Plant-species composition, age, size, and growth dynamics of a forest stand can have important influences on habitat selection and use by wildlife. Thus, **habitat models** enable resource managers to predict wildlife species occurrences and adjust forest management regimes. **Management regimes** can be adjusted to benefit wildlife by altering forest yield and productivity, regeneration, and tree composition (Mannan et al. 1996, Roloff et al. 2001). Three general types of models are available to resource managers: **silvicultural models**, **single-species wildlife-habitat models**, and **multispecies wildlife-habitat models**.

For purposes of modeling forest dynamics, a forest stand is defined as a contiguous group of trees sufficiently uniform in species composition, age class, site quality, and condition to be a distinguishable unit (Smith et al. 1997). In contrast, the term “forest” connotes a more landscape-level approach and is a collection of stands administered as an integrated unit.

Silvicultural Models

Silvicultural models display and predict forest composition and structure at different levels of scale. Three types of silvicultural models exist: (1) stand-based models, (2) individual-tree models, and (3) landscape or regional models (Gadow and Hui 1999).

Stand-Based Models

The **stand-based model** is the traditional model, which uses forest stand as the unit of management. These models esti-

mate timber growth and potential yield (software lists in Ramm and Miner [1986] and Mannan et al. [1996]) and take into account climate, soil, and native-tree communities. **Potential yield** is estimated by predicting forest height and basal area that are functions of stem density within a given stand (Gadow and Hui 1999). Although these models traditionally have been used to predict timber growth and yield, these components of forest stands have important implications for wildlife. In addition, some models predict basal area as a function of stand age, initial basal area, and changes in diameter distributions within a stand. These models typically require data on tree development under natural growing conditions in response to thinning regimes, which are species-specific and vary with environmental conditions. Data on forest-stand growth are available from government research organizations (e.g., USFS) and through University research cooperatives (e.g., Loblolly Pine Growth and Yield Research Cooperative at the Virginia Polytechnic Institute and State University).

The development of an even-aged forest stand may be predicted using **stand-based models** that consider average stand height, basal area, and stems per hectare (density). Several models recently have been used to model the development of height based upon stand age (e.g., Zeide 1993, Shvets and Zeide 1996). Other models have been developed to project stand basal area primarily for commercially valuable species, such as slash pine (*P. elliotti*; Pienaar et al. 1990).

In uneven-aged, mixed-species forest stands, **size-class models** can be used to project the development of the stand by assuming that a representative tree of a particular diameter exhibits the attributes of all trees of that particular diameter class regardless of species (Smalley and Bailey 1974). Furthermore, size-class models assume that future diameters of trees may be predicted from known initial diameter and stand age. However, diameter growth also is influenced by crown surface area, stand density (manipulated by thinning regimes), tree height, stem quality, and competition among trees in a stand (Spurr and Barnes 1980).

Individual-Tree Models

Individual tree-growth models have been developed, resulting in an increased level of modeling resolution. These models depend upon knowledge of the precise location of a tree within the stand and its relation to neighboring trees, thereby enabling the calculation of competition indices (Clutter et al. 1983, Trepl 1994) and the application of more exact growth models to a given stand. In addition, individual-tree models (also called distance-dependent models) can be used that incorporate the effects of thinning on individual trees within a stand (Gadow and Hui 1999).

Several **model simulators**, such as **FOREST** (developed by Ek and Monserud [1974]), assume that potential growth of individual trees is reduced by competition from neighboring trees. **MOSES** estimates height and diameter growth and changes in tree height based on spatial positioning of

individual trees within the stand (Gadow and Hui 1999). **SILVA** is a growth simulator for individual trees, which was originally developed for mixed spruce-beech forests in Germany (Gadow and Hui 1999). Variables necessary to operate SILVA models include stand age, initial basal area, crown volume, and crown surface area, shading, and constriction.

Some models incorporate the relationship of environmental variables, such as light and temperature, to individual tree-diameter growth equations (Roloff et al. 2001). This inclusion makes it possible to predict the response of tree growth to varying environmental conditions. For example, Pastor and Post (1985) examined effects of climate, soil moisture, nitrogen availability, and light conditions on individual tree growth. These models often require detailed information about conditions within a forest stand (Qi and Gilles 1999).

Landscape or Regional Models

Models also are available that project the estimated yield of regional timber resources based upon site-quality categories (Shvidenko et al. 1995). These **regional models** permit resource managers to estimate standing volume of timber of a given age, assuming different harvest scenarios (Gadow and Hui 1999). Regional models have been developed to estimate yield of even-aged forest stands and managed stands with continuous cover forest (where trees are removed selectively). However, yield projections must be adjusted in stands that are not fully stocked (e.g., thinned stands). Yield projections for stands characterized by different site quality, tree species, and silvicultural practices do not exist (Gadow and Hui 1999).

Another modeling approach for regional application involves tracking the amount of land in different successional stages and forest types. For example, **FORPLAN** can be used to predict the amount of land in different forest types and growth stages over time (Kirkman et al. 1986, Mannan et al. 1996).

Silvicultural Model Application

The integration of forest and wildlife management using silvicultural models is illustrated by an approach to biodiversity conservation in western Massachusetts (DeGraaf et al. 1992, Smith et al. 1997). A mosaic of suitable forest-age classes and composition had to be created and maintained to provide appropriate habitat for an assemblage of vertebrate species that inhabit the area. Regeneration of white pine (*P. strobus*) and the development of vertical structure in some areas were among the specific recommendations. By collecting data on appropriate variables, resource managers could use the growth model SILVA, for instance, to predict how certain silvicultural practices affect the growth of white pine trees.

Wildlife-Habitat Models

Single-Species Wildlife-Habitat Models

Resource managers often use correlation models or species-habitat matrices to identify habitat requirements of individ-

ual forest-wildlife species in a given forest stand or type (DeGraaf et al. 1992, Roloff et al. 2001). These **correlation models**, consisting of tables listing vegetation types or environmental conditions associated with different wildlife species, provide an efficient means of predicting presence or relative abundance of different species. Correlation models have been developed for wildlife associated with ecosystems in the Sierra Nevadas, New England, and the southern United States (Verner and Boss 1980, DeGraaf and Yamasaki 2001, Dettmers et al. 2002, respectively).

Another type of single-species wildlife-habitat model is the **habitat-evaluation procedure** (HEP). HEP is based on indices of habitat quality, where quality is measured by vegetation structure, composition, and spatial arrangement (Roloff et al. 2001, Anderson and Gutzwiller 2005). **Habitat quantity** is calculated by multiplying the quality index by the corresponding amounts of each habitat type. This model assumes that a greater quantity of habitat for a particular species will result in higher abundance of that species (Roloff and Haufler 1997). HEP has been used extensively because this type of model can be applied to a range of habitats or ecosystems and it is relatively inexpensive to develop. However, HEP has been criticized because of its relative simplicity and subjectivity (Roloff et al. 2001).

The **habitat-suitability-index (HSI) model**, developed by the U.S. Fish and Wildlife Service, focuses on single species and generates a numeric value that assesses the capacity of a habitat to support a species as a function of vegetation structure and composition and spatial arrangement of differing habitat types (Division of Ecological Services 1980, Anderson and Gutzwiller 2005). A high HSI value for a particular wildlife species (based on a range of 0.0–1.0) indicates the habitat of interest likely contains that species (referenced in <http://policy.fws.gov/870fw1.html> for all published HSI models).

Bayesian and pattern-recognition models also have been used to examine the relationship between forest habitat and wildlife (Roloff et al. 2001). To use these models, a researcher must classify a habitat patch into a category of habitat suitability, identify which attributes dictate habitat-suitability categories, and assign a set of Bayesian probabilities that reflect the association between habitat attributes and each suitability category (Williams et al. 1977, Kirkman et al. 1986, Mannan et al. 1996). For example, Bayesian and pattern-recognition models have been used in modeling studies involving bald eagles (*Haliaeetus leucocephalus*; Grubb 1988) and mountain sheep (*Ovis canadensis*; Holl 1982).

Multivariate-statistical models show potential relationships between multiple environmental characteristics and a species' abundance and distribution (Morrison et al. 1992, Roloff et al. 2001). These models identify habitat variables that have the greatest effect on the occurrence or population of wildlife of interest. Several multivariate-statistical approaches used in wildlife-modeling studies include multiple regression, principal component analysis, discriminate

function analysis, regression tree analysis, and fuzzy logic (Roloff et al. 2001). Multivariate models have been developed for a variety of wildlife species because they have a low level of subjectivity (Digby and Kempton 1987), but they are limited by data availability and often are difficult to interpret and communicate (Roloff et al. 2001).

Habitat-preference models also can be used to examine how wildlife use varies among forest stands that differ in age, species composition, and structure in relation to the availability of these stands (Morrison et al. 1998, Roloff et al. 2001). Habitat preference can be examined by the amount of time a given wildlife species uses a particular habitat type relative to its availability. Often these models require use of remote methodology, such as radio- or satellite tracking of individual animals, to measure habitat use.

Multispecies Wildlife-Habitat Models

Multispecies wildlife-habitat models, such as **gap analysis**, have been developed (Scott et al. 1993). A gap-analysis model is based on the geographic distribution of assemblages of wildlife species in that it depicts "gaps" in species distribution or identifies areas of high species richness. Gap analysis is especially useful when portraying wildlife-habitat relationships across large areas (Roloff et al. 2001).

Multispecies wildlife-habitat models have been used to describe biodiversity based on vegetation attributes of a given area (e.g., Maurer 1994, Rosenzweig 1995, Roloff et al. 2001). These models assess wildlife community structure in terms of the number of species (e.g., species richness) or the number of individuals of each species.

Other types of multispecies models, focusing on well-defined groups of wildlife species or guilds, have been used to evaluate the effects of habitat changes on the overall functional, structural, and compositional conditions of ecosystems (Roloff et al. 2001). **Guild models** have been primarily developed for songbirds (e.g., O'Connell et al. 2000), but also have been applied to other taxa (e.g., salamanders; Hairston 1987). An example of a guild model, the **Bird Community Index**, is based on response guilds, which are defined as groups of bird species that require similar habitat, food, or other elements for survival (O'Connell et al. 2000). This model assumes that high-integrity environmental conditions will be reflected by the presence of guilds containing more specialist than generalist species. High-integrity environmental conditions are those that typify the habitat type or ecosystem in the absence of human disturbance.

Other guild models have used occurrence, abundance, and locations of ecological communities to predict animal responses. For example, Haufler et al. (1996) stratified landscapes into "**ecological land units**" based on similar disturbance regimes and geological conditions, which were then used to describe and predict floral and faunal diversity for planning purposes. Guild models have been criticized because often the guild as an entity exhibits little response to changes in habitat condition, whereas individual species within

Fig. 26.12. A hypothetical species–area curve. Each dot represents a forest stand of a given size. From Yahner (2000:105).

the guild may vary in their response to the same habitat changes (Mannan et al. 1996).

Forest-Fragmentation Models

Models developed from **island-biogeography theory** have been used to understand the effects of forest fragmentation on wildlife (MacArthur and Wilson 1967, Harris 1984, Yahner 2000). For instance, an important model, the **species–area curve**, predicts that species richness will increase as the size of a forest patch increases (Fig. 26.12). The relationship between forest patch size and species richness also is affected by the extent to which the patch is isolated from other similar habitat. Wilcox (1980) developed a model that predicted isolated, small forest patches would have lower rates of species colonization and higher rates of extinction than large, nonisolated patches. However, simulation models have indicated that forest patches connected by corridors, such as wooded fencerows, can maintain viable populations of wildlife (Merriam and Wegner 1992).

BIODIVERSITY CONSERVATION AND ECOSYSTEM MANAGEMENT

An inclusive and generally accepted definition of **biological diversity**, or **biodiversity**, is the variety of life and its processes at 4 interrelated levels: (1) genetic, (2) species, (3) community and ecosystem, and (4) landscape diversity (Keystone Center 1991, Society of American Foresters 1992, The Wildlife Society 1993, Noss and Cooperrider 1994, Yahner 2000, Knight and Landres 2002). In addition, biodiversity includes ecological structures, functions, and processes at each of these levels. The foremost goal of biological conservation is long-term maintenance of the world's species and other levels of biodiversity (Wiens 2002).

Biological diversity at the genetic level has been given increasing attention by wildlife biologists, as with isolated populations of black bear, which is a species of concern in some southern and eastern states (e.g., Wathen et al. 1985, Pelton and Van Manen 1994, Clark and Pelton 1999; reviewed by

Yahner 2001). Species diversity has been recognized by wildlife biologists as an important measure of wildlife community health since the founding of wildlife management as a discipline by Aldo Leopold (1933). The measurement of species diversity on a local scale (i.e., **alpha diversity**) has been emphasized by researchers over the years in numerous studies (Samson and Knopf 1982), such as those studies that examine bird diversity in even-aged stands (e.g., Yahner 1993). **Community or ecosystem diversity** is important when managing for species requiring critical habitats or features in extensive forest tracts, as with the threatened Allegheny woodrat (Balcom and Yahner 1996). **Landscape diversity**, which represents the largest scale of biodiversity, deals with interacting communities and ecosystems, viable populations of wildlife, and natural and human-induced disturbances to the landscape (Noss 1992). The conservation of biodiversity at the landscape level has important implications for ecosystem management (Petit et al. 1995). Moreover, a national strategy for biological conservation will require scientific information at all levels of biodiversity from genetic to landscape (Blockstein 1995).

Biodiversity conservation is closely linked with landscape ecology because the latter discipline deals with causes and consequences of the spatial configuration and the composition of landscape, such as types of land uses or presence of corridors in the landscape matrix (Wiens 2002). Furthermore, biodiversity conservation is intricately linked with ecosystem management because the latter focuses on maintenance of viable wildlife populations and perpetuation of all native ecosystems (National Ecosystem Management Forum 1993, Grumbine 1994, Petit et al. 1995, Yahner 2000). Federal agencies, including those involved with forest management, have adopted policies for ecosystem management (Grumbine 1997).

Ecosystem management applied to forests also includes consideration of values, such as safeguarding forest biodiversity and ecological sustainability (Wood 1994). Moreover, sound forest or ecosystem management views a forest as an interactive system of plants, animals, soil, water, and climate (Behan 1990). Thus, ecosystem management is an attractive concept for conservation of forest wildlife because it is concerned with more than a single species and addresses a range of spatial scales from individual forest stand to landscape (Reed 1995, Franklin 1997).

The future success of implementing ecosystem management will rely on effective partnership and compromise among agencies (e.g., state and federal) concerned with biodiversity conservation (Knight and Meffe 1997). Moreover, ecosystem management will require use of scientific principles, ranging from application of biological concepts, evaluating key components of ecosystems, and establishing protocols for inventorying, monitoring, and storing ecological data obtained from ecosystems (Christensen et al. 1996, Reichman and Pulliam 1996). A key example of how ecosystem management can be

viewed conceptually is in management of a taxonomic group, such as birds, and is well illustrated by Petit et al. (1995).

FORESTS FOR THE FUTURE

A major goal of natural resource managers and society concerned with forest management and wildlife must be to ensure continuation of a sustainable, productive, and healthy forest (Durning 1994). This will require a collegial and straightforward approach to enhancing forest health (DellaSala et al. 1995), which involves a management strategy for forests that encompasses a broad spectrum of resource and sociopolitical issues and requires cooperation among environmentalists, industry, landowners, natural resource managers, and recreationists (Thorne 1993, Yahner 2000).

At least 5 issues face the future successful management of forests: (1) biodiversity conservation and ecosystem management, (2) forest fragmentation, (3) education, (4) recreation, and (5) regional and global influences (Yahner 2000). A multispecies approach to forest wildlife management using sound principles developed by the rapidly growing disciplines of biodiversity conservation and ecosystem management, as well as landscape ecology, makes sense in today's era (after DeBell and Curtis 1993, Grumbine 1997, Wiens 2002). This is essential to the health and productivity of forests and to the well-being and quality of life of those who enjoy outdoor experiences in forests (Scavia et al. 1996).

Forest fragmentation and habitat loss will continue to be issues confronting sound management of forests (e.g., Robbins 1988, Litvaitis 1993, Yahner 1995, Brawn et al. 2001). A balance needs to be struck between ensuring a mosaic of adequate old-growth stands and early and midsuccessional habitats for forest wildlife. The wildlife profession has embraced this challenge as witnessed by a recent, concerted focus on this issue (e.g., Lorimer and Frelich 1994, Brawn et al. 2001, Thompson and DeGraaf 2001).

Education will be a key to the conservation of forests and associated resources (Yahner 2000). These forests, whether an urban woodlot or an extensive tract of national forest, can be invaluable as outdoor laboratories for education, as when introducing youth to appreciate the stewardship of our wildlands. In addition, forests serve as ideal research sites for monitoring of resources over the long term to bet-

ter understand and document trends in forest wildlife in relationship to changing landscapes or other perturbations. In many parts of the country, as in the eastern United States, forests are privately owned; thus, the Forest Stewardship Program, administered by the USFS, is a critical program for wildlife and natural resource professionals who are mandated to conserve and manage forest wildlife.

Recreation is a major value of forests, providing the public with birding, hunting, photography, observation, and other opportunities for viewing and enjoying wildlife resources (e.g., Hammitt et al. 1993). Thus, efforts should be made to enhance wildlife-viewing experiences (Harrington 1991), but a downside is the potential impact on wildlife of these activities (e.g., via road construction; Cole and Knight 1991).

Forest management, like most other aspects of today's world, has gone global. Landscape linkages, acid deposition, ozone depletion, and global climate change are just a few of the issues that require interagency and, more importantly, interstate and international cooperation (Yahner 2000). The scope of these issues has gone beyond a forested tract or state forest, thereby requiring economic, social, and political considerations at a scale unprecedented in wildlife conservation.

SUMMARY

Forest types, ownership, and legislation can affect the value of forests to wildlife. Plant-forest succession resulting from fire, chemicals, or management systems can have profound effects on forest wildlife. For example, uneven-aged forest management can influence wildlife distribution and abundance differently than even-aged forest management. Several practices (e.g., retention of unique habitat features or overstory trees in harvested stands) can have positive effects on forest wildlife. The effects of forest management, however, cannot be considered solely from the stand level (e.g., stand size), but must take into consideration landscape features (e.g., characteristics of surrounding landscape). Several types of models are available to predict wildlife species occurrences and adjust forest-management regimes. Successful forest management in the future will be contingent on biodiversity conservation and ecosystem management to ensure a sustainable, productive, and healthy forest for the benefit of wildlife while simultaneously providing educational and recreational values.

Managing Rangelands for Wildlife

INTRODUCTION

RANGELANDS ARE PLANT COMMUNITIES dominated by grasses, forbs, and shrubs. Their primary use by humans worldwide is for livestock grazing, but these communities also are habitat for wildlife, and grazing management strategies affect the quality and extent of wildlife habitat on rangelands (Krausman et al. 2009). Traditionally, wildlife-related concerns of range managers focused on predators of livestock and on wildlife species that are hunted. Today, managers are interested in biodiversity and a wide range of species. Management of public rangelands in the United States is constrained by federal and state laws, which require managers to address the impact of management activities on all wildlife.

The majority of rangelands used by wildlife in the United States are **public lands** administered by the **U.S. Forest Service** and **Bureau of Land Management**, both of which have multiple-use mandates. With existing laws such as the Endangered Species Act and Clean Water Act, and ecosystem management and ecosystem health policies of the major land management agencies in the United States, there is expanding need to address the ecology of rangelands as it relates to plants, soils, water, wildlife, and livestock.

Photographs, videos, Internet web sites, agenda-driven “science,” opinion pieces, the growth of advocacy groups, legal challenges (and threat of legal challenges), and society’s changing sentiments about use and condition of public rangelands have generated an abundance of confusion and uncertainty about rangeland management. What formerly was a field primarily limited to understanding livestock–big-game species relationships is now open to examination of livestock effects on all native flora and fauna, and the communities and ecosystems in which they exist.

The single greatest change influencing wildlife on western rangeland management during the 1990s has been the shift of concern from competition of livestock with big game such as deer (*Odocoileus* spp.) and elk (*Cervus canadensis*), to concern for all wildlife, and **biodiversity** in general. For terrestrial wildlife species, the fate of species such as the willow flycatcher (*Empidonax traillii*) and sage-grouse (*Centrocercus* spp.) now dominate livestock and wildlife issues in montane-meadow–riparian systems and sagebrush (*Artemisia* spp.) steppe, respectively, in many areas of the western United States. In California, for example, ungulates aren’t mentioned in a recent decision to amend management of >1.7 million ha on 11 national forests (U.S. Forest Service [USFS] 2001). Aquatic, riparian, and meadow-system rangeland management would, instead, be heavily influenced by habitat needs of the willow flycatcher, mountain yellow-legged frog (*Rana muscosa*), Yosemite toad (*Anaxyrus canorus*), and great gray owl (*Strix nebulosa*).

Effectively managing rangelands for wildlife requires achieving a specified level of **habitat structure** as represented by vertical and canopy cover, food items as represented by species composition, and adequate water quality and availability. Additionally, where livestock grazing is involved, there is a need to understand and manage for interspecific and social **interactions** between livestock and wildlife, as well as strategies to mitigate adverse effects. These interactions may be in the form of behavioral avoidance or attraction, direct mortality caused by livestock or habitat modifications, and indirect mortality caused by disease transmission. Wildlife–livestock interactions have greater application at a broad geographic scale rather than a site-specific study area.

