, Bayne and Hobson 1997, Pedlar et al. 1997, Saab 1999; but see Tewksbury et al. 1998), this pattern had not been well established in forested landscapes (reviewed by Chalfoun et al. 2002).

Management Recommendations for Forest-Reserve Design

Biologists and land managers increasingly recognize that successful conservation of forest-dependent wildlife requires management at both patch/landscape and broader landscape scales (e.g., Yahner 2000). However, identifying the appropriate number, size, and spatial arrangement of habitat patches for a focal species or group is not easy. An optimal landscape design could vary substantially across landscapes and regions,

especially when characteristics of matrices differ. In spite of apparent problems, there are several general strategies that can be used by land managers (e.g., Diamond 1975, Franklin and Forman 1987).

First, characteristics of the desired **forest reserve** must be carefully considered. Managers should retain or plan for large reserves of contiguous forest, although the optimal size can be difficult to determine (reviewed by Yahner 2000). **Minimum-area requirements** for area-sensitive bird species range from several hectares to thousands of hectares (see Fig. 26.10) and can vary widely among species, landscapes (i.e., forested versus fragmented), and regions (e.g., Northeast versus Midwest). Moreover, reserves should be sufficiently large to accommodate natural disturbances (e.g., fires, floods) and still provide forest habitat for wildlife (i.e., minimum dynamic area, Pickett and Thompson 1978). Shape of the reserve should maximize the ratio of forest interior to forest edge (i.e., square or circular in configuration) to provide more habitat for species that avoid or are negatively influenced by edges. The same guidelines can be applied to patches of shrubland habitat or harvests, if the management focus is early successional wildlife. In addition, both amount of fragmentation and type of adjacent land uses can influence minimum-area requirements (e.g., Rosenberg et al. 1999, 2003). Thus, suitability of a reserve for wildlife may decline as the surrounding landscape becomes more fragmented.

Second, distances among habitat patches should be minimized whenever possible to facilitate movement of individual animals among patches. A challenge for wildlife biologists in the future will be to identify the appropriate distance between contiguous habitats to ensure long-term viability of metapopulations (Fig. 26.11), such as those of New England cottontail (Litvaitis 1993). This information is contingent on a solid understanding of the dispersal behavior and mobility of the focal species or group. Unfortunately, these data are often lacking or difficult to obtain (e.g., Yahner and Mahan 2002).

Fig. 26.10. The probability of occurrence of 4 songbird species in relation to size of forest stand. From Yahner (2000:117).

Fig. 26.11. A hypothetical landscape containing a metapopulation (a group of interconnected populations of the same species). Populations are indicated by circles, and relative sizes of populations are given by numbers within circles. From Yahner (2000:135).

Third, when possible, efforts should be made to improve the suitability of the landscape matrix, thereby increasing probability of survival and/or successful dispersal of animals moving through the matrix. This might be accomplished in a variety of ways (e.g., from preserving “stepping stones” of forest habitat [e.g., small woodlots] to creating forested corridors, from adopting wildlife-sensitive agricultural practices to preserving “open spaces” within the fragmented landscape). When possible, the amount of urban or residential development should be limited adjacent to nature reserves and other forest habitats, because urban or suburban land uses are frequently associated with reduced diversity, abundance, and reproductive success of some Neotropical migratory birds (reviewed in Marzluff and Rodewald 2008). In some cases, these negative consequences can be quite subtle, resulting from complex interactions among different tropic levels. For example, urbanization surrounding forest preserves promoted invasion by exotic shrubs (e.g., Amur honeysuckle [*Lonicera maaackii*]; Borgmann and Rodewald 2005), which increased the vulnerability of understory nests to predation (Borgmann and Rodewald 2004, Rodewald et al. 2010). Currently, appropriate distances between nature reserves and developed areas or other disturbances are poorly understood (Ambrose and Bratton 1990). Understanding potential effects of urbanization on remnant habitats is especially important given the affinity of the public for living near

forested areas (e.g., Kaplan and Austin 2004), which can result in comparably higher development rates near parks, state forests, and other natural areas.

Fourth, edges should be irregular rather than straight, and contrast should be reduced between habitats at edges (e.g., Thomas et al. 1979c). Low-contrast, gradual edges can be made by allowing shrubs, saplings, and some overstory trees to remain along the harvest or development boundary. Edges can be feathered by retaining more trees closer to the forest interior and gradually fewer trees closer to the non-forested area.

Although these general strategies (e.g., maximizing area, minimizing edge and isolation) produce positive results in many landscapes, a manager also must be attentive to changes in the landscape, especially in terms of fragmentation, habitat loss, and new or expanding land uses. Management strategies may need to be adjusted based on future anticipated changes. For example, one cannot become complacent once a reserve of size X is protected because future development and disturbances to the surrounding landscape may greatly affect the ability of the reserve to provide quality habitat for a sensitive species.