Most state and federal agencies have unique missions and mandates (Salwasser et al. 1987); therefore, **management philosophies** and on-the-ground techniques differ markedly among agencies. Philosophical differences can be further exacerbated when adjacent tracts of land, managed by different agencies, have their own unique designations (e.g., specially designated area). Specially designated areas come in a variety of shapes and sizes, but in the United States they are typically managed by one of a few federal agencies (e.g., USFS, Bureau of Land Management, National Park Service, or U.S. Fish and Wildlife Service), and include such areas as wilderness, special research areas, wildlife refuges, sanctuaries, or any other site where certain activities or management tools (e.g., aircraft, mechanical equipment) may be precluded. These areas are usually small relative to the management prescriptions of adjacent properties and, thus, exist as non-contiguous islands that must be managed differently from surrounding landscapes.

Because of the varied and unique challenges confronting managers in today's world, this chapter is not intended to be an all-encompassing treatise. Rather, it presents a discussion of selected issues and techniques in an effort to provide the reader with a general understanding and appreciation for the complexities associated with managing rangelands. An extensive literature review is included and the reader is encouraged to explore the vast quantity of information that has been published on this subject, some of which also is summarized elsewhere (e.g., Krausman 1996). It is our hope this chapter adequately (1) provides an overview of rangeland management to benefit wildlife species and natural communities, with an emphasis on western North America, (2) identifies some of the topical issues and primary rangeland systems of concern, and (3) describes some of the techniques for accommodating wildlife and wildlife issues on rangelands.

PLANT SUCCESSION AND WILDLIFE MANAGEMENT GOALS FOR RANGELANDS

Plant succession is the gradual replacement of one assemblage of plant species with others through time until a relatively stable **climax community** is reached (Clements 1916).

As each group of plant species is replaced, the value of the community, as habitat to any particular species of wildlife, changes. The result is a succession of wildlife species as plant communities and populations of primary consumers undergo successional changes altering the different trophic levels (Kie et al. 1994).

Range Condition and Wildlife Habitat

Only a portion of the vegetation biomass in a rangeland will provide adequate nutrition for an herbivore. As body size decreases, diet selectivity generally increases (Van Soest 1994); consequently, many wild herbivores (which tend to be smaller than domestic livestock) consume much less of the vegetation resource than livestock, particularly cattle. Furthermore, domestic livestock may consume a greater proportion of poorer quality bulk forages because producers supplement diets of livestock to balance nutritional requirements for growth and reproduction at least for some portion of the year. Proper estimates of carrying capacity for wildlife on rangelands assume that all nutrients will be obtained from the range (Hobbs and Swift 1985).

Rangelands exist in many different **successional stages** and structural conditions because of the influence of fire, mechanical disturbance, herbicide treatment, and grazing by wild and domestic herbivores. Some plant communities respond to grazing in a predictable manner, depending on the plant species present (Dyksterhuis 1949). Some plant species are dominant in climax communities because they are superior competitors in the absence of disturbance. However, they begin to decline in vigor and abundance with increased grazing pressure (Dyksterhuis 1949). As they decline, other less palatable plants present at the climax stage become more abundant as competition is reduced. If grazing intensity is sufficiently heavy and occurs over a long period of time, new plant species, well adapted to heavy grazing, appear in the community. As a result, many **exotic species of plants** (e.g., spurge, thistles, brome grasses) become established and overall condition of the range is reduced.

In the past, rangelands have been managed on a concept of how close existing vegetation approximates a climax community, using terms such as excellent, good, fair, and poor (Dyksterhuis 1949). This procedure cannot be used on seeded rangelands, however, or those dominated by introduced, naturalized plant species such as the annual grasslands of California (Smith 1978, 1988). Also, **range condition** terms including **excellent, good, fair, and poor** are defined in terms of providing forage for livestock; whereas, habitat is species-specific and differs greatly among species. A site rated as poor may provide excellent habitat for wildlife adapted to early seral vegetation (e.g., white-tailed deer [*O. virginianus*]), whereas a site rated as excellent on this scale (e.g., grassland) may not be used at all by that species. More appropriate terms used for describing the condition of rangeland vegetation as they relate to wildlife needs are **climax, late seral, midseral, and early seral** (Pieper and Beck 1990).

Additional problems may arise when changes in livestock grazing practices do not immediately produce a change in rangeland vegetation. For example, some grassland sites in southeastern Arizona that had been converted to shrublands by heavy livestock grazing failed to revert to native grasses following 20 years without livestock (Valone et al. 2002). In contrast, other sites that were protected for up to 39 years exhibited an increase in grasses, suggesting that substantial time lags following protection from grazing were necessary (Valone et al. 2002).

Since 1990, range ecologists have been developing models of change in rangeland vegetation based on the concept of **multiple steady states** (Laycock 1991, 1994). These states are often portrayed as state-transition models (Westoby et al. 1989), wherein “states” are recognizable assemblages of species at a particular site that are stable over time. Such models are useful in understanding why some plant communities fail to respond immediately to changes in management practices. Parameterizing state-transition models, however, often requires large data sets on composition of rangeland vegetation collected over many years. If such data are available, state-transition models can provide more precise predictions about vegetation change (Allen-Diaz and Bartolome 1998) than the classical linear-succession model developed by Clements (1916) and may be useful in restoring degraded rangelands (Chambers and Linnerooth 2001).

Models of Rangelands as Wildlife Habitat

The system of classifying wildlife habitats according to **potential natural vegetation** and seral stage for coniferous forests (Thomas 1979) also has been applied to rangeland vegetation in southeastern Oregon (Maser et al. 1984). Habitat data were assembled for 341 species of vertebrates, assessing effects of different range management activities on those species by equating plant communities and their structural conditions with habitat values for wildlife. The structural conditions were grass-forb, low shrub, tall shrub, tree, and tree-shrub. As a plant community progresses from grass-forb to tree-shrub conditions through succession, changes occur in environmental variables important to wildlife. For example, herbage production tends to be highest in grass-forb communities, browse production highest in low-shrub and high-shrub communities, and canopy closure, canopy volume, and structural diversity highest in tree and tree-shrub communities (Maser et al. 1984). Management actions such as brush and weed control, water development, prescribed burning, seeding and planting, and grazing also can result in changes in structural conditions (Maser et al. 1984).

Accounting for needs of large numbers of wildlife species makes **land-use planning** difficult. To simplify the process, wildlife can be grouped into life forms based on the relationship of the species to their habitats. In southeastern Oregon, 2 characteristics of each species (where it feeds and where it reproduces) were used to distinguish 16 life forms.

For example, dark-eyed juncos (*Junco hyemalis*) and mule deer (*O. hemionus*) characterize those species that feed and reproduce on the ground. Other examples of such life forms include the long-toed salamander (*Ambystoma macrodactylum*) and western toad (*Anaxyrus boreas*), which feed on the ground, in shrubs, or in trees, and reproduce in water (Maser et al. 1984).

Beyond generalized models of wildlife habitat associations, managers occasionally estimate **nutritional carrying capacity** of rangelands. Most models of range supply and animal demand sum the available nutrients supplied by forage in the habitat and then divide by the animal's nutritional requirements (Robbins 1973, Hobbs et al. 1982). However, these models are simple and fail to make predictions based on varying levels of nutritional quality required by individuals (e.g., pregnant or lactating females, breeding males, migrating adults, etc.; Hobbs and Swift 1985). To avoid overestimating the number of animals that existing plant biomass can support, carrying capacity models should consider minimum dietary nutrient concentration (Hobbs and Swift 1985, Hanley and Rogers 1989).

The influence of grazing also can affect wildlife species richness, diversity, density, and abundance. Some conclusions, for example that grazing tends to increase abundance of common species, but reduces the overall diversity of species (Bronham et al. 1999, Rambo and Faeth 1999), provide a community approach that may contribute to additional generalizations when other taxonomic groups are considered.

CONTEMPORARY ISSUES IN RANGELAND MANAGEMENT

Key Rangelands of Concern

Riparian, montane meadow, and aquatic habitats continue to remain a high priority for conservation and management on western rangelands. Minimizing soil erosion and maintaining or restoring water quality are paramount in sustaining these systems for the future. Meeting these 2 umbrella objectives may accommodate the needs of some wildlife species that inhabit these systems. Increasing concern now exists for other wildlife habitats that are rangelands. This interest has arisen largely because of growing concern for biological diversity, but also for specific wildlife species that are declining and/or are being petitioned for listing under the federal Endangered Species Act. While there are numerous other plant communities and wildlife habitats that comprise rangelands throughout the world, the following systems or habitats are currently of great issue on public rangelands in the western United States.

Sagebrush Steppe

Foremost of concern among rangeland habitats at present are the expanses of **sagebrush-perennial-bunchgrass range** that dominate much of public land in the West (e.g., Paige and Ritter 1999). From a timing perspective, just as range

livestock management has been challenged in the 1990s to work toward avoiding negative effects to the riparian zone and to more effectively use upland range, livestock use of uplands has now come under scrutiny as well. Recent research indicating that sage-grouse are declining and that they nest most successfully when there is an herbaceous understory ≥ 18 cm in height (Sveum et al. 1998) has created an additional challenge for livestock managers on public lands—how to avoid affecting riparian zones while ensuring adequate herbaceous cover to meet the needs of at least one nesting species in sagebrush–grass communities. Use and management of fire, herbicides, proximity to urbanization and agriculture, use of off-road vehicles, and power lines also are contributing factors affecting quality of wildlife habitat on these rangelands.

Other habitats of concern geographically associated with **sagebrush steppe** are browse communities dominated by antelope bitterbrush (*Purshia tridentata*), mountain mahogany (*Cercocarpus* spp.), or saltbush (*Atriplex* spp.). Often, these communities serve as a seasonal range for wildlife, such as in winter, but are grazed by livestock in summer.

Desert

Concern about potential effects to the desert tortoise (*Gopherus agassizii*) from livestock grazing and other uses prompted the Bureau of Land Management to recently issue a grazing decision to help protect this species in California **desert systems**. These systems are particularly susceptible to effects of grazing because they require a long time for recovery of vegetation growth and vigor if they are able to recover at all (e.g., Krueger et al. 2002). Additionally, concern exists for native frogs relying on the rare and often heavily affected riparian and aquatic areas of the desert Southwest (Jennings and Hayes 1993).

Aspen

Habitats dominated by quaking aspen (*Populus tremuloides*) support a high diversity of wildlife on western ranges (Debye 1985). These habitats also serve as valuable grazing (Sampson and Malmsten 1926) areas for livestock because of the proximity of food, cover, and usually water. There is growing concern that this community is on the decline in managed forests and ranges throughout the West because of lack of stand regeneration resulting from browsing by herbivores, fire suppression, and disease (e.g., California Department of Fish and Game 1998, Knight 2001). In turn, succession to dominance by conifers or by shrub communities (e.g., sagebrush) may result, thereby decreasing the value as wildlife habitat or as grazing rangeland.

Integrating Wildlife Objectives and Range Livestock Management

Livestock grazing results in effects on rangelands and wildlife species (Krausman et al. 2009). It can either decrease or improve the conditions for wildlife depending on the species

or community attribute of interest. A goal for public-land resource managers is to identify the acceptable level of livestock impact, apply appropriate standards and guidelines, and then monitor their effects. Implementing management decisions to meet wildlife species and habitat objectives, as well as broader goals of ecosystem health on public rangelands, often are emotionally charged socioeconomic (if not sociopolitical) decisions. These decisions often involve reducing use or eliminating livestock in the area of concern for a period of time to allow recovery. Numerous case studies and demonstration areas have illustrated that these actions are effective in some rangeland habitats such as riparian and aspen communities.

Within the field of wildlife–livestock interactions, addressing **competition** between livestock and large native herbivores was a primary emphasis on western public lands during the 1950s–1980s; during the 1990s, the emphasis shifted to developing strategies to protect and restore riparian areas from overgrazing by livestock. Preventing livestock from negatively affecting riparian areas and achieving better distribution of grazing animals throughout upland areas were desired objectives. More recently (mid-1990s to present), there is evidence demonstrating the importance of standing herbaceous vegetation for nesting sage-grouse, a vegetation component that could be difficult to meet without significant change in grazing management strategies. Thus more encompassing ecosystem–landscape–biodiversity concepts for management of rangelands have evolved in recent years. These have caused further shifts in the directions of many interest groups, government agencies, and academicians.

On public rangelands, recent objectives go beyond achieving and maintaining good to excellent range conditions for livestock and wildlife. Instead, objectives have broadened to conserve biodiversity, improve ecosystem health, and meet habitat requirements of federally listed, or potentially listed, wildlife. These objectives could be represented in many cases by increased herbaceous cover, soil maintenance, reduction in invasive species, and clean water. A more general approach would be to define positive ecological changes through rangeland management actions. Across landscapes, achieving such positive changes likely would satisfy most concerns for wildlife simply because such large-scale changes have been needed for decades.

Examples of species receiving substantial attention at present are the willow flycatcher and great gray owl, which rely on high-quality mountain meadow–willow (*Salix* spp.) riparian complexes, and sage-grouse, which rely on a combined habitat structure of sagebrush and standing herbaceous vegetation. The former 2 species continue to represent the needs and concerns related to grazing effects on montane meadow and riparian areas, while the burgeoning sage-grouse issue has been labeled the range equivalent of the spotted owl (*S. occidentalis*) issue because desired herbaceous cover levels will be difficult to achieve on grazed rangelands.

Investigations of Wildlife–Livestock Relationships

Studies of wildlife and livestock interactions are typically conducted to increase understanding of direct and indirect effects of livestock (as the manipulated perturbation or stressor) on a native species and/or its habitat. Much of the existing work was retrospective, rather than experimental, in that it was conducted with livestock as part of the system rather than as an introduced perturbation with treatments and controls. This difference also reflects one of the fundamental social debates regarding livestock on public lands in the United States: are humans, and the effects they bring, part of the biotic community or ecosystem (e.g., Box 2000)?

Unquestionably, the science on wildlife–livestock relationships varies in terms of its rigor, thoroughness, results, and applicability to real systems. It indicates that the presence of large, nonnative herbivores is beneficial to some species and detrimental to others. Some initial investigations of wildlife–livestock relationships examined how cattle and mule deer distributed themselves throughout a common range (Julander and Robinette 1950, Julander 1955, Julander and Jeffery 1964) instead of manipulating cattle to measure how deer responded with and without cattle in the same area. Unfortunately, the ability to conduct replicated experiments at appropriate spatial and temporal scales to assess livestock grazing effects on a wildlife population is logistically difficult. Conclusions from retrospective studies, that deer or other wildlife species preferred the steeper slopes while livestock preferred the flatter areas, became dogma in range science and suggested that a harmonious coexistence occurs despite a lack of objective supporting experimental evidence.

Perhaps the most acceptable generalization that can be made is that increasing the **grazing level** (often termed heavy, uncontrolled, excessive, or severe grazing) above some site-based threshold results in effects that are not desirable to any interest. Further confounding our ability to generalize among wildlife–livestock investigations is that stocking rates, number of grazing levels (nongrazed or grazed in some studies; none, light, moderate, or heavy grazing in others), time of year grazed, vegetation communities, time lags to examine the response (e.g., Dobkin et al. 1998), and wildlife species of interest are not consistently applied or comparable.

During the 1950s–1980s, the primary wildlife emphasis on public rangelands was competition among large ungulates and livestock. Kie et al. (1994) summarized much of the knowledge in this area, and large herbivores continue to be of interest (e.g., Austin 2000). Rangeland science, however, has broadened to include examinations of livestock effects on nontraditional wildlife and biodiversity. The body of literature examining the effects of livestock on taxonomic groups such as amphibians (Jennings and Hayes 1993, Denton and Beebee 1996, Bull and Hayes 2000), reptiles (Bock et al. 1990, Bostick 1990, Kazmaier et al. 2001), birds (Dobkin et al. 1998, Goguen and Mathews 1998, Sveum et al.

1998, Belanger and Picard 1999, Beck and Mitchell 2000), small mammals (Hayward et al. 1997), and invertebrates (Bronham et al. 1999, Rambo and Faeth 1999) continues to grow, as does the number of review papers on livestock grazing effects on biological diversity and ecosystems (Fleischer 1994, Belsky and Blumenthal 1997, Larsen et al. 1998, Belsky et al. 1999, Jones 2000).

Using livestock as a tool to manage wildlife habitat has been advocated for many years and examples of how this benefits one or more wildlife species do exist (Severson 1990). For example, Leopold et al. (1951) described the benefits of livestock in opening up paths for deer and other wildlife throughout willow-dominated montane meadow systems. Other examples describe the benefits of livestock in helping maintain or enhance vegetation species diversity (Rambo and Faeth 1999, Humphrey and Patterson 2000) or enhancing forage quality for other large herbivores (Clark et al. 2000). Whether the mechanical benefits, or more importantly, ecological benefits are needed every year is rarely (but should be) asked in the context of the entire system affected. Have Leopold et al.'s (1951) willow meadows been opened up “enough,” or do they need to be continually grazed summer-long in high mountain ecosystems, such as those in the Sierra Nevada?

Accommodating Wildlife and Habitat Objectives on Rangelands

A common link between the wildlife biologist and the range manager is the vegetation community and the wildlife habitats represented. From a wildlife perspective, perhaps an efficient technique would be to develop habitat objectives such as percent cover, desired plant species composition, and structural conditions of vegetation that are desired for a species, a suite of species, or a community as a whole, rather than a targeted species population objective. This approach leaves the range or livestock manager with the task of identifying potential strategies for managing livestock to achieve wildlife objectives. Identifying how wildlife species respond to livestock grazing might be of value in assessing whether the overall effects of the grazing level are acceptable or not; this process for wildlife would be analogous to characterizing plant species as **increasers, decreasers, or invaders** in response to livestock grazing (e.g., Stoddart et al. 1975).

The concept of maintaining or enhancing biodiversity on multiple-use rangelands should also capitalize on interjecting management diversity in terms of grazing systems used. Interjecting unpredictable changes in habitat structure by resting habitats that normally are grazed continuously adds to this kind of diversity. Additional study and information on how individual species respond would help distinguish between desirable and undesirable trends in species responses.

Historically, land-use plans prepared by the USFS and Bureau of Land Management, in collaboration with state wildlife agencies, often developed population objectives for

species such as deer, elk, or pronghorn (*Antilocapra americana*). A more measurable approach would involve moving from a specific population target and, instead, focusing on achieving a desired habitat condition across the landscape—at the scale of allotments, resource areas, districts, or entire national forests.

Role of Monitoring and Assessment in Addressing Wildlife–Livestock Issues

“The lack of biological data is, without a doubt, one of the greatest single factors in retarding development of a larger conservation program” (California Department of Fish and Game 1926:28).

Because of the inherent controversy and often-polarized views of wildlife and livestock relationships, difficult management decisions are often tabled in the absence of adequate data on species trends or ecological condition of the system in question. Consequently, among the most valuable activities that can be undertaken for the benefit of wildlife on rangelands is the collection of scientifically defensible data on distribution, abundance, status, trend, and habitat relationships. Ranging from basic inventory to implementation of long-term monitoring and experimental investigation of cause-and-effect relationships, scientific data aid management decisions. A meaningful progression of actions to examine and understand wildlife and livestock relationships might involve assessing

- (a) wildlife habitat requirements and preferences,
- (b) livestock use of habitats preferred by wildlife,
- (c) livestock and wildlife effects on those habitats and vegetation communities,
- (d) livestock effects on wildlife species, and
- (e) wildlife responses over time.

The effects studied range from **direct influences** of livestock on species (e.g., trampling of frogs) to numerous **indirect effects** (e.g., the frogs’ effect on prey species or hiding cover). Far more likely than experimental manipulations, however, are study and characterization of habitat conditions including structure and composition of vegetation and how it influences species productivity and abundance. An adaptive element would include mechanisms to change livestock management strategies as information is gained or to test specific hypotheses with an experimental or manipulative approach.

MANAGING LIVESTOCK ON RANGELANDS

Heavy livestock grazing has been detrimental to many wildlife species in western North America (Smith 1977, Galizioli 1979, Peek and Krausman 1996). **Uncontrolled grazing** clearly can affect the structure and composition of wildlife habitats. When adverse effects occur, elimination of livestock can improve habitat conditions, although in many

situations changes in livestock management practices can result in similar benefits. When properly managed, livestock grazing can be used to improve habitat for wildlife dependent on early seral-stage plant communities (Longhurst et al. 1976; Urness 1976, 1990; Kie and Loft 1990; Ohmart 1996). Information on relationships between livestock and wildlife is available in a variety of books, symposium proceedings, and review papers (Smith 1975, Townsend and Smith 1977, Schmidt and Gilbert 1978, DeGraaf 1980, Wallmo 1981, Peek and Dalke 1982, Thomas and Toweill 1982, Menke 1983, Severson and Medina 1983, Halls 1984, Severson 1990, Krausman 1996).

The relationship between grazing and wildlife habitat is complex, and managers employ differing **grazing strategies** to achieve a variety of objectives, including livestock production, sustainable grazing, and wildlife habitat enhancement (Krausman et al. 2009). Livestock influence wildlife habitat by modifying plant biomass, species composition, and structural components such as vegetation height and cover. The impact of livestock grazing on wild ungulates can be classified as direct negative, indirect negative, operational, or beneficial (Mackie 1978, Wagner 1978). An example of a direct negative impact is competition between cattle and deer for a resource such as food or cover (Mackie 1978, Wagner 1978). Competition occurs when 2 organisms use a resource in short supply, or when one organism harms another in the process of seeking the resource (Birch 1957, Wagner 1978). Factors influencing effects of livestock on wildlife include diet similarity, forage availability, animal distribution patterns, season of use, and behavioral interactions (Nelson and Burnell 1975, Severson and Medina 1983).

Indirect negative impacts of cattle grazing include (1) gradual reductions in vigor of some plants and in amount and quality of forage produced, (2) elimination or reduction of the ability of forage plants to reproduce, (3) reduction or elimination of locally important cover types and replacement by less favorable types or communities, by direct actions over time or by changing the rate of natural succession, and (4) general alterations and reduction in the kinds, qualities, and amounts of preferred or otherwise important plants through selective grazing, browsing, or other activities (Mackie 1978).

Operational impacts are associated with livestock management (Mackie 1978) and include fence construction, water development (Evans and Kerbs 1977, Wilson 1977, Yoakum 1980), brush control (Holechek 1981), and disturbance associated with handling of livestock. For example, deer may temporarily move from pastures when cattle round-ups occur (Hood and Inglis 1974, Rodgers et al. 1978).

Small mammals also influence rangeland vegetation (Moore and Reid 1951, Wood 1969, Batzli and Pitelka 1970, Turner et al. 1973, Borchert and Jain 1978) and compete with livestock for forage (Fitch and Bentley 1949, Howard et al. 1959). Because of their size and susceptibility to predation,

tion, rodents, lagomorphs, and other small mammals are highly dependent on the structure of vegetation in their habitats (Grant et al. 1982, Parmenter and MacMahon 1983, Bock et al. 1984). Grazing by livestock influences vegetation structure in those habitats and can significantly affect small mammal populations (Reynolds and Trost 1980).

Livestock grazing adversely affects many grassland birds, although moderate grazing can be neutral or beneficial to some species (Buttery and Shields 1975). Livestock management practices also can affect birds indirectly. For example, an organophosphate insecticide externally applied to cattle to control warbles may kill American magpies (*Pica hudsonia*) and cause secondary mortality among red-tailed hawks (*Buteo jamaicensis*) eating carcasses of the poisoned magpies (Henny et al. 1985).

Livestock management practices that can affect wildlife habitats and populations include livestock numbers, timing and duration of grazing, animal distribution, livestock types, and specialized grazing systems. These practices can be modified to reduce or eliminate adverse effects on wildlife and, at times, to enhance wildlife habitats (Severson 1990).

Livestock Numbers

Livestock numbers, or stocking rates, usually are specified by **animal unit-months (AUMs)**. One AUM is 1 animal unit (one mature cow with a calf, or equivalent) grazed for 1 month (Heady 1975:117). Livestock effects on wildlife become more pronounced with increasing stocking rates. A few cattle in a pasture may have no discernible effect on wildlife, but beyond some threshold wildlife response may increase rapidly. A range manager's traditional definition of proper grazing is based on maintaining a mix of plant species valuable as livestock forage and preventing soil erosion. Optimum livestock densities for wildlife may occur at different, and often lower, stocking rates. Thus, as with most effects of livestock on wildlife, responses can be difficult to interpret because of inherent site differences (Johnson 1982), and differences in grazing intensity, timing, and duration.

Timing and Duration of Grazing

Moderate cattle grazing of riparian areas in late autumn in Colorado had no detectable impact on 6 species of birds dependent on the grass-herb-shrub layer for foraging, nesting, or both (Sedgwick and Knopf 1987). However, summer grazing can eliminate habitat specialists such as willow flycatchers, Lincoln's sparrows (*Melospiza lincolnii*), and white-crowned sparrows (*Zonotrichia leucophrys*; Knopf et al. 1988b).

The time of year that livestock are present can alter the composition of plant communities. Heavy grazing during a period of rapid growth of one plant species will favor other species that grow more rapidly at other times. For example, spring grazing of annual grasslands in California reduces grass cover and encourages growth of summer-maturing forbs such as turkey-mullein (*Croton setigeru*), the seeds of

which are readily eaten by mourning doves (*Zenaida macroura*; Kie 1988). Conversely, many wildlife species are most susceptible to livestock-induced changes in habitat during their reproductive seasons. Birds that nest on the ground or in shrubs can experience reproductive losses if their nests are trampled or otherwise destroyed by cattle. For example, willow flycatchers in California breed exclusively in riparian deciduous woodlands, and prefer willows as nesting substrate (Valentine et al. 1988).

Flycatchers prefer to nest near the edges of willow clumps or along livestock trails (Valentine et al. 1988, Sanders and Flett 1989) and are, therefore, susceptible to physical disturbance. In one study, 4 of 20 willow flycatcher nests in a 4-year period were destroyed by cattle before young fledged, and 4 other nests were destroyed after young fledged (Valentine et al. 1988). When cattle stocking levels were reduced and 75% of the remaining cattle were confined to a fenced pasture away from willow flycatcher nest sites until 15 July, no willow flycatcher nests were lost (Valentine et al. 1988).

Excessive grazing can accelerate loss of hiding cover early in summer when mule deer fawns are young (Loft et al. 1987; Fig. 27.1). These conflicts can be minimized or eliminated by delaying grazing until later in the year (Kie 1991).

Livestock Distribution

Livestock congregate around sources of water, supplemental feed, and mineral blocks; their effects are most pronounced in those areas. **Riparian zones**, because of their abundant forage and water, are good examples of livestock concentration areas. Cross-fencing, developing alternative water sources, and providing feeding supplements on upland sites away

Fig. 27.1. Net change in mule deer hiding cover from ground level to 2 m, from the beginning of summer until mid-August, as a function of cattle-stocking rate (AUM/ha = animal unit-months per hectare). After Loft et al. (1987).

from riparian areas, more evenly distribute livestock. However, in certain situations, wildlife can benefit from patchy livestock distribution because some areas are lightly grazed. For example, many species of wildlife inhabit ecotonal areas (edges), and patchy distribution of livestock across home ranges of those species enables selection of grazed versus nongrazed patches to serve as foraging areas or refugia.

Types of Livestock

Effects of grazing on wildlife depend on the species of livestock. Differences in diet between cattle and domestic sheep dictate the effects they have on plant species composition. Also, cattle usually range within the confines of a fenced allotment, but sheep often are herded. Herded bands of sheep may have enhanced some habitats for mule deer in California (Longhurst et al. 1976) by repeated grazing and browsing that stimulated regrowth of more palatable shrubs and herbaceous vegetation. However, transmission of diseases from domestic sheep to mountain sheep (*Ovis canadensis*) may have eliminated many populations of the latter from California (Wehausen et al. 1987), and disease transmitted from domestic goats has occurred in some populations of mountain sheep (Jansen et al. 2006). Further, there is increasing evidence that transfer of diseases from domestic sheep to mountain sheep can have severe consequences for wild sheep populations (George et al. 2008), and models predict those effects to occur at the level of the landscape (Clifford et al. 2009). As a result, professional organizations (e.g., Desert Bighorn Council Technical Staff 1990), federal agencies, and nongovernmental organizations have adopted management policies or recommendations that reduce the probability of contact between domestic sheep or domestic goats and mountain sheep (Bureau of Land Management 1992, U.S. Fish and Wildlife Service, and California Department of Fish and Game 2002, Wild Sheep Working Group 2007, Schommer and Woolever 2008).

Competition between pronghorn and domestic sheep is greater than between pronghorn and cattle because of increased overlap in forage preferences. On overgrazed sheep ranges, insufficient forb growth was available for pronghorn during the critical midwinter period, and pronghorn die-offs were common (Buechner 1950). In general, domestic sheep are more likely than cattle to affect pronghorn adversely (Autenrieth 1978, Salwasser 1980, Yoakum 1980, Kindschy et al. 1982), and even moderate use by sheep during the winter dormant period can leave range units unsuitable for pronghorn until plant regrowth in spring (Clary and Beale 1983). Cows with calves often exhibit grazing patterns different from those of steers, and differences among breeds of cattle and sheep may occur.

Specialized Grazing Systems

Many **specialized grazing systems** exist, although most can be classified into 3 types (Heady 1975, Stoddart et al. 1975).

Continuous grazing allows livestock to graze season-long or year-long. **Deferred grazing** refers to delaying or deferring grazing until after most of the range plants have set seed. Deferred grazing allows plants to grow, store carbohydrates, and reproduce at high rates. **Rotational grazing** involves dividing a range unit and rotating livestock through different pastures.

Combinations of periodic deferment and rotational grazing are called **deferred-rotation grazing systems**. The most common of these is the **4-pasture deferred-rotation system**, in which 4 range units or pastures are used, with 3 being grazed year-long and the fourth being deferred for 4 months. The pastures are then rotated each year.

Rest-rotation grazing is similar to a deferred-rotation system, but the period of rest consists of a full year or more. **Short-duration grazing systems** are similar to deferred-rotation systems, except that ≥ 8 small pastures are used; stocking rates are high in each pasture as it is used, but livestock are present for only short periods of time. Timing of livestock grazing is critically important to most rangeland wildlife species; therefore, rotational grazing systems designed to consider wildlife have the greatest potential to reduce adverse effects.

Rest-rotation grazing may have the most potential to provide benefits to wildlife, but the value of this technique recently has been questioned (Briske et al. 2008) and conclusive evidence of a direct cause and effect between rotational grazing and enhancements to wildlife production is limited (Krausman et al. 2009). This system often is economically disruptive because it foregoes livestock forage, but such losses may be compensated by benefits derived from wildlife-related recreation on public lands. For example, development of a rest-rotation grazing system in a single deer-hunting zone in California might specify that each range unit would be grazed only 1 of 3 years. The value of unused livestock forage, calculated on the basis of net economic value at US\$12.82/AUM, would equal about US\$71,000 over each 3-year grazing cycle. However, increased deer populations and additional hunting opportunities would be valued at US\$6.5 million over the same period (Loomis et al. 1991).

Using Livestock to Manage Wildlife Habitat

In some situations, livestock grazing can be used to manage wildlife habitat (Longhurst et al. 1976, 1982; Holechek 1980, 1982; Urness 1982, 1990; Severson 1990; Krausman et al. 2009). Livestock grazing has been applied to the management of habitat for species as diverse as mule deer (Smith et al. 1979, Willms et al. 1979, Reiner and Urness 1982), northern bobwhites (*Colinus virginianus*; Moore and Terry 1979), and Canada geese (*Branta canadensis*; Glass 1988). For example, cattle grazing in late winter and spring on foothill, annual grasslands in California, encourage growth of forbs that are valuable to many wildlife species.

In other situations, application of **prescribed grazing** has met with mixed results. Too often, the intent of using livestock grazing has been to manage habitat for a single species, whereas entire communities actually are affected. Using livestock to maintain a plant community in an early seral stage often will benefit those wildlife species dependent on such habitat, while simultaneously affecting species associated with climax communities (Kie and Loft 1990).

The prescription, or strategy, for grazing is important. Maximizing benefits to wildlife from changes in grazing will involve reductions in livestock numbers and shortening grazing seasons compared to management plans designed to maximize livestock production. Livestock grazing by itself is neither good nor bad for wildlife, but depends on a variety of factors, including wildlife species of concern, livestock numbers, timing and duration of livestock grazing, livestock distribution, and kinds of livestock (Kie and Loft 1990). Wildlife and range managers should avoid generalizations and evaluate the role of livestock on wildlife and their habitats independently for each species, grazing plan, and management situation.

MANAGING RANGELAND BY ANTHROPOGENIC MANIPULATION

Fire

Rangeland species evolved under the influence of fire and, hence, many are fire-adapted. The natural occurrence of fire varies among regions as a result of fuels, topography, climate, and ignition source. The effect that fires have on landscapes is further dependent upon fire size, intensity, frequency, time of year during which they occur, and resulting burn patterns (Riggs et al. 1996). The interval at which fire occurs on a landscape varies as a function of active fire suppression, prior fire regime, plant community, and geographic location (Wright and Bailey 1982).

Effects of fire on wildlife populations may be positive or negative depending upon the temporal scale under consideration (short- versus long-term), species involved, and characteristics of the burn. Fire effects on wildlife may be characterized as those directly affecting diet and those relating to habitat structure. Although effects on forage quality tend to be rather short-lived following a fire (Hobbs and Spowart 1984), structural changes may persist for decades, as is the case when forested and shrub stands are eliminated (Bunting 1986, Everett 1986, West and Yorks 2002). Effects of fire on bird and small mammal populations tend to be related to modifications of vegetation structure (Blake 1982, Bock and Bock 1983, Niemi and Probst 1990, Riggs et al. 1996).

Diet quality may be altered by fire as a result of alterations to floristic composition of plant communities, chemical composition of plant tissues, and structure of the plant canopy (Riggs et al. 1996). Although investigators have observed increases in both crude protein (Hobbs and Spowart

1984, Cook et al. 1994) and in vitro digestibility (Hobbs and Spowart 1984) in forages following fire, some of the greatest nutritional benefits may be derived through increases in foraging efficiency (Hobbs and Spowart 1984, Canon et al. 1987). Fire removes litter and dead standing herbage of low nutritional value (Van Soest 1994) enabling herbivores to more efficiently select nutritious plant material (Hobbs and Spowart 1984). The effects of burning on forage quality and stand composition and canopy among graminoids and herbaceous species persist for 1–3 years (Hobbs and Spowart 1984), and fire frequency strongly influences habitat selection by some species (Holl et al. 2004, Bleich et al. 2008). Ultimately, effects on animal condition and productivity are most definitive; Svejcar (1989) noted increases in cattle performance when they were feeding on burned tallgrass prairie.

Grazing prior to burning proportionately reduces nitrogen losses in forage (Hobbs et al. 1991), and grazing that precedes fire in tallgrass prairie reduces spatial variability of patches and improves animal performance (Hobbs et al. 1991). However, grazing of dry prairies following fire can inhibit forage recovery, and preference for burns by cattle may require adjustments to stocking rate (Erichsen-Arychuk et al. 2002).

Riggs et al. (1996) discussed the economics of **prescribed fire** and reported the larger the prescribed fire, the more cost-effective, because fixed costs are applied over a greater area. They cautioned, however, that beneficial effects of fire treatments on wildlife habitats and populations should outweigh issues focusing too heavily on the amount of area burned. The role of fire varies from region to region and ecosystem. Thus, prescriptions should be tailored to specific project areas.

Other Methods of Vegetation Manipulation

In addition to burning and grazing, vegetation manipulation of rangelands may occur through use of hand tools, mechanical equipment, and chemical spraying. The goals, as well as logistic and financial constraints, will affect which method is most suitable for any given area. Mechanical treatments are used to remove undesirable **overstory** species that inhibit growth of **understory** forage species (Bleich and Holl 1981, Fulbright and Guthery 1996, Holechek et al. 1998, Stephenson et al. 1998). Herbicide application may be used to control either unwanted brush or herbaceous species.

Although there may be social and legal constraints that affect use of **herbicides**, their application may be appropriate in some cases. In contrast to mechanical removal of vegetation, application of herbicides over large areas is typically less expensive and time consuming. Herbicides may be applied by hand, or with sprayers mounted to tractors or aircraft (Koerth 1996). The Herbicide Handbook Committee (1994, 1998) provides a thorough review of the types of chemicals available and their known effects.

Mechanical removal of brush from rangelands for the benefit of wildlife tends to be most successful when applied to patches inter-mixed in a landscape mosaic (Fulbright and Guthery 1996). In contrast, extensive clearing is detrimental to species dependent on woody plants. Major techniques for large-scale brush removal include use of roller choppers, shredders (e.g., rotary axe), and crushers for top-growth removal or, conversely, whole plant removal by root plowing, chaining and cabling, disking, and bulldozing and power grubbing (Bleich and Holl 1981, Fulbright and Guthery 1996). Additional considerations when selecting mechanical methods include topography, extent of resprouting, soil type, and size of the area to be treated (Holechek et al. 1998).

MANAGING RANGELAND AND RIPARIAN AREAS

Riparian areas are important habitats for terrestrial and aquatic wildlife (Carothers and Johnson 1975; Thomas et al. 1979*d, e*; Platts and Raleigh 1984; Skovlin 1984; Platts 1990). Their importance is a result of being obligate habitat for many aquatic species, of the uniqueness of their soil and vegetation complexes that produce diverse vegetation structure and concomitant diverse biological communities, and of their limited extent across a diversity of landscapes. Their value for a given species of wildlife is a function of water availability (for example, mule deer in the Sonoran Desert versus wildlife in the Prairie Pothole Region of North America), life stages, animal movements, weather, and other factors.

Riparian vegetation and its structural arrangement are important for wildlife. Many vertebrate and invertebrate species depend directly or indirectly on riparian vegetation for food, cover, or other life requisites. Some wildlife use riparian zones disproportionately more than any other habitat. For example, of 363 terrestrial species in the Great Basin of southeastern Oregon, 288 depend directly on riparian zones or use them more than other habitats (Thomas et al. 1979*d, e*). Herpetofaunas also are strongly associated with riparian areas (Jones 1988). Riparian soils and substrates are important to amphibians, reptiles, and small mammals because these wildlife forms often inhabit subsurface environments. The temperate microclimate, availability of moisture, and greater biomass production of these areas provide for complex food webs.

The value of riparian areas to wildlife is only generally described, owing to the difficulty of long-term observations. Mule (Thomas et al. 1979*e*) and white-tailed (Compton et al. 1988) deer select woody riparian vegetation for cover and forage. Selected bird species have demonstrated an affinity for distinct layers of vegetation (Gutzwiller and Anderson 1986). Riparian zones provide migration routes for birds, bats, deer, and elk (Wauer 1977), and are frequently used by deer and elk as travel corridors between high-elevation summer ranges and low-elevation winter ranges. Moreover, ri-

parian habitats are strongly selected by mountain lions (*Puma concolor*) in some areas (Dickson and Beier 2002).

Riparian habitats are of further importance because they comprise only about 1% of the landscape in the United States (Knopf 1988). Further, >70% of the original riparian habitats in the United States have been lost through a variety of land use practices (Megahan and King 1985). Barclay (1978) reported that natural riparian habitats within the Oklahoma grasslands have nearly vanished, and channelization was responsible for conversion of 86% of bottomland forests to other land uses. In the southwestern United States, many historically perennial streams are largely ephemeral watercourses today (Johnson et al. 1989).

Central to development of **management strategies for riparian areas** are (1) an understanding of what constitutes a riparian area, (2) their internal functions and processes, (3) the influences on riparian ecosystems, and (4) their importance to wildlife. Elmore (1989) argued that a fundamental understanding of the functioning of riparian ecosystems was initially necessary to evaluate benefits and incorporate management actions into land use plans.

Rivers and streams transport water and sediments (Jensen and Platts 1987). Thus, riparian habitats are unique products derived from the dynamic processes that a given stream produces and are influenced by the interactions of climate, geology, geomorphology, hydrology, pedogenesis, and chemical and biological processes. Little information is available, however, on wildlife-riparian interactions. As a result, wildlife management considerations frequently are excluded from land use plans (Dwyer et al. 1984, Dickson and Huntley 1987). Substantial work has been done on riverine-riparian dynamics (reviewed by Curtis and Ripley 1975; Thomas et al. 1979*d, e*; Brinson et al. 1981, Kauffman and Krueger 1984; Platts and Raleigh 1984; Skovlin 1984; Warner and Hendrix 1984; DeBano and Schmidt 1989; Platts 1990).

Value, Structure, and Function of Riparian Areas

Several authors have proposed riparian terminology; both Swanson et al. (1982) and Johnson and Lowe (1985) suggest that disparity exists among users. They defined **riparian areas** as the sum of the terrestrial and aquatic components characterized by (1) presence of permanent or ephemeral surface or subsurface water, (2) water flowing through channels defined by the local physiography, and (3) the presence of obligate, occasionally facultative, plants requiring readily available water and rooted in aquatic soils derived from alluvium. Riparian ecosystems usually occur as an ecotone between aquatic and upland ecosystems, and have distinct and variable vegetation, soil, and water characteristics. Typically, riparian areas are viewed as riverine habitats with perennial surface flows and associated plants and soils. However, surface flows may be ephemeral or periodic, as in desert washes or arroyos of the southwestern United States.

Riparian vegetation typically functions to allow necessary sediment transport and natural erosional processes. It also effectively reduces accelerated erosion that could result in loss of riparian habitats (Miller 1987a). Riparian trees supply large organic debris and function to influence the physical (morphology), chemical (nutrient cycling), and biological (flora and fauna) components of the system (Bisson et al. 1987). Changes in stream channel structure and habitat diversity can occur when large organic debris is removed (Bilby 1984). Structural diversity, an important feature of riparian vegetation (Jain 1976, Anderson and Ohmart 1977), is affected by consequences of natural or human-caused habitat disruption.

Management Problems and Strategies

Management of riparian habitats is important because of the role of these ecosystems in water quality and nutrient recycling (Stednick 1988), and because riparian vegetation is considered to be the most sensitive and productive North American wildlife habitat (Carothers and Johnson 1975). Indeed, no other habitat in North America is as important to noncolonial nesting birds; riparian areas are equally important to many other terrestrial vertebrates (Szaro et al. 1985).

Riparian zones are easily affected by natural or induced changes on their watersheds, including grazing (Kauffman and Krueger 1984, Skovlin 1984, Chaney et al. 1990). Moreover, problems seemingly related to riparian habitats alone cannot be resolved by considering only that habitat. As a result, management of riparian areas should be considered both onsite (within the riparian zone) and offsite (outside the riparian zone), which accounts for all adjacent uplands that exert influence over the watershed. Onsite activities such as grazing management and vegetation treatments are performed within riparian habitats; offsite activities include logging, road construction, and slash burning. Management activities outside the riparian zone may change the quantity and quality of water entering the riparian area (Stednick 1988). A variety of range management options are available for sustaining health of riparian habitats, including complete protection (Stromberg and Patten 1988), multiple-use approaches, and exclusive use.

Livestock grazing is perhaps the greatest biological threat to riparian habitats in the western United States, given that about 91% of the total rangeland is grazed (Chaney et al. 1990). Improper livestock grazing affects all 4 components of the riverine-riparian system—channel, stream banks, water column, and vegetation (Platts 1990). Livestock grazing problems usually are the result of improper distribution of cows and not simply too many (Severson and Medina 1983). Concentrated livestock use results in sparse tree or shrub stands of low vigor, generally with substantial dead material on the ground, a tight, sod-bound soil, and lack of tree or shrub reproduction. Damage occurs in several ways. One is compaction of soil, which reduces moisture infiltration and increases runoff. Another is constant removal of

herbage, which allows soil temperatures to rise and increases evaporation from the soil surface. A third is physical damage to the trees or shrubs by rubbing, trampling, and browsing (Severson and Boldt 1978). The primary method for resolving overuse of riparian areas has been modified grazing strategies, which have met with mixed results (Dwyer et al. 1984, Skovlin 1984, Chaney et al. 1990).

Isolated case studies have demonstrated that revised grazing management improved conditions, but also that condition of riparian habitats continues to decline (Resource and Community Economic Development Division 1988). Myers (1989) reported 74% of the grazing systems evaluated failed to positively improve rangeland health within 20 years; however, riparian vegetation usually improves from grazing relief within 4–6 years, depending on severity of use (Platts and Nelson 1989). Areas with severe overuse require greater periods of time (>15 yr) for native species such as sedges (Cyperaceae) to displace species adapted to overuse (Elmore and Beschta 1987).

Conventional grazing systems (Heady 1975) were developed with consideration only for production and maintenance of forage plants, primarily graminoids. Application of these systems to maintain woody streamside vegetation and stream bank integrity likely will not be satisfactory, given the eco-physiology of shrubs and trees. Platts (1990:6) provided an excellent description of grazing strategies designed to complement restoration objectives with livestock management, and suggested that, “the solution is to identify and develop compatible grazing methods,” given our state of knowledge of the functions of riparian systems. Indeed, at least one grazing strategy is available that would provide riparian areas with the necessary rest or protection needed to restore, maintain, or enhance their productivity. The least acceptable option is “no use” by ungulates and this option may be attractive in situations where restoration is a major objective of overall riparian management. Another recommendation is to fence critical reaches of riparian habitats in an effort to maintain the integrity of the streamside zone (Platts 1990).

A good management strategy for sustaining rangeland riparian areas will (1) maintain the productivity of the vegetation (e.g., structure, species composition), (2) maintain the integrity of stream dynamics (e.g., channel and bank stability), and (3) recognize that several factors (e.g., soils, vegetation, hydrology, and animals) interact to maintain a dynamic equilibrium within the riparian zone. Successful management in riparian areas is dependent on application of knowledge from the physical sciences, such as hydrology and geomorphology, combined with an aggressive program that provides adequate protection to the structure, composition, and diversity of vegetation in such areas.

DEVELOPING RANGELAND WATER SOURCES

Increasing the amount of water available to wildlife has been used to enhance habitat for a variety of species inhabiting

arid rangelands (Kie et al. 1994, Lynn et al. 2006, O'Brien et al. 2006) and other "nontarget" wildlife may benefit from that activity if water developments are carefully planned or existing developments are modified appropriately (Tuttle et al. 2006). Techniques include improvement of natural springs, seeps, and waterholes, and construction of artificial devices to capture and store rainfall (Tsukamoto and Stiver 1990, Young et al. 1995, Arizona State University College of Law 1997). Recently, development of rangeland water sources has been questioned (Broyles 1995) and become controversial (e.g., Broyles and Cutler 1999, Rosenstock et al. 2001), and it is an issue that will require substantial effort to resolve (Rosenstock et al. 1999, Krausman et al. 2006).

Many methods have been used to make subsurface water available to wildlife including manual techniques, explosives, prescribed fire, and chemicals. Recently, horizontal well technology has been applied to development of springs and seeps for wildlife (Kie et al. 1994). Handwork, although time-consuming and costly, may be the most practical way to accomplish some types of developments (Weaver et al. 1959). Helicopters can be used to transport personnel and hand tools into remote sites, thereby allowing development of those sites (Bleich 1983).

Water sources can be improved with explosives (Weaver et al. 1959), but caution is necessary to ensure that water-yielding subsurface formations are not altered drastically and water flow is not interrupted. When such damage does occur, it is usually the result of a heavy charge opening a crack that allows water to escape. Explosives should be used only on marginal seeps where sufficient water is not immediately available and they can be used safely. Explosives also are useful in clearing channels to allow storm flows to bypass a spring, or to lay pipe to be used for gravity flow of water to a basin (Weaver et al. 1959).

Prescribed fire can be used to remove phreatophytic vegetation, resulting in a decrease in the transpiration of subsurface water and increased surface flows (Biswell and Schultz 1958, Weaver et al. 1959). Use of prescribed fire requires extreme caution and periodic reburning may be necessary to maintain surface flows. However, the importance of small patches of desert riparian vegetation to a multitude of species makes any substantial reduction in the occurrence of such vegetation undesirable (Bleich 1992). Where prescribed fire can be used to temporarily clear a spring site or seep so that other development may proceed, its use may be desirable, but its role is limited.

Herbicides increase surface flows by eliminating vegetation responsible for evapotranspiration of subsurface water. They can be particularly useful where water is limited; loss of cover or shade may be more than offset by making a permanent water supply available to wildlife (Weaver et al. 1959). The limited distribution of native, riparian vegetation in arid areas makes widespread use of herbicides undesirable. Herbicides can, however, be used to control saltcedar or tamarisk (*Tamarix* spp.) at desert water sources (Sanchez

1975). Control of these exotic species can be successfully accomplished on a small scale by hand-cutting and herbicide application (Sanchez 1975, Neill 1990).

Development of Springs

Development of springs should (1) provide at least one escape route for wildlife to and from the site that takes advantage of the natural terrain and vegetation, (2) provide an alternate escape route where feasible, (3) protect water developments from livestock while allowing access for wildlife, (4) reduce the possibility of wildlife drowning by providing gentle basin slopes or ramps in tanks, (5) maintain or provide adequate natural cover, plantings, or brush piles around the watering area; (6) provide, where applicable, a sign to inform the public of the purpose of the development, (7) provide for development of sufficient capacity to supply water whenever it is needed for wild animals, and (8) provide livestock and public access to water outside the protected water development (Yoakum et al. 1980, Bleich 1992, Kie et al. 1994). If shy animals are involved, water for human consumption can be piped some distance from the wildlife water source. For example, sustained camping should be discouraged within a 1-km radius of water used by mountain sheep.

Ramps or walk-in wells offer a simple and inexpensive method of making water available to wildlife (Weaver et al. 1959). Unless the ramp is cut through rock, however, the sides must be boarded to keep material from sloughing into the excavation. Ramps should be a minimum of 1 m wide to allow large animals to enter and exit easily. Ramps also are important for escape in other types of water developments such as livestock troughs (Wilson 1977) and guzzlers (Andrew et al. 2001).

Construction of small basins or pools at a water source is an effective way to conserve water and make it readily available to wildlife. Basins may be constructed with rock, cement, or masonry, or they may be gouged from solid rock near the source when small seeps originate in a rock stratum. A simple basin, constructed with hand tools, can be chiseled into solid rock and will effectively store water for years. Where appropriate, power tools and explosives can be used to create larger storage basins. When explosives are used, care must be taken not to damage the source of the water, or the rock face so that it cannot be modified to store water. A major advantage of this type of development is that it is nearly indestructible.

Rock basins can be enlarged with cement and rocks or masonry materials. Similarly, these materials may be used to construct diversions to protect a basin from debris caused by storm flows, or to create an artificial basin at a location where the development of a solid rock basin is impractical. Special masonry techniques may be necessary to ensure a bond between the mortar and rock (Gray 1974).

Many springs and seeps occur in canyon bottoms. Even when developed, such springs are subject to damage by water

from storms. A method of development that often is satisfactory is to bury a length of perforated asphalt or plastic pipe packed in gravel, at the spring source, and pipe the water to a basin or trough away from the canyon bottom and danger of flooding. Placing large rocks over a source after it has been developed and capping the development with concrete increases protection. Alternatively, a redwood spring box may be installed at a water source, allowing access for maintenance, with water piped to a trough in a safe location.

Plastic pipe is a good choice for use because it is lightweight, durable, and not subject to rust or corrosion; further, repairs are easily accomplished. Any type of pipe should be buried sufficiently deep to prevent freezing, trampling by livestock and wild ungulates, or damage from floods. A continuous downhill grade will help prevent air locks from developing in the pipe and ensure constant flow of water. When water is to be piped away from excavated springs, a trough constructed of concrete or masonry is preferred because it will not rust. If the trough poses a potential hazard for small animals and birds, a ramp should be installed to facilitate access to the water (Bond 1947).

Horizontal Wells

Traditional techniques used to develop springs and seeps have several disadvantages: (1) flow of water from the source cannot be controlled; (2) variable flow may be inadequate to generate enough water to create a surface source; and (3) exposed spring water and the source may be susceptible to contamination (Welchert and Freeman 1973). Horizontal well technology can overcome some of these disadvantages (Coombes and Bleich 1979; Bleich 1982, 1990; Bleich et al. 1982a).

Horizontal wells have several advantages: (1) success rate, particularly in arid regions where historical sources may have failed, is high; (2) amount of water can be readily controlled, thus reducing waste; (3) the area is not readily subject to contamination; (4) they are relatively inexpensive to develop; and (5) maintenance requirements are low. Horizontal wells also have disadvantages: (1) the initial cost of the equipment necessary to construct them can be high (although private contractors can do the work with their own equipment); (2) transporting the necessary equipment to remote sites can be difficult; and (3) some horizontal wells require a vacuum relief valve to prevent air locks from interrupting the flow.

Site selection is the most important and difficult step in development of a horizontal well. Several factors, including presence of historical springs and seeps, distribution of phreatophytes, and presence of an appropriate geological formation, must be evaluated (Welchert and Freeman 1973). Dike formations (a tilted, impervious formation that forms a natural barrier to an aquifer) and the contact formation (a perched water table over an impervious material) are both suitable

for horizontal well development. Developing a dike formation requires the impervious barrier be penetrated to tap the stored water (Fig. 27.2), while a contact formation is developed by penetrating at or above a seep area at the boundary of an impervious layer (see Fig. 27.2).

Tinajas

Tinajas are rock tanks created by erosion that hold water. In some desert mountain ranges, tinajas may provide the only sources of water for wildlife. The capacity of tinajas can range from a few liters to >100,000 L of water.

Several techniques are available to increase storage capacity of tinajas. Sunshades can be used to reduce evaporation of water (Halloran 1949; Halloran and Deming 1956, 1958; Weaver et al. 1959). Shades can be constructed by anchoring eyebolts into the canyon walls, installing cables, and attaching shading material such as sheet metal to the cables (Weaver et al. 1959). In Arizona, sunshades have been built with a framework of 5-cm pipe placed into holes drilled into bedrock, with shading material then attached to the framework (Werner 1984).

Some tinajas can be deepened or enlarged with explosives (Halloran 1949, Weaver et al. 1959), but use of this method risks damage to the tinaja. A safer, and potentially more ef-

Fig. 27.2. Horizontal wells can be developed in dike or contact formations. The position of the well relative to the aquifer and impervious barrier is critically important to the success of the well. After Welchert and Freeman (1973).

fective, method involves constructing an impervious dam on the downstream side, combined with a pervious structure to divert debris around the tinajas, but allowing water to flow into them (Werner 1984). Deep, steep-sided tinajas often pose special problems for wildlife, because individuals can become trapped when water levels are low. Pneumatic equipment or explosives can be used to chisel or blast access ramps in such situations (Halloran 1949). Mensch (1969) used explosives to create an escape ramp at a natural tinaja in which 34 mountain sheep had died within a 2-year period.

Sand Dams

Some of the earliest techniques designed to increase water availability in arid regions involved construction of **sand dams** or **sand tanks** (Sykes 1937; Halloran 1949; Halloran and Deming 1956, 1958). These devices originally were constructed by placing a concrete dam across a narrow canyon. One or more pipes that could be capped to prevent water from draining penetrated the dam. The dammed area then filled with sand and gravel washed in by floods. Water soaks into the sand and gravel, and is stored, protected from excessive evaporation (National Academy of Sciences 1974).

Sand dams must be securely anchored in bedrock, and the design and construction of the dam may be the most important aspect of the entire system (Bleich and Weaver 1983). Seepage at the bedrock interface could be a significant source of water loss; therefore, Bleich and Weaver (1983) emphasized that techniques used must result in an efficient bond between cement and bedrock (Gray 1974).

Storage volume of sand dams can be increased in a variety of ways (Sivils and Brock 1981, Bleich and Weaver 1983), but dams should not be too large. Compounds such as calcium aluminate can be added to the concrete to decrease set-up time (Gray 1974); however, sand dams should be no greater than 12 m long and 3 m high (Halloran and Deming 1956, 1958). Water stored behind sand dams can be piped to a trough some distance from the dam (Sivils and Brock 1981), or used to flood natural or constructed potholes downstream.

Precipitation in arid regions often occurs as violent thunderstorms; therefore, washes and canyons often flow with large amounts of water over a short period of time. These brief flows may not allow sufficient time for stormwater to saturate areas behind sand dams, especially if the underground storage capability has been enhanced (Sivils and Brock 1981, Bleich and Weaver 1983). Rock-filled baskets or gabions anchored into bedrock can be placed across a wash or canyon perpendicular to the direction of flow to slow water velocity. Such structures also raise and widen the wash.

Reservoirs and Small Ponds

A **reservoir** consists of open water impounded behind a dam. Reservoirs can be constructed by building a dam directly across a drainage or by enclosing a depression on one side of a drainage and constructing a ditch to divert water into

the resulting basin (Yoakum et al. 1980). They also recommended that reservoirs be designed to provide maximum storage with minimum surface area to reduce evaporation. Major points to consider in selection of reservoir sites include the following: (1) suitability of soils for dams (clays with a fair proportion of sand and gravel; i.e., 1 part clay to 2–3 parts grit), (2) the watershed area above the dam should be sufficiently large to provide water to fill the reservoir, but not so large that excessive flows will damage the spillway or wash out the dam, (3) channel width and depth, with a bottom easily made watertight and channel grade immediately above the dam as flat as possible, (4) easy access for wildlife to the water, and (5) an adequate spillway naturally incorporated into the development.

The base thickness of the dam must be ≥ 4.5 times the height plus the crest thickness. Slopes of the dam should be 2.5:1 on the upstream face and 2:1 on the downstream face. Minimum width of the top of all dams should be 3 m. Fill of the dam should be $\geq 10\%$ higher than the required height to allow for settling. Freeboard (depth from the top of the dam to the high-water mark when the spillway is carrying the estimated peak runoff) should not be < 60 cm, and the spillway should be designed to handle double the largest expected volume of runoff. A natural spillway is preferred and it should have a broad, relatively flat cross-section. Water should be taken out through the spillway well above the fill, and then reenter the main channel some distance downstream. Spillways should be wide, flat-bottomed, and protected by riprapping, or by facing with rocks. The entrance should be wide and smooth, and the grade of the spillway channel should be low so the water will flow through without cutting (Hamilton and Jepson 1940).

New reservoirs usually do not hold water satisfactorily for several months. Bentonite clay spread over the bottom and sides of the basin and face of the dam will help seal the impoundment. The basin also can be lined with polyethylene or another appropriate material, with 15–30 cm of dirt rolled evenly over the top (Portland Service Center 1966). Other artificial materials such as Hypalon® (Water Saver Company, Denver, CO) are superior to polyethylene, because of their strength and resistance to ultraviolet radiation. These liners can be custom-made for reservoirs of different sizes.

Dugouts

Large earthen catchment basins built to collect water for livestock were commonly called **charcos** by early settlers along the Mexican border, and **dugouts** by pioneers in other areas (Yoakum et al. 1980). Dugouts can be placed in almost any type of topography, but are most common in areas of comparatively flat, well-drained terrain. Such areas facilitate maximum storage with minimum excavation. Dugouts can be small, rectangular excavations (Fig. 27.3). All sides should be sloped sufficiently to prevent sloughing (usually $\leq 2:1$) and

Fig. 27.3. Dugouts, also known as charcos, can be constructed to provide water for wildlife on rangelands. After Yoakum et al. (1980), Kindschy et al. (1982).

one or more relatively flat side slopes ($\leq 4:1$) should be provided to facilitate access for large mammals (Bureau of Land Management 1964).

Adits

Adits (Fig. 27.4) are short, dead-end tunnels that extend into solid rock constructed with a downward sloping floor to allow access by wildlife (Halloran and Deming 1956, 1958). Adits have been constructed in Arizona and other western states, primarily to benefit mountain sheep (Parry 1972, Weaver 1973).

Personnel skilled in hard-rock blasting techniques should be used to construct adits. These water storage depots should have openings $\geq 2 \times 3$ m and be ≥ 4 –5 m in length. The water storage depth should be ≥ 4 m to ensure a dependable water supply (Halloran and Deming 1956, 1958). Commercial masonry sealers should be used to prevent

Fig. 27.4. An adit is a short tunnel that has been blasted into solid rock to store water for wildlife. The entrance to the adit must be at the same elevation as the bottom of the wash in which it is located.

seepage of water through rock fractures (Halloran and Deming 1956, 1958; Gray 1974; Werner 1984).

The opening of an adit must be at approximately the same elevation as that of the wash in which it is placed; therefore, it may be necessary to construct a diversion that allows flood waters to enter, yet causes debris, sand, and boulders to bypass the adit. Boulders placed on the upstream sides of adits can be used for this purpose (Halloran and Deming 1956, 1958). Another effective, but simple, technique involves construction of a rock gabion (Werner 1984).

An adit also can be designed to store water from a natural source, such as a seasonal or permanent spring (Werner 1984), and water sometimes can be diverted into adits from natural slick-rock aprons above the site. Further, adits also can be used to store water that normally would be unavailable, and water can be pumped from the adit into a nearby tinaja (Werner 1984). In such instances, the adit should be covered to reduce evaporation. Shade structures have been used to reduce evaporation at adits in which stored water is directly available to wildlife (Halloran and Deming 1956, 1958).

Guzzlers

Guzzlers are permanent self-filling structures that collect and store rainwater and make it directly available to wildlife. Guzzlers can be constructed to provide water for small animals only, or for animals of all sizes.

Several techniques can be used to collect water for guzzlers. Aprons that collect rainfall can be of manufactured or natural materials, including concrete or sheet metal aprons, but asphalted, oiled, waxed, or otherwise treated soil aprons can be used (Glading 1947, Fink et al. 1973, Rauzi et al. 1973, Myers and Frasier 1974, Frasier et al. 1979, Johnson and Jacobs 1986, Rice 1990, Lesicka and Hervert 1994).

Guzzlers useful for wildlife generally store water in underground tanks, and wildlife walk a ramp to enter the guzzler

to drink (Halloran and Deming 1956, 1958; Lesicka and Hervert 1994; Fig. 27.5). However, water also can be stored in underground or aboveground concrete, plastic, metal, or fiberglass tanks (Garton 1956*a, b*; Roberts 1977; Bleich et al. 1982*b*; Remington et al. 1984; Werner 1984; Bardwell 1990; Bleich and Pauli 1990; deVos and Clarkson 1990; Gunn 1990; Lesicka and Hervert 1994). Aboveground tanks (Fig. 27.6) usually have a float valve to regulate water at a drinking trough away from the water storage tanks (Roberts 1977, Werner 1984, Bleich and Pauli 1990). Underground tanks generally have no moving parts (Lesicka and Hervert 1994) and are not as subject to mechanical failures as are designs that incorporate a float valve. Moreover, guzzlers that store water for large mammals below the surface of the ground are nearly undetectable by humans more than a few meters from them (Fig. 27.7); current designs present little risk of drowning to native vertebrates (Lesicka and Hervert 1994), including desert tortoise (Andrew et al. 2001).

The most important step in installation of a guzzler is locating a suitable site. A guzzler should not be placed in a wash or gully where it may collect silt or sand or be damaged by floodwaters, but many guzzlers have been installed in areas lacking critical habitat components (Lewis 1973). When constructing a guzzler for small animals, Yoakum et al. (1980) recommended that (1) size of the water-collecting apron be proportioned so the storage tank will need no water source other than rainfall to fill it; (2) a site should be chosen where digging is comparatively easy; and (3) the tank should be placed with its open end away from the prevailing wind and, if possible, facing in a northerly direction to reduce water temperature, evaporation, and growth of algae.

Tanks usually are made of concrete or plastic. Occasionally, steel tanks are used as are used heavy-equipment tires

Fig. 27.5. Contemporary underground guzzlers store up to 40,000 L of water and have no moving parts. Wildlife walks down a ramp to reach stored water. Guzzler design by Lesicka and Hervert (1994).

Fig. 27.6. Guzzlers constructed with aboveground storage tanks generally have a float-valve to control the water level in the drinking trough. Guzzlers of this type store up to 10,000 L of water for use by large mammals in the Mojave Desert, California.

Fig. 27.7. Underground guzzlers are nearly invisible to humans that are more than a few meters away, making them especially useful in designated wilderness areas. Guzzler design by Lesicka and Hervert (1994).

(Elderkin and Morris 1989, Morris and Elderkin 1990). The plastic guzzler is a prefabricated tank constructed of fiberglass impregnated with plastic resin. Only washed gravel aggregates should be used for construction of concrete tanks, or the concrete may disintegrate in several years. Tanks made of steel are used for guzzlers in some areas and give satisfactory service. Use of tanks constructed of other artificial materials is relatively new.

Concrete sealed with bitumul, galvanized-metal sheet roofing, glass mat and bitumul, rubber or plastic sheets, asphalt, and plywood have been used successfully for water-collecting surfaces. Durable materials such as concrete or

metal are least expensive to maintain, although soil cement appears to be a promising material (Rice 1990); and Lesicka and Hervert (1994) successfully used areas of native desert soil. Efficiency (percent of water collected) and lifespans (yr) vary among materials (Fairbourn et al. 1972): steel (98%, 25 yr) is best, followed by asphalt roofing (86–92%, 8 yr), plastic covered with 2.5 cm of gravel (66–87%, 8–15 yr), butyl rubber (98%, 15–20 yr), asphalt paving (95%, 15 yr), and liquid asphalt soil water (90%, 5 yr).

The area of the water-collecting surface needed to fill a guzzler (Fig. 27.8) depends on the storage capacity of the guzzler, minimum annual rainfall at the site, and type of collecting surface. Each 10 m² in apron surface area will result in collection of about 1 L of water for each centimeter of rainfall. Calculations should be based on minimum precipitation expected, rather than the average or maximum, to prevent guzzler failure during drought years. When different types of aprons are used, required surface area can be calculated from the harvest efficiencies (Fairbourn et al. 1972). Leakage, evaporation, and heavy use by wildlife also may dictate a larger apron.

Big-game guzzlers are designed to collect water from either artificial (Gunn 1990) or natural aprons (Stevenson 1990, Lesicka and Hervert 1994). Using slick-rock catchments to collect runoff from bare rock areas is a common technique (Bleich et al. 1982b, deVos and Clarkson 1990, Stevenson 1990). These guzzlers take advantage of the fact that rock surfaces yield nearly 100% of the precipitation falling on them as runoff. Several authors (Bardwell 1990, Gunn 1990, Stevenson 1990, Lesicka and Hervert 1994) provide design specifications and other recommendations for construction of these catchments. Bardwell (1990), Bleich and Pauli (1990), deVos and Clarkson (1990), and Gunn (1990) provide information

regarding performance of these units over time. These investigators also evaluated techniques used in the construction of big-game guzzlers and evaluated the reliability of materials.

One of the most important considerations when constructing guzzlers is that all anthropogenic devices are subject to failure; regular monitoring is an essential aspect of any maintenance program. Recently, methods of monitoring the status of water sources that incorporate remote sensing have been developed (Hill and Bleich 1999) for use in areas that are difficult to reach, or that have otherwise restricted access, such as wilderness areas. This technology does not replace biannual visits, which are necessary to detect potential failures, or correct those that already may have occurred (Bleich and Pauli 1990, Hill and Bleich 1999).

The effectiveness and performance of some big-game guzzlers depends on plumbing components. For example, Bleich and Pauli (1990) reported that frozen pipes and fittings accounted for 35 of 98 failures among 22 guzzlers over an 11-year period. Furthermore, of the 98 failures, float-valve malfunction accounted for 31, design and construction flaws for 9, and natural disasters for 6. Other problems, including rusted tanks, rusted drinker boxes, and vandalism, accounted for 17. Overall, each of the 22 guzzlers evaluated averaged 4.4 mechanical failures over an 11-year period, but each was in service an average of 87% of that time. Mechanical failures did not necessarily lead to an inoperative guzzler, but did require effort to repair them.

The most complete guide for construction of guzzlers currently available was prepared by Brigham and Stevenson (1997) and is available on request from the National Applied Resources Sciences Center, Bureau of Land Management, Department of the Interior, P.O. Box 25047, Denver, Colorado, USA.

Fig. 27.8. Size of an apron necessary to fill a guzzler is dependent upon total annual rainfall and storage capacity of the guzzler. The relationship portrayed is based on the assumption the apron yields 100% of rainfall as runoff. After Yoakum et al. (1980).

CONSTRUCTING RANGELAND FENCES

The relationship between fences and wildlife on rangelands in the western United States has been a point of contention for the past century. **Fences** constructed to control domestic livestock can adversely impact some wildlife species. For example, fences can be major obstacles or traps to pronghorn (Martinka 1967, Spillett et al. 1967, Oakley 1973) and mule deer (Yoakum et al. 1980, Mackie 1981). Proper fence design and use of appropriate construction materials can reduce adverse effects. Details of fence construction on rangelands used by pronghorn, mule deer, elk, bison (*Bison bison*), and collared peccary (*Pecari tajacu*) are available elsewhere (Bureau of Land Management 1985, Karsky 1988). Preventing the movement of some wildlife species may be desirable, and specific fence designs can accomplish that goal (Longhurst et al. 1962, Messner et al. 1973, deCalesta and Cropsey 1978, Jepson et al. 1983, Karsky 1988).

Fences and Pronghorn

The severity of pronghorn-fence problems varies among areas. Fences are primarily a problem for herds moving seasonally to and from wintering areas on northern rangelands (Oakley 1973). However, seasonal movement problems also were reported in New Mexico (Russell 1964, Howard et al. 1983) and Texas (Buechner 1950, Hailey 1979), especially during drought years.

If fencing is necessary, only that required to provide proper livestock control and minimize hindrance to pronghorn and other wildlife should be used. Unrestricted passage for all age classes during all seasons and all weather conditions should be provided (Yoakum et al. 1980). Fencing water areas on dry summer rangelands may be as detrimental to pronghorn as fencing migration routes. If a fenced water development is provided specifically for pronghorn, the area should encompass ≥ 1 –2 ha of relatively level terrain (Yoakum et al. 1980).

Fence specifications to control livestock on pronghorn range have evolved over many years (Spillett et al. 1967, Autenrieth 1978, Salwasser 1980, Yoakum 1980, Kindschy et al. 1982, Bureau of Land Management 1985). Fences should consist

of 3 strands of wire, the bottom strand being smooth (Fig. 27.9). Four- to six-strand barbed-wire fences limit pronghorn movements and should not be used. The bottom wire should be ≥ 40 cm aboveground. Absence of stays between posts will facilitate the occasional movement of pronghorn through the fence (Yoakum et al. 1980, Kindschy et al. 1982, Hall 1985).

New fences should be **flagged** with white cloth so pronghorn can become familiar with their locations. By the time a white rag tied to the top of each fence post deteriorates, pronghorn will have become accustomed to the fence (Kindschy et al. 1982). Painting the top of steel fence posts white also helps make the fence more visible to pronghorn (Hall 1985).

Where snow accumulation restricts pronghorn movements, let-down or adjustable fences should be used (Yoakum et al. 1980). A let-down fence can consist of a wooden stay at each fence post to which the wires are attached. The stay is secured to the fence post with a wire loop at the top and either a second loop or a pivot bolt at the bottom.

Let-down fence sections may be designed to permit pulling the let-down sections back against sections of perma-

Fig. 27.9. Recommended specifications for wire fences constructed on ranges used by pronghorn, mule deer, and mountain sheep. Note the use of a smooth bottom wire on all designs, and the lack of stays on fences for use on pronghorn ranges. *Pronghorn specifications after Yoakum (1980) and Kindschy et al. (1982); Mule deer specifications after Jepson et al. (1983); Mountain sheep specifications after Hall (1985) and Brigham (1990).*

nently standing fence. Let-down fences should provide for adjustments in wire tension. When the wire is so taut that it does not lie flat on the ground or is so loose that wire loops are formed, a hazard is created for people and animals (Bureau of Land Management 1985). **Adjustable fences** (Fig. 27.10) that allow the movement of one or more wires can allow pronghorn passage during periods when livestock are not present (Anderson and Denton 1980). Adjustable fences are particularly useful when winter snow depths exceed 30 cm (Yoakum et al. 1980).

Pronghorn passes are structures that resemble cattle guards intersecting a fence (Spillett et al. 1967, Mapston and ZoBell 1972, Yoakum et al. 1980, Howard et al. 1983). Suitable locations for pronghorn passes make use of the tendency of individuals to parallel a fence, looking for a way to cross. The pass capitalizes on the ability of pronghorn to jump laterally over obstacles. Pronghorn passes have been built and tested under a variety of conditions (Spillett et al. 1967, Howard et al. 1983). Some adult pronghorn quickly learn to use the facilities, but others do not. Pronghorn fawns often are unable to negotiate the passes. Pronghorn passes are of limited value and should not be used as a panacea for pronghorn access problems (Bureau of Land Management 1985).

Net-wire fences prevent the movement of pronghorn fawns in particular, and should not be used on public rangelands where pronghorn occur (Autenrieth 1978, Yoakum 1980). However, some adults may become adept at jumping a net-wire fence up to 80 cm high. Higher net-wire fences can be used where the goal is to restrict the movement of animals, such as in live-trapping, control of animals in research projects, decreasing crop depredations, or restricting access to hazardous areas such as highways.

Fences and Mule Deer

The relationship between livestock fences and mule deer has not raised the political furor that it has for pronghorn. However, throughout North America where fences have been built, they likely have caused far greater mortality to deer than to pronghorn. Deer are more apt to be trapped as individuals, whereas large numbers of pronghorn may be restricted. Also, deer frequently are caught in fences in isolated

areas not readily witnessed, whereas pronghorn mortalities in open country are easy to observe.

Deer often crawl under fences when not hurried, but jump them when startled or chased (Mackie 1981). When a deer jumps a fence, its feet can become entangled between the top 2 wires, resulting in death. Limiting total fence height to 96 cm can reduce this problem (Bureau of Land Management 1985; see Fig. 27.9). If the top wire is barbed, it should be separated from the next wire by 30 cm; otherwise, it should be a smooth wire (Jepson et al. 1983). Unlike fences used on pronghorn ranges, wire stays should be placed every 2.5 m between posts to keep the top wires from twisting around the leg of a deer (Yoakum et al. 1980, Bureau of Land Management 1985).

The effective height of a fence as a barrier to deer moving uphill is increased on steep slopes. For example, a 110-cm fence on a 20% slope is equivalent to a 140-cm fence on level ground. On a 50% slope, it is equivalent to a 190-cm fence on level ground (Kerr 1979, Anderson and Denton 1980). Thus, height adjustments should be made accordingly.

Let-down fences along seasonal travel routes for deer help ensure free movement. The let-down feature of the fence also helps prevent damage from snow loading during winter. Movements of mule deer also can be aided with an adjustable fence. Net-wire fences no higher than 90 cm allow movement of adult deer, but prevent passage of fawns. They should not be placed on summer and autumn migration routes used by deer.

Fences and Mountain Sheep

The construction of **wire fences** on ranges used by mountain sheep (for example, to exclude livestock from water developments) presents particular problems. Mountain sheep are likely to become entangled in a fence when placing their head through the top 2 wires. This problem is minimized if the 2 top wires are no greater than 10 cm apart (Brigham 1990). A 3-wire fence should be used with wires spaced at 51-cm, 38-cm, and 10-cm intervals (see Fig. 27.9), allowing mountain sheep movement under the bottom wire and between it and the middle wire (Bureau of Land Management 1985, Brigham 1990). Six-wire fence designs (Bureau of Land

Fig. 27.10. Adjustable fence modifications made to facilitate movement of pronghorn and other ungulates. After Anderson and Denton (1980).

Management 1985) are dangerous to mountain sheep and should not be used (Brigham 1990). To minimize the probability of mountain sheep becoming entangled, fences consisting of uprights and 2 parallel rails easily can be constructed (Andrew et al. 1997; Fig. 27.11).

Electric Fences

Electric fences often are used to control livestock or feral hoof-stock such as burros, and some designs pose little hindrance to movement of wildlife. Electric fences are most effective on moist sites, where 2 wires may be sufficient to control cattle. On sites with ≥ 60 cm of rain annually, an electric fence can be made of 2 smooth wires at heights of 60 cm and 90 cm aboveground (Bureau of Land Management 1985, Karsky 1988). The top wire is electrified and the bottom wire serves as the ground. The wires are free-running at all posts, and pose little danger of entrapping mule deer. On drier sites, electric fences require more wires to function effectively (Karsky 1988), and the added wires can adversely affect movements by wildlife.

Wood and Steel Fences

Fences can be constructed entirely from wood posts and rails in a variety of designs, with raw materials obtained at the site or manufactured materials (Bureau of Land Management 1985, Karsky 1988, Andrew et al. 1997). Wood fences are usually expensive, but can be attractive and may require less maintenance than wire fences. Construction options include post and pole, log worm, log and block, and buck and

pole designs (Karsky 1988). The same principles apply to wood fences as to wire fences in minimizing hindrance to wildlife movements. The top rail or pole of a wooden fence should be kept low to allow mule deer to jump over and the bottom rail or post kept sufficiently high to allow the movement of fawns. Andrew et al. (1997) designed an inexpensive rail fence using t-posts and rebar, which was totally effective in reducing access to water sources by feral asses and yet provided unimpeded access by mountain sheep and mule deer.

Rock Jacks

In many areas, soils are too shallow and rocky to allow steel fence posts to be easily driven into the ground (Hall 1985). At such sites, **rock jacks** are often constructed in the form of wood-rail cribs or wire baskets. The cribs or baskets are filled with rocks and serve as anchors to which wire fences can be secured. Cover and dens for small mammals are provided if the bottom rail of a rock jack is kept 10–15 cm above the ground (Hall 1985). Use of rocks ≥ 30 cm in diameter also will provide crevasses suitable for use by small mammals (Maser et al. 1979b, Hall 1985).

Fences to Exclude Wildlife

Excluding selected wildlife species from certain areas may be desirable. Elk, mule deer, and other species often heavily depredate orchards, vineyards, and other crops; appropriate fence designs can help alleviate such problems. Highways can be hazardous to mule deer and other ungulates that need to reach critically important seasonal ranges. Fences

Fig. 27.11. A simple fence, constructed of metal t-posts and rebar spaced at appropriate intervals, effectively excludes feral asses from water sources in desert ecosystems, yet allows passage by native ungulates. After Andrew et al. (1997).

can be used to channel their movement to suitable **underpasses** and minimize collisions with vehicles. Experimental plots used in research often require exclusion of one or more species of wildlife. Finally, fencing can be used as an alternative to other control measures in reducing predation on livestock.

A 1.8-m upright **net-wire fence**, or one slanted at 45° to a total height of about 1.3 m, can be used to exclude mule deer (Longhurst et al. 1962, Messner et al. 1973, Karsky 1988). Electric fences with 4–6 wires also discourage deer movements (Karsky 1988).

Fences can be used to reduce or eliminate the need for lethal control of coyotes (*Canis latrans*), which can be excluded from pastures by either woven wire (Thompson 1979, de-Calesta and Cropsey 1978, Jepson et al. 1983) or electric fences (Gates et al. 1978, Dorrance and Bourne 1980, Karsky 1988, Nass and Theade 1988). To be effective, a **woven-wire fence** must be ≥ 170 cm high, have mesh openings no larger than 10×15 cm, and have an overhang to prevent jumping and an apron to prevent digging, each ≥ 40 cm wide (Thompson 1979). A 7-wire electric fence (4 hot wires alternating with 3 ground wires) totaling 130 cm in height also can be used (Dorrance and Bourne 1980). Other electric fence designs are available to deter coyotes (Karsky 1988). In general, fencing to control coyotes is expensive, and probably justified only to protect small areas of high production capacity, such as irrigated pastures.

SUMMARY

Management of livestock on public rangelands has become a divisive and contentious issue. Land management agencies increasingly are criticized for failing to give appropriate consideration to grazing issues that affect wildlife, or wildlife habitat, on public lands. The single greatest change influencing conservation of wildlife on western rangelands during the 1990s has been the shift from an emphasis on competition of livestock with big game to concern for biodiversity in general.

We chose to not criticize current grazing practices, but to present a reasonable review of contemporary issues related to livestock management on public lands. Further, we have attempted to (1) provide an overview of rangeland management to benefit wildlife species and natural communities, with an emphasis on western North America, (2) identify some of the topical issues and primary rangeland systems of particular concern, and (3) describe some of the methods for accommodating wildlife and wildlife-related issues, including habitat enhancement techniques, on rangelands. Students and others making use of information in this chapter are encouraged to further explore the vast literature on management of rangelands and livestock, and to use that information to ensure the persistence of healthy and productive rangeland ecosystems, particularly as they relate to the issue of wildlife conservation.

Managing Inland Wetlands for Wildlife

MURRAY K. LAUBHAN,
SAMMY L. KING, AND
LEIGH H. FREDRICKSON

INTRODUCTION

THE SUCCESSFUL MANAGEMENT of wetlands is **complex and challenging** because it requires the correct application of information from **multiple disciplines** on **heterogeneous landscapes**. The United States is a leader in the application of wetland management strategies on public and private lands and has willingly invested huge amounts of public and private monies in many different programs. The result has been the protection, restoration, and enhancement of millions of hectares of wetlands through establishment of **National Wildlife Refuges** and **state wildlife management areas**, the **Wetland Reserve Program**, and conservation easements established by **nongovernmental organizations** (e.g., Ducks Unlimited, The Nature Conservancy). In the National Wildlife Refuge System alone, **>500 National Wildlife Refuges** and **203 Waterfowl Production Areas** protect **>12 million ha of wetlands** (R. L. Fowler, Division of Realty, U.S. Fish and Wildlife Service, personal communication).

Undoubtedly, **wetland conservation** efforts in the United States surpass those of any other country. However, despite the monetary investments in wetlands protection and restoration, the potential benefits of these activities have not been fully realized. Numerous refuges and other public lands are **threatened by activities outside their borders** that alter ecological processes within protected areas (Pringle 2000). Further, as **water becomes more limited**, **increasing conflicts** are expected between human uses and wetland and wildlife conservation (Naiman and Turner 2000, Postel 2000).

Within the conservation arena, most activities involve **creation, enhancement, restoration, and manipulation** of habitats. However, many programs and projects have led to less than optimum results. In some cases, this has resulted because well-defined **habitat-based goals** and objectives at different **spatial and temporal scales** have been lacking. As a result, it has been difficult to evaluate past actions because there often is little to measure other than number or size of projects. Further, funding has focused more on project **implementation** rather than on **planning and evaluation**. Coupled with increasing **societal demands** on natural resources, the lack of clearly articulated goals causes confusion and stimulates **controversy** among entities regarding the need and purpose of **acquiring and managing wetlands**. Because of increasing interest and investment in wetland protection, restoration, and management, opportunities are increasing for employment as well as the correct and efficient use of human and monetary resources to promote **wetland benefits** to society.

The goal of this chapter is to describe an approach that leads to an improved process for wetland management and restoration decisions across multiple temporal and spatial scales. Our approach emphasizes a **multiscale decision-making process** rather than a comprehensive overview of techniques at the local scale because the decision process has been grossly underemphasized in the wetland-wildlife literature. Failure to develop and follow a well-defined decision-making process frequently has led to limited project success, often at great monetary expense. Individuals interested in wetland conservation and management must have a broad understanding of many topics, including **hydrology, geomorphology, soils, plant ecology and taxonomy, and wildlife biology**. In addition, a basic understanding of **policies, societal values, and economics** regarding wetlands is becoming increasingly important. This chapter should be viewed as an **introduction to management of wetland systems** and we encourage biologists to explore the vast amount of literature regarding the ecology and management of these unique and valuable systems.

HISTORY OF WETLAND ATTITUDES

Perception of the values and importance of wetlands in the conterminous United States has varied dramatically through time, as evidenced by changes in federal regulations governing wetland protection and use. **Regulations** largely mirror public attitudes; therefore, a brief synopsis of policies and laws provide a convenient and suitable method of illustrating changing perceptions. Further, regulations influence how wetlands are **defined, classified, and managed**. Thus, understanding current regulatory issues is important for managing wetland resources today.

Prior to the mid-1800s, wetlands were not regulated and were generally perceived negatively (Vileisis 1997). In 1849, the federal government passed the **Swamp Lands Act**, which granted swamps and overflow lands in Louisiana to the state for reclamation. In 1850, this act was applied to 12 other states and, in 1860, to 2 additional states (Shaw and Fredine 1956). The 1850 act resulted in the transfer of nearly **26 million ha** of land that was considered wet and unfit for cultivation to the states (National Research Council 1995). This legislation clearly indicated the government promoted wetland drainage and reclamation (Dahl and Allord 1997). Further, in 1899, the **Rivers and Harbors Act** granted the U.S. Army Corps of Engineers authority to regulate certain activities in navigable waters (Vileisis 1997). At this time, wetlands did not receive protection and the U.S. Army Corps of Engineers interpreted navigable waters narrowly (Silverberg and Dennison 1993). Consequently, the general nature of policies and land-use trends until the 1930s facilitated the removal of wetlands.

The 1930s through the 1960s was a period of competing government policies. Federal legislation was enacted that

encouraged wetland preservation and restoration and also provided incentives to continue wetland drainage. For example, the **Migratory Bird Hunting Stamp Act** of 1934 was among the first legislative acts to initiate wetland acquisition and restoration. In contrast, the government shared the cost of draining wetlands for agricultural production in the 1940s (Burwell and Sugden 1964), the **Water Protection and Flood Prevention Act** of 1954 increased the drainage of wetlands near flood control projects (Erickson et al. 1979), and the U.S. Department of Agriculture subsidized or facilitated wetland losses through many public-works projects and technical practices (Erickson 1979).

In 1972, amendments to Section 404, of the **Federal Water Pollution Control Act** (a.k.a., **Clean Water Act**) were enacted and became a primary protection mechanism for wetlands in the United States, which remains important today. Anyone interested in **dredging, filling, or affecting “waters of the United States”** must apply for a **permit** from the **U.S. Army Corps of Engineers**. Normal farming, ranching, and silvicultural activities are exempt from the Clean Water Act; however, these activities must follow certain guidelines. The Clean Water Act does not specifically mention wetlands and early enforcement was focused on protecting only navigable waters. Court decisions in 1975, however, expanded the scope of the Clean Water Act to include protection of wetlands (Mitsch and Gosselink 2000). Originally, only wetlands adjacent to navigable waters were protected, but in 1977, the U.S. Army Corps of Engineers adopted a **regulation [33 CFR 328.3(a)]** that protected intrastate wetlands and other water bodies that could affect interstate commerce. Later rulings by the U.S. Army Corps of Engineers and the U.S. Environmental Protection Agency (Tiner et al. 2002) afforded protection for **isolated wetlands** (i.e., wetlands with no apparent surface water connection to perennial rivers, streams, estuaries, or the ocean). The basis for this ruling was that migratory birds use these wetlands and, therefore, interstate commerce associated with bird-watching and waterfowl hunting would be affected. The interpretation of these rulings became known as the “**migratory bird rule**.” The passage of this new judicial interpretation of the act required the U.S. Army Corps of Engineers and U.S. Environmental Protection Agency to develop a regulatory definition of a wetland.

During the 1980s, several actions indicated increased recognition of wetland values and functions. The loss of wetlands to agricultural conversion was curtailed by the wetland conservation (**Swampbuster**) provision in the **1985 Food Security Act**. This provision stated that farmers converting natural wetlands to croplands after December 1985 would not be eligible for federal program benefits (National Research Council 1995). However, the **effectiveness** of the provision was compromised because the dynamic nature of wetland functions was not recognized. Thus, in the years immediately following passage of the act, the trend was to

capture all water in a watershed to create **deepwater habitat**. During this period, additional policies were enacted that **eliminated incentives** to destroy wetlands and encouraged acquisition and protection of wetlands. For example, the **Emergency Wetland Resources Act** of 1986 authorized the purchase of wetlands and required establishment of a National Wetlands Priority Conservation Plan.

By the mid-1990s, nearly every federal agency that administered public lands had some form of **wetland restoration and compensation program** (Scodari 1997). For example, the U.S. Fish and Wildlife Service and the U.S. Natural Resources Conservation Service established wetland restoration programs in the 1990s. In addition, further wetland legislation was enacted, including the **Water Resources Development Act** of 1990. This act established a new interim goal for the water resources program of “**no overall net loss** of the Nation’s remaining wetland base as defined by acreage and function” and a long-term goal “to increase the quality and quantity of the Nation’s wetlands” (<http://www.fws.gov/laws/lawsdigest/wat1990.html>).

Although recent federal legislation clearly advocates the importance of wetlands, there is still **no federal regulation specifically designed to govern wetland preservation and use** (Gaddie and Regens 2000). Consequently, the fate of wetland resources is still not secure. This is exemplified in several court cases debating the “migratory bird rule” interpretation of the Clean Water Act. In the 2001 case titled “**Solid Waste Agency of Northern Cook County (SW-ANCC) vs. U.S. Army Corps of Engineers**,” the Supreme Court ruled that the U.S. Army Corps of Engineers did not have authority under **Section 404** of the Clean Water Act to regulate isolated wetlands solely because they provided migratory bird habitat. However, the effects of this ruling remain unclear and additional cases involving interpretation of the Clean Water Act have been brought before the Supreme Court. For example, in the 2006 cases titled “**Rapanos vs. United States**” and “**Carabell vs. United States**,” the Supreme Court addressed where the federal government can apply the Clean Water Act, specifically by determining whether a wetland or tributary is a “water of the United States.” The justices issued 5 separate opinions in Rapanos, with no single opinion commanding a majority of the Court. Ultimately, the final determinations of these and future cases can have severe ramifications because a large percentage of wetlands in some areas of the United States are isolated and provide unique resources that are critical to the long-term sustainability of many species of flora and fauna (Tiner et al. 2002). **Isolated wetlands** that may be particularly affected by these and future rulings include **salt flats, channeled scabland wetlands, playas, prairie pot-holes, Carolina bays, vernal pools, and Rainwater Basin wetlands** (Tiner et al. 2002). Although certain isolated wetlands received some protection under various state statutes or the **Swampbuster provisions** of the **Food Security Act**

of 1985, protection is ineffective in many states and nonagricultural areas (Petrie et al. 2001). Therefore, a ruling that allows widespread destruction or modification of isolated wetlands would significantly affect the nation’s wetland resources.

DEFINING WETLANDS

The diversity of wetland types makes it difficult to develop a single definition of a wetland (National Research Council 1992). Much of the difficulty arises because factors influencing physiognomy of wetlands are numerous and include **climate, soils, topography, landscape position, hydrology, and water chemistry** among others. These factors vary over a wide range of temporal and spatial scales. Wetlands range from **barely perceptible depressions** that hold surface water for, at most, a few weeks in some years, to **large basins** that are flooded to some extent every year. Wetlands can support plant communities ranging from small carnivorous plants in northern bogs to baldcypress trees (*Taxodium distichum*) that are several meters in diameter in southern forested wetlands. Finally, wetlands occur **along river systems** with frequent overbank flooding, **in regions of permafrost** where snowmelt is captured in depressions formed in frozen ground, and **in arid regions** where ecological conditions are often driven by **groundwater**.

Historically, wetlands were defined based on specific purposes, such as individual research studies or general classification and inventory. However, recognition that wetlands are a critical **part of the nation’s social, cultural, and economic network** resulted in development of federal statutes to protect and govern wetland uses. The diverse functions of wetlands have **complicated delineation and management** because public opinion regarding the fate of a wetland often is based on specific attributes rather than the entire suite of functions. For example, the **flood retention** benefits associated with a given wetland may be favored more than **benefits for wildlife**. As a result, modifications or management to increase flood storage may be advocated even though this may decrease wildlife benefits. Consequently, decisions regarding wetlands often occur within a strong **political context** (Hollis 1998). To help resolve such issues, the federal government established regulations to identify and protect certain wetland types. Enforcement of these regulations requires a **clear and legally defensible definition of wetlands** because regulation often is viewed as a form of **land use restriction** imposed by the **federal government on private landowners**. Detailed definitions have been developed by the federal regulatory agencies responsible for wetland identification and delineation: U.S. Environmental Protection Agency, U.S. Fish and Wildlife Service, U.S. Department of Agriculture, and the U.S. Army Corps of Engineers. Each agency developed its definition based on laws and regulations that protected specific inter-

ests (Federal Interagency Committee for Wetland Delineation 1989). Wetlands that meet these requirements are often termed **jurisdictional wetlands** to separate them from wet areas that may provide similar functions, but do not meet legal criteria. With the exception of the U.S. Fish and Wildlife Service definition, which incorporates nonvegetated areas (e.g., mudflats, gravel beaches), all 4 definitions are conceptually similar because they include **3 basic attributes** for defining a wetland: (1) **hydrology** that results in surface saturation or inundation, (2) presence of **hydric soil**, and (3) **hydrophytic vegetation**. However, even these definitions were too general to be used directly; thus, technical manuals were developed for identifying and delineating wetlands (Waterways Experiment Station 1987, Office of Wetlands Protection 1988, Soil Conservation Service 1994). The technical guidance for interpreting these 3 basic wetland attributes differed among manuals (reviewed by National Research Council 1995). This prompted an attempt to consolidate the manuals and adopt a uniform approach for delineating wetland boundaries by all federal agencies (Federal Interagency Committee for Wetland Delineation 1989). This manual was withdrawn due to criticism and each agency reverted to using their original manuals (National Research Council 1995).

Although beneficial, development of **legal definitions** to protect wetlands is often **problematic**. First, according to definitions of the U.S. Army Corps of Engineers and U.S. Environmental Protection Agency, not all wetland types meet established legal criteria and, therefore, are **not protected** under existing laws. For example, in the arid West, wetlands may be completely dry for several years and the **concept of average conditions** is difficult to apply (National Research Council 1995). These **intermittently flooded wetlands** are not protected even though they support a distinct water-dependent biota (Kantrud et al. 1989) and can help maintain water quality (Johnston et al. 1990). Also, many **riparian zones** are excluded from consideration as wetlands, especially in arid and semiarid western states (Johnson et al. 1984, Kusler 1985, Lowe et al. 1986). These areas comprise 1% of the total land base in the western United States, but are used by more species of breeding birds than any other habitat in North America (Knopf et al. 1988a). Second, **delineating wetland boundaries** can be **difficult**. Analysis of vegetation is often used to identify boundaries (National Research Council 1995), but location of hydrophytic vegetation may change due to variation in short- and long-term hydrology (van der Valk and Davis 1976, Weller 1981, Zedler 1987, Stromberg et al. 1991). Transitional areas between uplands and wetlands are critical to the flow of energy and nutrients; therefore, **incorrect boundary identification** may **jeopardize** the long-term **health and sustainability** of some **jurisdictional wetlands**. Finally, wetlands within a regulatory context are considered as discrete units independent of the surrounding landscape. However, values of wetlands are of-

ten dependent on **conditions at larger scales**. For example, the long-term sustainability of many vertebrate populations (e.g., amphibians) depends on type and condition of terrestrial communities surrounding wetlands (Gibbs 1993, Burke and Gibbons 1995, Fischer and Fischenich 2000, Semlitsch 2000a, Higgins et al. 2002, Saunders et al. 2002).

In this chapter, we use the **definition of wetlands** provided by Cowardin et al. (1979): **wetlands are** transitional areas between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water. This definition is not regulatory, but it is used to report the status of the nation's wetlands to Congress (National Research Council 1995). Specifically, wetlands must have one or more of the following **3 attributes**: (1) at least periodically, the land supports predominantly **hydrophytes**; (2) the substrate is predominantly undrained **hydric soils**; and (3) the substrate is nonsoil and is saturated with water or **covered by shallow water** at some time during the growing season each year. This definition is more inclusive because the temporal nature of some wetlands is acknowledged by stating that hydrophytic vegetation and hydrologic indicators need only be present periodically (National Research Council 1992). In contrast, the U.S. Environmental Protection Agency and U.S. Army Corps of Engineers definitions require evidence of all 3 attributes (hydrophytes, hydric soils, and hydrology). Thus, some areas considered wetlands by the Cowardin et al. (1979) definition **might not be considered jurisdictional wetlands** according to federal statutes.

The Cowardin et al. (1979) definition captures the dynamic nature of wetlands and identifies the importance of hydrology. **Hydrology is a key component** because water modifies and affects the substrates in wetlands, which together **influence** specific responses in water, soils, vegetation, invertebrates, birds, and fish (Mitsch and Gosselink 1993). Another strength of this definition is the reference to "**systems**," a critical concept that should be considered in defining a wetland (National Research Council 1995). The term "**transitional**" also correctly implies that wetlands form a continuum connecting terrestrial to aquatic ecotypes and are influenced by the type of terrestrial (e.g., grass, forest) and aquatic (e.g., lake, ocean) environments of which they are a part.

WETLAND CLASSIFICATION

The concept of classifying wetlands has been in existence for over a century. Early attempts at classification largely were motivated by interest in **converting wetlands** for agriculture (Wright 1907) and used only a few general categories (e.g., river swamps, lake swamps, upland swamps) on the basis of location. Other systems were related to the amount of inundation and used terms such as permanent, wet, and periodically swampy (Dachnowski 1920). By the 1950s, the

need for classifying wetlands broadened to other purposes, including a need to differentiate wetlands from other land-cover types for regional and national planning (Tiner 1997). However, most methods were developed for use by states.

By 1974, >50 schemes had been developed, but only one was national in scope (Office of Biological Services 1976). However, the need for a nationwide classification scheme became evident with the advent of federal wetland regulations, including passage of the **Emergency Wetland Resources Act** of 1986 that required the U.S. Fish and Wildlife Service to conduct **wetland status and trend studies** and report the results to Congress each decade. In addition, new approaches to management and scientific study (e.g., ecosystems) required access to information that was consistent across political boundaries. Numerous large-scale wetland classification systems were devised to facilitate surveys and inventories for management and conservation purposes (reviewed by Finlayson and van der Valk 1995). Of all the systems developed, the one developed by the U.S. Fish and Wildlife Service (Cowardin et al. 1979) is most useful and has become the national and international standard for identifying and classifying wetlands (Gopal et al. 1982, Mader 1991). This system is **based on ecological principles** rather than attempting to satisfy the needs of particular user groups (Cowardin and Golet 1995, Tiner 1997). It **designates wetland types on the basis** of hydrology, vegetation, soils, geomorphic and chemical factors, and size. The system uses a **hierarchal approach** to group wetlands into ecologically similar categories at different levels of resolution. There are **5 systems, 8 subsystems, 11 classes, 28 subclasses**, and a large number of dominance types based on plants or substrates. Thus, wetlands can be differentiated into **55 ecologically distinct types**, providing uniformity in wetland terminology. This system has been used by the **National Wetland Inventory** to map wetlands, special aquatic sites, and deep-water habitats of the United States for 3 decades.

Brinson (1993) developed another classification system, known as the **hydrogeomorphic method**. This approach **identifies the wetland classes present in each region, defines the functions** that each class of wetlands performs, and **establishes reference sites** to define the range of functioning of each wetland class. The 3 primary factors used to classify wetlands are **geomorphic setting, water source, and hydrodynamics** (Brinson 1995). **Geomorphic setting** is the landscape position of the wetland, and categories include depressional, slope-flat, peatland, riverine, and fringe. Water source may be precipitation, groundwater discharge, and surface or near-surface inflow. **Hydrodynamics** are differentiated into 3 qualitative categories: vertical fluctuation of water table, unidirectional flow, and bidirectional flow. Further groupings and classifications occur at regional and local levels.

The hydrogeomorphic method is mentioned because it has been particularly valuable in **restoration** and **mitigation**

activities. In fact, use of **functional assessments** has been identified as the preferred option for evaluating performance of wetland mitigation banks (Federal Register 1995). Although numerous issues regarding use of this system have arisen (Magee 1996, Brinson et al. 1997), it represents an improvement compared to using area assessments as the sole attribute in measuring restoration or mitigation success. Users must consider that wetland functions, even among wetlands of similar vegetation structure, vary according to hydrologic characteristics and geomorphic settings. Guidelines have been established using the hydrogeomorphic method to assess wetland functions in the 404 Regulatory Program, as well as in other regulatory, planning, and management situations (Brinson et al. 1995). A benefit of this approach is the ability to **standardize the analysis of wetland functions** to quantify gains and losses for compensatory mitigation, compare project alternatives, identify the effects of a proposed project, and assess mitigation requirements or success, as well as other applications (Smith et al. 1995, Brinson and Rheinhardt 1996). Thus, a wetland being examined based on regulatory statutes can be compared to reference sites that have been extensively studied and functionally evaluated. The amount of wetland area needed to replace the lost functions can be calculated based upon the functional values of the reference wetland. This information can be used to establish ratios or indices to estimate how much mitigation is required. Similarly, comparisons of functional equivalency between reference wetlands and **mitigation banks** also can be used to identify the amount of credit a mitigation bank should receive.

DISTRIBUTION AND STATUS

Wetland Loss

At the time of colonial America (1600s), wetlands constituted **11% of the landscape** (National Research Council 1992) and encompassed an estimated **89.5 million ha** in the conterminous United States (Dahl 1990). However, **wetland drainage and modification** began with colonial settlement and continued as the human population expanded westward.

Consequently, **<40.1 million ha** of wetlands remained by the mid-1970s when federal regulations were enacted that protected some wetlands. However, between the mid-1970s and mid-1980s, wetlands continued to be **lost** at an **annual rate of 117,360 ha** (Dahl and Johnson 1991). By the mid-1980s, wetlands constituted only **5% of the landscape** and distribution had been severely altered (National Research Council 1992). For example, wetland losses exceeded 20% in all 48 conterminous states except New Hampshire (9%) by the mid-1980s. Further, wetland losses exceeded 85% in 6 states and 50% in 22 states (Dahl 1990).

The **2004 National Wetland Inventory** revealed that **freshwater and marine-estuarine wetlands** comprised **94.7% (41.5 million ha)** and **5.3% (2.1 million ha)** of the **43.6 mil-**

lion ha of wetlands in the conterminous United States, respectively (Dahl 2006). For the first time in >50 years there was a **net gain in wetlands** due to **creation and restoration** activities associated with regulatory actions and agricultural conservation programs; between 1998 and 2004 there was a **77,630-ha increase** in total wetland area (12,900 ha annually) and an **increase of 89,140 ha in freshwater wetland area** (Dahl 2006). However, wetland losses and gains were not distributed equally among habitat types. For example, **freshwater emergent marshes decreased by 57,720 ha**, but **freshwater forested wetlands increased by 221,950 ha**. It also is important to note that the area of **freshwater ponds increased 281,500 ha** and **without including ponds, wetland gains would not have exceeded wetland losses**. Many ponds function differently from traditional wetland systems; therefore, the **above statistics can be misleading** (Dahl 2006).

Wetland Alteration

Comprehensive data necessary to document trends in **wetland alteration** are not available. However, there are national reports and studies that indicate the **majority of wetlands** remaining in the lower 48 states **have been altered**. One of the most comprehensive reports was developed by the H. John Heinz III Center for Science, Economics and the Environment (2002). According to this report: (1) of 140 large river sites sampled, about **50% had phosphorus concentrations** that exceeded EPA standards (600 ppb) for preventing excess algal growth; (2) **60% of streams** sampled ($n = 867$ sites) exhibited **major changes** in the magnitude of **high or low flows, or the timing** of these flows; (3) approximately **800 (20%) of 4,000 native animal species** that depend on streams, lakes, wetlands, or riparian areas are **considered “imperiled” or “critically imperiled”**; (4) **213 (61%) of 350 watersheds** sampled contained **1–10 nonnative species**; (5) about **940 (60%) of the 1,560 wetland communities** whose status is known are considered to be **at risk**; and (6) approximately **23% of streams and rivers** have **farmlands or urban development within 30 m of the water’s edge**. Although these figures do not provide quantitative estimates of wetland area affected, they indicate that aquatic environments ranging from rivers to reservoirs have been **severely impacted** in some manner (biologically, physically, and chemically) due to human activities.

Causes of Wetland Loss and Alteration

The causes of wetland losses in the United States have received much attention (Dahl and Allord 1997). Wetlands have been **drained** for various reasons, including disease prevention, agricultural production, transportation and communication network development, natural products production, and urban development (Dahl and Allord 1997). From the mid-1950s to the mid-1970s, **conversion** of wetlands for agricultural purposes was responsible for **87% of wetland**

losses in the United States (Frayer et al. 1983), with losses due to tile and open-ditch drainage averaging 222,580 ha annually (Office of Technology Assessment 1984). Between the mid-1970s and mid-1980s, agriculture remained a primary cause of wetland loss, but **losses decreased** to 54%. This trend continued into the 1990s, with agriculture responsible for only 26% of wetland losses from 1986 to 1997 (Dahl 2000). From 1998 to 2004, 28,640 ha of wetlands, or 17% of net wetland gains, were gained by **converting agricultural lands to wetlands**, whereas **urban and rural development** combined accounted for **61% of all freshwater wetland loss** (Dahl 2006).

The **National Resources Inventory** is another source of information to document conditions and trends in natural resources on **nonfederal lands** in the United States. The U.S. Department of Agriculture’s Natural Resources Conservation Service, in cooperation with the Iowa State University Statistical Laboratory, conducts the National Resources Inventory. Compiled at 5-year intervals beginning in 1987, this inventory **captures data on features** such as land cover and use, soil erosion, wetlands, and habitat diversity at >800,000 scientifically selected sample sites. In 1997, federal and nonfederal land accounted for about 163 million and 607 million ha of land in the conterminous United States, respectively. Further, approximately **59% of wetlands occurred on forestland** and **16.5% on agricultural** cropland, pasture, and land in the Conservation Reserve Program. On nonfederal land, annual average net loss of wetlands was 13,150 ha (Office of Water, Wetlands, Oceans and Watersheds 2000). Of the total losses recorded during this period, **development** was responsible for **49%**, followed by **agriculture (26%)**, **silviculture (12%)**, and **miscellaneous (13%)**.

Impacts of Wetland Loss and Alteration on Wildlife Resources

Impacts of wetland loss on fish and wildlife resources are **difficult to assess**, but they have been severe. There are numerous reports documenting the decrease in prairie breeding habitats (Tiner 1984, Pederson et al. 1989) and the demise of waterfowl stopover and winter habitats (Korte and Fredrickson 1977, Frayer et al. 1989, Dahl and Johnson 1991). This information is supported by national and regional reports on status and habitat conditions of migratory birds, including wading birds, waterfowl, shorebirds, and Neotropical migrant songbird species. Of the **50 shorebird species** considered in the **United States Shorebird Conservation Plan**, **5 (10%)** are considered **highly imperiled**, **22 (44%)** are **species of high concern**, and **15 (30%)** are of **moderate concern** at a national scale (Brown et al. 2001). Similarly, the **North American Waterbird Conservation Plan** provides a continental scale framework for the conservation and management of 210 species, including seabirds, coastal waterbirds, wading birds, and marsh birds in 29 nations (Kushlan et al. 2002). Of the **166 species of colonial**

waterbirds assessed in the plan, **12 (7%)** are **highly imperiled**, **43 (26%)** are of **high concern**, and **52 (31%)** are of **moderate concern**. Approximately 34% of these species use freshwater wetlands for nesting and foraging.

The U.S. Fish and Wildlife Service has produced a report that identifies migratory and nonmigratory birds of the United States of conservation concern (Division of Migratory Bird Management 2002). The species considered in this report are nongame birds, game birds without hunting seasons, subsistence-hunted nongame birds in Alaska, and species categorized as candidate, proposed, and recently delisted from the Endangered Species Act. Assessment scores used by the 3 major bird **conservation plans** (U.S. Shorebird Conservation Plan, North American Waterbird Conservation Plan, and Partners In Flight) were used in assessing conservation status at 3 geographic scales: national, U.S. Fish and Wildlife Service regions, and Bird Conservation Regions. At the national level, this report considers 131 bird species (12% of all native species) to be of conservation concern. At the scale of individual U.S. Fish and Wildlife Service regions ($n = 8$), the number of **species listed** ranges from **28 to 87** ($\bar{x} = 45$). The number of **species considered being of conservation concern** within the 24 Bird Conservation Regions encompassing the lower 48 states ranges from **10 to 48** ($\bar{x} = 26$). The North American Bird Conservation Initiative has endorsed **Bird Conservation Regions** as the basic ecological units to be used in planning and evaluation of all-bird conservation efforts (North American Bird Conservation Initiative Committee 2000a, b). Although not all of the species occurring in the lists are considered wetland dependent, palustrine and riparian wetlands often fill a crucial niche in the annual life cycle of many species on these lists.

A similar scenario is evident for amphibians and reptiles, but data are less complete compared to birds. **Natural fluctuations and local extinctions** are common in both **reptiles and amphibians** (Blaustein et al. 1994). Thus, although observed population trends of many species have declined, **determining** whether these **trends** constitute natural fluctuations or unnatural declines is **difficult** because most field studies have not been conducted for a sufficient period (Pechmann and Wilbur 1994). However, the number of reported declines and the documentation of adverse effects suggest that **amphibian declines** represent a **serious threat** and **reptiles** appear to be in **even greater danger of extinction** (Gibbons et al. 2000). For example, **27 and 87 species of herpetofauna** are **listed as threatened and endangered**, respectively, under the **Endangered Species Act**. This list includes 37 turtles (33 endangered, 4 threatened), 14 frogs and toads (9 endangered, 5 threatened), and 12 salamanders (8 endangered, 4 threatened). On a global scale, the **World Conservation Union** has assessed 6,260 amphibian species and lists **38 species as extinct**, **1,276 species as critically endangered** ($n = 489$) or **endangered** ($n = 787$), and **715 species as exhibiting a high vulnerability** to becoming endangered

(International Union for the Conservation of Nature 2009). There are many factors known or suspected to be associated with population declines of amphibians and reptiles, including **habitat loss and modification, introduced invasive species, disease, pollution, and global climate change** (Gibbons and Stangel 1999). However, many scientists consider habitat loss and alteration to be the largest single factor contributing to the declines of many amphibians and semiaquatic reptiles (Alford and Richards 1999, see also Buhlmann 1995 and Buhlmann and Gibbons 1997 for specific examples).

WETLAND FUNCTIONS AND VALUES

Wetland functions are diverse and include the **biological, physical, and chemical processes** that occur in, or are associated with, wetlands. The most widely valued wetland function is providing **habitat for wildlife** and contributing to the **maintenance of biodiversity** (National Research Council 1992). The U.S. Fish and Wildlife Service estimates that up to **43% of federally threatened and endangered species** require wetland habitats during some part of their annual cycle (Office of Water, Wetlands, Oceans and Watersheds 2000), and **>50% of protected migratory birds rely on wetlands** (Wharton et al. 1982, Office of Water, Wetlands, Oceans and Watersheds 2001a). In addition, wetlands support **31% of the plant species** occurring in the conterminous United States, even though wetlands comprise only **5% of the land surface** (Office of Water, Wetlands, Oceans and Watersheds 2001a).

Although the importance of wetlands to wildlife is well known, wetlands also perform numerous other functions. Intact wetlands positioned at low topographic positions relative to uplands **moderate flood events** by storing and slowly releasing floodwaters. In addition, trees and other wetland vegetation **slow flow velocity** and distribute floodwaters over floodplains. In combination, these functions can **decrease the frequency and intensity** of floods and **reduce** downstream **erosion**. In some cases, wetlands and other water retention facilities often provide a level of flood protection otherwise provided by expensive dredging operations and levees.

Wetlands also help **reduce shoreline erosion**, as well as **maintain** (e.g., groundwater recharge) and **improve water quality** (e.g., sediment accretion, nutrient uptake). As water passes through wetlands, excess nitrogen and phosphorus is processed, organic pollutants decompose, and suspended sediments are trapped. Wetlands may be capable of **removing between 70% and 90% of the nitrogen** entering a system (Gilliam 1994), whereas the estimated mean **retention of phosphorus is 45%** (Johnston 1991). However, **excessive additions of nitrogen and phosphorus** can **cause** the development of large **algal blooms** that consume oxygen and result in **low oxygen concentrations** (i.e., hypoxia) that cannot be tolerated by many aquatic organisms (Office of Water, Wetlands, Oceans and Watersheds 2001b).

Hypoxia can occur naturally, but **human activities** have undoubtedly **increased the frequency, extent, and severity** at which this condition occurs. In the conterminous United States, the largest known area of hypoxia occurs off the Louisiana coast, but other areas include Long Island Sound and Chesapeake Bay (Turner and Rabalais 2003). Wetlands also have been reported to **remove 20–100% of metals**, depending on individual site characteristics and metal type (Taylor et al. 1990, Delfino and Odum 1993, Gambrell 1994). In terms of quantity, **sediment is the major pollutant** of wetlands, lakes, estuaries, and reservoirs in the United States (Baker 1992). Sediment quality also is an environmental concern because it may act as both a sink and source for water-quality constituents. As with some nutrients, **sedimentation naturally occurs** in many wetlands. However, excessive sedimentation can negatively impact aquatic plant and animal communities (Rybicki and Carter 1986, Dieter 1991, Jurik et al. 1994, Walters et al. 1994, Gleason and Euliss 1998). In some cases, sediment accrual can actually result in the loss of all basin volume (Luo et al. 1997).

Finally, many wetlands may be important in **carbon sequestration** and reduction of atmospheric concentrations of **greenhouse gases** that are linked to **climate change** (Mitsch and Gosselink 1993). Although much attention has been focused on bogs, forested wetlands, and tidal marshes, restored prairie **wetlands** also have been recently identified as **carbon sinks** (U.S. Environmental Protection Agency 2003). **High primary productivity** by plants that fix carbon through photosynthesis, high rates of organic matter uptake, and low decomposition rate of organic matter are characteristics that result in the **net storage of carbon** in wetlands. For example, a study of coastal marshes in Florida indicated that soils in high and low marshes contained 73% and 287% more organic carbon, respectively, than did nearby upland forest soils (Choi et al. 2001). Conversely, **freshwater wetlands** are considered to be among the ecosystems **most vulnerable to climate change** (Bates et al. 2008). This assessment is due, in part, to the limited capacity of wetlands systems to adapt to hydrologic changes. **Climate change could alter** recharge rates of local and regional groundwater systems, as well as modify direct precipitation and evaporation rates that could significantly alter wetland functions (Winter and Woo 1990, Woo et al. 1993), particularly in regions where precipitation and evaporation are similar. **Such changes**, even if relatively small, can significantly **affect** wetland plants and animals (Burkett and Kusler 2000, Keddy 2000), and ultimately diminish many current wetland functions.

Wetland values, which are **based on functions**, usually are **associated with goods or services** that society recognizes as worthy, desirable, or useful to humans. The **reasons** that wetlands are often legally **protected** are **related** to their **societal values** rather than ecological processes

(Mitsch and Gosselink 1993). Thus, the value of a wetland often depends on type and location as well as human perception. Although it is difficult to determine the **economic value** of individual wetlands or wetland systems, according to one assessment of natural ecosystems, the economic value of wetlands worldwide was estimated to be **\$14.9 trillion** (Costanza et al. 1997; all currency given in U.S. dollars). One of the most consistently reported wetland values is the provision of recreational opportunity. Ninety-seven percent of all Americans >16 years of age participate in some sort of outdoor recreation, with 33% of Americans reporting that they birdwatch (Cordell and Herbert 2002). Based on the **National Survey of Fishing, Hunting, and Wildlife-Associated Recreation**, 87.5 million U.S. residents spent \$122.3 billion to fish, hunt, or watch wildlife in 2006 (U.S. Fish and Wildlife Service and U.S. Census Bureau 2007). **Sportspersons spent \$76.7 billion** in 2006, including **\$42.0 billion on fishing, \$22.9 billion on hunting, and \$11.7 billion on equipment** and other items related to fishing or hunting. A total of **71.1 million Americans watched wildlife** and spent **\$45.7 billion on items related** to these activities in 2006. The number of people participating in **wildlife recreation increased by 6%** in 2006 compared to 2001 (U.S. Fish and Wildlife Service and U.S. Census Bureau 2001, 2007), although the increase was primarily attributable to an **8% increase in wildlife watchers**. Although the economic benefits reported in **these studies encompass all habitats**, wetlands obviously contribute to the economic value of outdoor recreation.

The economic value that wetlands provide in relation to water purification and flood protection has been estimated in some regions. In South Carolina, for example, the **Congaree Bottomland Hardwood Swamp** annually **removes pollutants** that would require \$5 million to remove using a wastewater treatment facility (Office of Water, Wetlands, Oceans and Watersheds 2000). The U.S. Army Corps of Engineers found that protecting wetlands along the **Charles River in Massachusetts** saved \$17 million in potential flood damage (Thibodeau and Ostro 1981), the **Minnesota Department of Natural Resources** estimated that replacing the natural floodwater storage function of wetlands is \$2,430/ha-m (\$300/ac-ft) of water (Rivers and Trails Conservation Assistance 1995), and in **western Washington** the value of wetlands for flood protection ranged from \$14,600/ha to \$20,600/ha (Leschine et al. 1997). In contrast, drainage of wetlands and diversion of the **Mississippi and Missouri rivers** from their original floodplains were partially responsible for the billions of dollars in damage to businesses, homes, crops, and property that occurred due to the 1993 Mississippi River flood (Office of Environmental Policy 1993, Parnett et al. 1993).

Wetlands also are commercially **important sites for production of natural products**, including fish, shellfish, fur,

and timber. **Landings of crab, shrimp, and salmon** were valued at **\$1.17 billion** in 2004 and the dockside **value of fin fish and shellfish** in the United States was **\$3.7 billion**. In addition, the **fishery processing business** was valued at **\$7.2 billion** and U.S. consumers spent an estimated **\$54.4 billion for fishery products** in 2000 (Office of Water, Wetlands, Oceans and Watersheds 2006). Species dependent on wetlands for food or habitat comprise **>75%** of the commercial harvest (Feierabend and Zelazny 1987, Office of Water, Wetlands, Oceans and Watersheds 1994). The commercial harvest of fish and shellfish in **Louisiana's coastal marshes** alone was worth **\$244 million** in 1991 (Office of Water, Wetlands, Oceans and Watersheds 1995). **Many mammals and reptiles harvested** for their skins are dependent on wetlands, including muskrat (*Ondatra zibethicus*), American beaver (*Castor canadensis*), mink (*Mustela vison*), northern river otter (*Lontra canadensis*), and American alligator (*Alligator mississippiensis*). The nation's harvest of muskrat pelts was worth **>\$124 million** in 2004 (U.S. Environmental Protection Agency 2006). Finally, forested wetlands have the potential to provide a substantial amount of wood products. The value of **bottomland hardwoods and cypress swamps** in the southeastern United States alone has been estimated at about **\$8 billion** (Johnson 1979).

Wetlands supply humans with a number of important products (e.g., fish, timber, wildlife), but they also perform an unusually large number of ecological functions that support economic activity (Barbier et al. 1997). However, **not all wetlands perform every function, nor do wetlands perform all functions equally well**. Factors that influence the kind of functions a wetland performs include **wetland type** (palustrine, riverine), **position** in the landscape, **type of landscape** (e.g., agriculture, forest), **size, soils, vegetation** composition, residence **time of water**, and the **nutrient, sediment and chemical concentrations** of water (Novitzki et al. 1997). In addition, wetland functions have value at several different spatial scales, including internal, local, regional, and global. For example, **water storage** functions and provision of migratory bird resources are applicable at regional scales, whereas the effects of wetlands on **air quality** (e.g., carbon and nitrogen cycles) are most appropriate to consider at a global level. Finally, there are different methods available to **measure the value of wetlands**, including **ecology, sociology, and economics**. Some products such as commercial fish and timber harvest can be directly assigned monetary value, but it is difficult to calculate economic return on **ecosystem services** such as **biodiversity, clean air and water, and floodwater attenuation** (Barbier et al. 1997). Consequently, there are a great number of **uncertainties** that must be considered when attempting to **assign values to wetlands**.

Wetlands often provide public goods that are not priced the same as other services and goods; thus, many private in-

dividuals and firms make economic choices that affect the status of wetlands on the basis of costs and benefits that neglect or undercount broader social issues (Leschine et al. 1997). For example, lands enrolled in conservation programs administered by the U.S. Department of Agriculture in the **Prairie Pothole Region** were estimated to reduce total soil loss by an average of 1,940,254 tons/year, sequester approximately 244,960 tons/year of soil organic carbon, and store approximately 56,513 ha-m of water in wetlands if they filled to maximum capacity (Gleason et al. 2008). It has been suggested that **failure to adequately account for non-market environmental values** in development decisions is a **major reason wetlands have been lost and converted** to other uses (Barbier et al. 1997). However, there are increasing efforts to conduct total wetland valuation studies that capture both direct and indirect values. A total valuation study of Louisiana's coastal wetlands resulted in an estimate of \$983/ha based on an 8% discount rate (Costanza et al. 1989). Using a variety of techniques, the authors calculated that commercial fishing and trapping, recreation, and storm protection services accounted for 19%, 2%, and 79% of the total, respectively.

Wetland management in today's society requires **strategic planning** and a **diverse set of skills** because decisions regarding the values of wetlands must be based on many **competing interests**. Managers must also recognize and address the increasing pressures being placed on wetlands as a result of an increasing human population and economic wealth. Since 1950, there has been a 40% increase in per capita demand for grain, a 100% increase in fish, and 33% in timber (Watson 1999). In addition, **decisions** that were historically made within fish and wildlife agencies are **now made with citizen involvement**. These pressures often form the basis for decisions regarding the fate of individual wetlands and entire landscapes. In many cases, **decisions** are often **biased in favor** of uses that have **marketed products** that **result in conversion and exploitation** of environmental resources (Barbier et al. 1997). Uses with marketable products often are advocated because there is a belief that technological advances will allow replacing the wetland functions lost by modifying or destroying the wetland. However, functions and values lost often are not completely replaced, especially with regard to the abiotic and biotic processes necessary to support healthy and sustainable fish and wildlife populations. Therefore, in addition to making decisions regarding how to manage land, **managers must** also create opportunities to **inform public officials and interested individuals** on the need to conserve or restore wetlands for a wide variety of reasons, including value as wildlife habitat. This will require development of new and **interdisciplinary approaches** to problem solving, including use of information from other disciplines (e.g., political, economic, and social) during the decision-making process.

WETLAND CHARACTERISTICS

Traditionally, wetlands often have been created, restored, or managed without accounting for differences in structure and function affected by abiotic and biotic factors. One of the most common approaches has been to acquire a site, and implement a familiar development or management scenario that has worked elsewhere, without considering environmental conditions including geomorphic and current ecological processes (e.g., nutrient cycling). **Such an approach often fails**, because these processes are naturally variable in space and time. Consequently, **wetlands** often have been **described as sieves** that are continually **modified and influenced by myriad factors** that **affect both short- and long-term productivity and values** (Fig. 28.1). For example, the type and quantity of nutrients that are imported and exported from a wetland varies among locations, seasons, and years (Hammer and Bastian 1989). Examples of **abiotic factors** that influence wetland processes **include hydroperiod, climate, soil, and disturbance** (e.g., fire, herbivory) regimes (see Fig. 28.1). **Biotic factors** include those that are stationary within a wetland basin (e.g., plants) and those that operate at larger scales (e.g., waterbirds, pathogens). Failure to incorporate this information into the decision-making framework prior to site acquisition, development, or management often has resulted in the inability to sustain long-term productivity and, ultimately, the inability to reach desired goals and objectives. In this section we provide information on the primary abiotic and biotic factors, and their interrelationships with wetland structure and function, because **this information represents the cornerstone of effective management**.

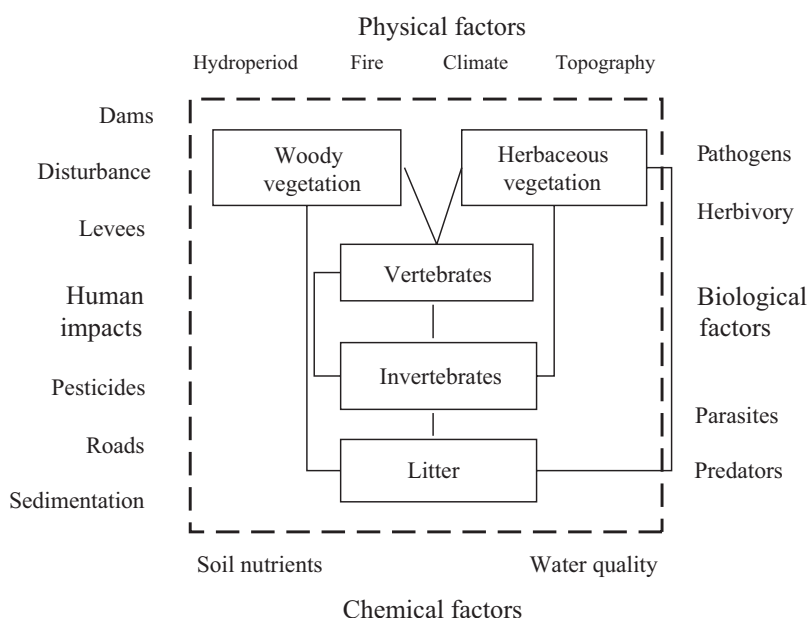

Fig. 28.1. Factors influencing wetland characteristics, functions, and values.

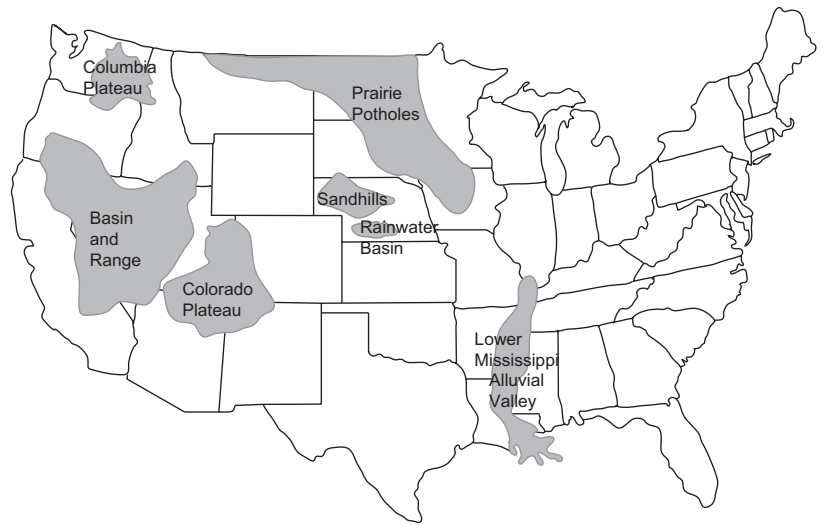

Geomorphic Setting and Soils

Geomorphology is the study of landforms and the processes that shape them. A basic understanding of geomorphic processes is critical because they are responsible for the formation of many wetlands (Klimas et al. 2003). Furthermore, the geologic formation underlying wetlands and the geomorphic processes operating on those formations greatly influence hydrologic condition, water quality, and hence, vegetation structure and wildlife habitat quality (Bornette et al. 1998, Hupp 2000, Johnson 2000, Batzer and Sharitz 2006).

Landforms on the earth's surface can be grouped into 4 categories: structural, weathering, erosional, and depositional. **Structural landforms** (e.g., mountains, rift valleys) include those created by massive earth movements such as tectonic and volcanic activity. In contrast, **weathering landforms** (e.g., karst, patterned ground) are created by the physical or chemical decomposition of rock. **Erosional** (e.g., river and glacial valleys) and **depositional** (e.g., deltas, floodplains) landforms are the result of the erosion or deposition, respectively, of surface materials caused by wind, water, glaciers, and gravity. Landforms that have been influenced by more than one of the above processes are termed **polygenetic**, whereas landscapes that have undergone several cycles of development are termed **polycyclic**.

Wetlands occur in all of the above landforms and many are the result of polygenetic and/or polycyclic processes (Fig. 28.2). For example, in the Rocky Mountains, wetlands occurring in mountain valleys often differ from those occurring in intermountain basins due to distinctly different **geologic origins, weather, and resulting soil types** (Windell et al. 1986). Mountain valleys were shaped by erosional forces

Fig. 28.2. Landforms in the Intermountain West and Great Plains regions of the United States.

of water and, at higher elevations, by glacial movements (Wright 1983). In contrast, intermountain basins were largely formed by ancient tectonic and volcanic events (Windell et al. 1986). Depending on topographic position and underlying geologic material, the **direct or indirect effects of glaciers** in mountains have resulted in the formation of many different types of palustrine wetlands, including **cirque basins; spring, seep, and snowbed wetlands; tarns; kettles; and terminal or lateral moraine lakes.**

Wetland morphology and structure should **not** be viewed as **static**. Geomorphic processes continually influence wetland characteristics at both local and landscape scales. For example, **tectonic activity** continues to influence the rise and fall of the earth's surface, thereby affecting the presence, location, and hydrological characteristics of wetlands (Forsberg et al. 2000, Jain and Sinha 2005). Broad-scale events, such as the formation and eventual drainage of Lake Bonneville, occur on much longer time scales, but dramatically alter the wetland landscape (Oviatt 1997, Louderback and Rhode 2009). Smaller scale tectonic events, such as the continual uplift of valley floors, can slowly alter morphological and hydrological characteristics of wetlands. For example, in the Basin and Range province of Idaho, faults are moving and pulling mountain ranges farther apart, thus making the valleys wider (Alt and Hyndman 1989). The effects of these smaller scale events on wetland processes are difficult to discern because of simultaneous anthropogenic and climatic effects, but changes are occurring.

The **integration of current and past geomorphic processes** also is evident in the **Lower Mississippi River Alluvial Valley**. Erosional and depositional events caused by glaciations and fluvial geomorphic actions were the most important processes involved in the formation of the Lower Mississippi River Alluvial Valley (Saucier 1994). Although levees and dams have altered rates, fluvial geomorphic pro-

cesses continue to influence wetland formation and location in the region (Saucier 1994). Saucier (1994) mapped the location of point bars, abandoned channels, natural levees, valley trains, backswamps, and other features from Cairo, Illinois to the Gulf Coast. The results of this study and others illustrate that **floodplains** are comprised of many **different soil types** that often are **intermixed** and distributed in **complex patterns** depending on **type of parent material**, type of **erosional forces** acting on the environment, and **sediment deposition patterns and rates** through time (Wharton et al. 1982, Stanturf and Schoenholtz 1998, Richardson 2000). Current depositional environments overlay soils and landforms that were a result of historical depositional environments, thus creating a complex mixture of soils and hydrologic environments that have important implications to the distribution and restoration of wetland plant and animal communities (Klimas et al. 2009).

Glaciation also was the **dominant force** creating **pot-hole wetlands** in the Columbia Basin (Bretz 1923) and Prairie Pothole Region of the northern Great Plains (Sloan 1972). However, south of the Missouri River to about the Nebraska–South Dakota boundary there is greater evidence of erosion (Laubhan and Fredrickson 1997). Further south in the central and southern Great Plains, wetlands exhibit a depositional rather than an erosional surface. In the central Great Plains, multiple hypotheses of wetland genesis have been proposed, but all involve weathering or erosion. Wetlands in this region are thought to have formed due to **deflation** (i.e., removal of loose fine-grained material by wind action), **differential compaction of unconsolidated materials**, and solution of **soluble layers** (Shimer 1972). For example, the numerous isolated wetlands in the Rainwater Basin (see Fig. 28.2) of south-central Nebraska typically developed in depressions where leaching concentrated clay particles in the subsoil (Erickson and Leslie 1987). In contrast, the **Sandhill**

Region of Nebraska was formed as wind-blown sand accumulated against low hills and ridges (Tiner 1984). In this region, wetland type and distribution is largely affected by the dynamics of a large underground reservoir that is part of the **Ogallala Aquifer** (Bleed and Flowerday 1990). **Playas**, the dominant palustrine wetland type in the southern Great Plains, also are thought to have formed by deflation (Reeves 1966).

Wetlands in the **Great Basin Region** of the **Basin and Range Province** formed due to different processes (Duffy and Al-Hassan 1988). First, **alluvial fan** deposits of **Quaternary** age occurred along the margin of depressions and, in many cases, individual fans coalesced to form a **piedmont plain or bajada**. Second, the depression filled with deposits of mixed **fluvial** and **lacustrine** origin. Third, extreme periods of rainfall created pluvial lakes that inundated the area. As conditions became drier and warmer, pluvial lakes **evaporated**, resulting in **saline lakes** and **playas**. Notable water bodies include Walker and Pyramid lakes, which are remnants of Lake Lahontan, and the Great Salt and Utah lakes, which are remnants of Lake Bonneville (Fiero 1986). Additional wetlands were formed as erosional material was transported by streams and deposited at the base of mountains or farther out in depressions (Snyder 1962, Burkham 1988). An alluvial fan from one mountain may extend outward and merge with a fan from an adjacent range (Lamke and Moore 1965), which typically results in a nearly flat area where fine-grained deposits accumulate and surface flooding may occur during wet periods (Mabbutt 1979, Burkham 1988).

Examples of wetlands formed by weathering include **tinajas**, also called potholes or weathering pits. Tinajas are depressional wetlands eroded from bedrock and are abundant on friable sandstones of the **Colorado Plateau**, where they locally create a distinct dome-and-pit landscape (Spence and Henderson 1993). Most theories regarding formation of tinajas include a combination of physical, chemical, and biological weathering processes that promote mineral decomposition, followed by removal of the decomposed material by wind or water (Twidale and Bourne 1975, Godfrey 1980). The aridity of the region also contributes to wetland development by limiting vegetation cover, which permits wind deflation, and by concentrating salts that facilitate rock disintegration (Goudie 1991).

Wetlands that formed of similar processes may differ markedly **depending on parent material, climate, and other factors**. For example, **depressional wetlands** referred to as potholes occur in both the Columbia Basin and the northern Great Plains. Potholes in both regions resulted from glaciation and have many similar attributes, including size (8 ha in the Great Plains and from 1 to >32 ha in the Columbia Basin), location (typically in areas with a high water table), and isolation (Harris 1954, Johnsgard 1956, Sloan 1972, Stewart and Kantrud 1972, Laubhan and Fredrickson 1997, Tiner et al. 2002). However, glaciers in the Columbia Basin scoured

basalt deposited by lava flows (Bretz 1923, Fenneman 1931), whereas the advance and retreat of glaciers in the Great Plains deposited **glacial drift**, a general term that includes unsorted rock **debris** called **till**, sorted sand and gravel called **outwash**, and **fine-grained sediments** deposited in lakes (Sloan 1972). These **differences in the composition of material underlying the potholes** in each region can **influence hydrology, soil and water chemistry** (e.g., nutrients, pH), and other factors important in **affecting** the composition of wetland **flora and fauna**. Thus, applying standard techniques across sites that appear similar may not be successful due to differences in topographic position, soils, or hydroperiod (Stanturf and Schoenholtz 1998).

The **importance of material that becomes the substrate of wetland basins** due to geomorphic processes also is **critical for understanding wetland structure and function**. For example, glacial deposits vary in texture and chemical composition, which affects the quantity of wetlands, their **hydrologic connectivity**, and water quality (Winter 1989). In contrast, different rock types, climate, and geomorphic processes (e.g., glaciation, erosion) have resulted in a complex mosaic of heterogeneous, discontinuous soil types in the Rocky Mountains (Retzer 1962, Price 1981). Relatively undeveloped soils are common in areas dominated by fragmented bedrock, talus, or recent glacial moraine deposits (Rink and Kiladis 1986). In comparison, tinajas in the Colorado Plateau are covered with sandy sediments or alternating layers of materials that vary in organic content (Netoff et al. 1995). The amount of sediment deposited in the basin, in combination with hydrology, largely affects vegetation composition (Netoff et al. 1995).

Floodplain systems also exhibit **differential patterns of sediment erosion and deposition** that results in a **diversity of wetland types and soil conditions** (Leopold et al. 1964, Wharton et al. 1982, Stanturf and Schoenholtz 1998, Richardson 2000). **Geomorphic features, such as** natural levees, point bars, backswamps, abandoned channels, oxbows, sloughs, and swales greatly influence abiotic conditions (e.g., hydroperiod, soil, and drainage characteristics). Natural levees adjacent to a river are formed when heavier, coarse-grained sediments (e.g., sand) are deposited as the river overtops its bank during flood events and the water velocity is slowed by vegetation (Hupp 2000). In contrast, water is ponded for much longer periods in backswamps and fine sediments are filtered out, forming heavy clay soils. Such differences impact hydrology, which influences the floristic and structural characteristics of vegetation (Kellison et al. 1998, Ward 1998, Heitmeyer et al. 2002). The diversity of these sites is important for providing habitat for a wide range of species, including amphibians, reptiles, waterbirds, and fish (Bellrose et al. 1979, Burbrink et al. 1998, Hoover and Killgore 1998, Wigley and Lancia 1998). However, differences among floodplain wetlands often have been overlooked in many restoration efforts because these features have not been recognized.

Hydrologic restoration of sloughs and swales has been underemphasized or ignored in many efforts. Further, **improper site selection** is a **leading cause of failure in bottomland hardwood reforestation** (Allen et al. 2001, Lower Mississippi Valley Joint Venture 2007) and management efforts (King and Fredrickson 1998). Development of management units ringed by levees in areas where a natural levee or point-bar exists may lead to failure because sandy deposits may make it difficult to maintain water levels, particularly during drought conditions.

Historically, forces that altered surface features and created wetlands were the result of natural events that influenced large areas and occurred thousands of years ago. However, **geomorphic processes** continue to occur through time and act to **alter wetland structure and function**. These processes are now largely influenced by **anthropogenic activities**, including agriculture, physical structures such as levees, and urban development. During the Mississippi River flood of 1993, deep scouring often occurred at sites where man had placed barriers (such as roads, railroads, or levees) in the floodplain. Thus, the distribution and connectivity of scour sites to the river was largely influenced by human development (Galat et al. 1998). Development of reservoirs in the pothole area of the Columbia Basin has **elevated groundwater levels** and has **increased the hydroperiod** and **lowered salinities** in many wetlands that are not actually submerged (Johnsgard 1956). Repeated agricultural cultivation has reduced the porosity of the upper horizons, causing serious erosion of **loessal** (i.e., wind-blown) soils (Daubenmire 1942, Busacca 1991). Excessive sedimentation can result in dramatic habitat alterations in a relatively short time (Bellrose et al. 1979, Kleiss 1996, Oswalt 2003). In addition, activities such as **stream channelization** (the process of straightening streams and steepening their gradient) can alter hydrologic and geomorphic processes throughout an entire **watershed**, thus influencing vegetation communities and reducing habitat quality for a variety of fish and wildlife (Fredrickson 1979, Shankman and Pugh 1992, Oswalt 2003). These influences must be considered when developing restoration and management plans because areas properly designed based on local site conditions may still fail because of offsite conditions. Thus, restoration plans must often be developed for larger scale landscapes and involve all affected stakeholders (National Research Council 1999).

Hydrology and Climate

The **hydroperiod**, or the timing, depth, duration, and frequency of flooding, is the single most important factor **controlling the establishment and maintenance** of specific wetlands and wetland processes (Mitsch and Gosselink 2000). In fact, the hydrological regime separates wetlands systems from true terrestrial and aquatic systems. The hydroperiod influences chemical and physical properties of wetlands, and ultimately affects the biota (see Fig. 28.1).

Components influencing hydroperiod include those that affect the amount of water entering and leaving a wetland (Marble 1992, Batzer and Sharitz 2006). **Precipitation, groundwater, surface water, and tidal fluctuations** represent important **inflow components**. Possible **outflow components** include **evaporation, transpiration, groundwater and surface water discharge, and tidal fluctuations**. These components are often placed in an equation, termed a **water budget**, to express the relationship between **inflow** and **outflow**. This equation is based on the premise that the amount of water in a wetland is equal to the water that enters a wetland minus the amount of water discharged from the wetland. A generalized form of this equation is

$$\begin{aligned} \text{water volume} = & \text{precipitation} + \text{surface water inflow} \\ & + \text{groundwater inflow} - \text{evaporation} - \text{transpiration} \\ & - \text{surface water outflow} - \text{groundwater outflow.} \end{aligned}$$

The relative importance of parameters in the equation varies depending on several factors, including geomorphic setting, landscape position, and climate. **Tidal fluctuations** are a primary determinant of hydroperiod in coastal wetlands, whereas changes in surface water are a controlling influence in riparian wetlands. Palustrine wetlands also exhibit wide variability relative to the importance of inflow and outflow parameters. All Physiographic Provinces composing the Intermountain West (Columbia Plateau, Colorado Plateau, Basin and Range, Rocky Mountains) exhibit either semiarid or arid climates (Bailey 1995) and, with the exception of high-elevation wetlands in the Rocky Mountains, experience **negative annual precipitation/evapotranspiration ratios** (Nelson and Tiernan 1983, Hidy and Klieforth 1990, Bailey 1995). Because of the general aridity and high evapotranspiration rates of the region, temporary hydroperiods are widespread, and permanently flooded palustrine wetlands are few (Williams 1985). However, differences in abiotic features within and among provinces alter the contribution of various input and output parameters that determine hydrologic cycles. In the Columbia Basin portion of the Columbia Plateau, the hydroperiod of many remnant natural wetlands is affected primarily by **precipitation** and **evaporation** cycles; however, larger lakes and permanently flooded potholes also receive water from **springs** and have **surface outlets** to streams (Whittaker and Fairbanks 1958). **Precipitation** also is of primary importance in the hydroperiods of natural wetlands of the Basin and Range Province, but factors such as **elevation, aspect, slope, climate, and soil properties** also are important (Snyder 1962, Beatley 1974, Eakin et al. 1976, Ehleringer 1985, Duffy and Al-Hassan 1988). In general, spring months represent the primary, and often the only, soil-moisture recharge period (Caldwell 1985, Ehleringer et al. 1991).

External drainage plays a prominent role in the hydroperiod of wetlands in the Colorado Plateau. Surface waters entering wetlands connected to rivers are exported via riv-

ers, with approximately 90% of the region drained by the Colorado River and its tributaries (Thornbury 1965). Surface water availability is further influenced by local climatic conditions that vary considerably depending on elevation, landscape position, and aspect (Comstock and Ehleringer 1992). Consequently, although natural marshes are common in the Basin and Range Province, they are an uncommon feature of the Colorado Plateau (Harper et al. 1994). In Arizona, most natural marshes are largely seasonal, the hydrology being dependent on summer precipitation and snowmelt rather than groundwater (Brown 1985).

Wetland hydrology in the Rockies is complex because the relative contribution of surface (direct and indirect) and groundwater components varies depending on numerous physical and climatic factors. The majority of water inflow to wetlands results from indirect precipitation occurring in the watershed. In contrast, direct precipitation is probably the least significant source of water (Knud-Hansen 1986), except in terrain depressions where snow has accumulated (Willard 1979) and in bogs (Cooper 1986).

Historically, most wetland managers focused solely on surface water and ignored the dynamics of groundwater, including its quality, volume, and seasonality. However, given the current and future human demands for water (Postel 2000), understanding groundwater conditions will be increasingly important for successful wetland management. Groundwater processes are affected by geology, watershed topography, soil characteristics, and season (Rink and Kiladis 1986). In the Rockies, snowmelt at higher elevations supplies a large volume of water that can contribute to groundwater dynamics. Heterogeneous, coarse-textured soils create complex groundwater flow-paths that result in groundwater seep areas at lower elevations. In the Intermountain West and the Prairie Potholes of the northern Great Plains, groundwater can be a critical water source and influence wetland geochemistry (Winter and Rosenberry 1995). Because of complex geomorphologic features and

differences in groundwater connectivity, wetlands immediately adjacent to each other can have very different salinities and mineral content. In many river systems, during certain times of the year or along certain stretches of river, the aquifer is recharged by stream flow. During low flow periods, however, groundwater may be the primary source of water for both the river and associated floodplain wetlands.

The influence of groundwater is often more evident in geographic regions that have a negative precipitation/evaporation ratio because groundwater flow often allows plants with low salinity tolerance to exist among plants with high salinity tolerance. The influence of groundwater on wetland hydrology is more difficult to identify in areas where precipitation exceeds evapotranspiration because groundwater constituents are diluted by precipitation. However, in some systems, groundwater may be more important than precipitation or surface flooding at particular times of the year.

Depletion of aquifers due to withdrawal for agricultural irrigation and drinking water is an increasing problem, but the impact on wetlands depends on the connectivity between wetlands and groundwater (Postel 2000). **Perched wetlands**, which have an impervious layer between the wetland and the groundwater table (Mitsch and Gosselink 2000), are disconnected from the aquifer and groundwater effects are minimal. However, groundwater is an important hydrologic component of **recharge, flow-through, and discharge wetlands** (Fig. 28.3). Flow-through wetlands have both surface and groundwater flow and discharge some water into the ground. Discharge wetlands typically occur at low topographic positions and receive some surface flow, but groundwater discharging into the wetland influences the geochemistry. Although this classification may seem straightforward, **a given wetland may change status**. For example, if a local aquifer becomes depleted, a discharge wetland may shift to a recharge wetland (Richardson et al. 2001). Thus, water depth and duration may decline in the wetland, resulting in ecological and functional changes.

Fig. 28.3. The influence of groundwater and surface water, relative to discharge, flow-through, and recharge wetlands.

Short- and long-term hydrologic conditions affect many abiotic factors. Water fluxes affect nutrient cycling in wetland basins by influencing the type and quantity of nutrients that enter and exit wetlands, and decomposition rates (Livingston and Loucks 1979). Hydroperiod and water source (e.g., groundwater versus surface water) also affects water quality, nutrient cycling, and soil conditions (Gambrell and Patrick 1978, Wharton et al. 1982, Mitsch and Gosselink 2000). These abiotic conditions in turn influence biotic components of wetlands, including composition, distribution, and productivity of wetland vegetation (Bedinger 1979, van der Valk and Welling 1988, Squires and van der Valk 1992) and invertebrate community composition and structure (Eakin et al. 1976, Kadlec 1982, Duffy and Al-Hassan 1988, Dobrowolski et al. 1990, Williams et al. 1990, Comstock and Ehleringer 1992). **Ultimately, vertebrate use of wetlands is indirectly and directly affected by the hydrologic regime** (Table 28.1). Hydroperiod indirectly affects vertebrates by affecting vegetation composition and structure as well as food resources for waterbirds (Weller and Spatcher 1965, Weller and Fredrickson 1974, Kaminski and Prince 1981, Ball and Nudds 1989, Weller 1999).

Similar interactions occur with respect to herpetofauna that often spend only short periods in wetlands. For example, many species of amphibians require vegetation for attachment of egg masses, and both adults and larval forms require invertebrates for food. Therefore, **wetland vegetation is extremely important for amphibians** because com-

position **affects** (1) type, quantity, and nutritive quality of plant foods available (Table 28.2); (2) distribution, density, and structure that provides cover and egg attachment sites; and (3) quantity and type of substrate for invertebrates. Hydrologic regime also directly influences wildlife use because time of flooding relative to the life-history cycle of the organism, duration of flooding, and water depth affect availability of resources (e.g., foods, cover) for waterbirds (Laubhan and Roelle 2001). For example, many waterbirds (e.g., dabbling ducks, shorebirds) require shallow water depths to forage efficiently (White and James 1978, Reid et al. 1989; Fig. 28.4). Foods and cover in wetlands that are flooded too deep are largely unavailable to these species. In addition, successful recruitment of many amphibian species is enhanced in wetlands that dry seasonally because this prevents fish and invertebrate predators from becoming established (Pechmann et al. 1989, Semlitsch 2000b).

Algae

Historically, biologists have focused on the structure and biomass of **emergent plants** in wetland systems, but have **overlooked** the importance of **algae**. However, algal **biomass can equal that of submersed macrophytes** (Goldsborough 2001). Further, algae can be **important sources of primary production and dissolved oxygen** as they **transform and retain nutrients, serve as habitat** for other organisms, and often form the **base of wetland food webs** (Murkin 1989, Stevens et al. 1989, Murkin et al. 1992, Browder et al. 1994, MacIntyre et al. 1996, Wetzel 1996, Robinson et al. 2000, Stevenson 2001). In **saline systems**, the algal biomass within a wetland often exceeds the biomass of macrophytes (Zedler 1980) and is of critical importance for invertebrate fauna. In freshwater systems, algae are important in the decomposition process and provide important nutrition for invertebrates. Epiphytic algae are an important food for many macroinvertebrate grazers (Allanson 1973). Algae readily respond to available nutrients in the water column and may form massive blooms, particularly when water temperatures are warm. During **slow drainage** of a wetland, **algae are retained** within a basin because they tend to attach to vegetation or other substrates, thus preventing the export of important nutrients. However, algae are sensitive to many physical and chemical factors, including human activities (Pan and Stevenson 1996, Stevenson et al. 1999). Fertilizer runoff can result in excessive addition of some nutrients (e.g., phosphorous) that can stimulate extensive algal blooms that deplete dissolved oxygen concentrations and cause fish mortality, or reduce light penetration below thresholds required for growth of some aquatic plant species.

Vascular Vegetation

Wetland **vascular plants** can be divided into **4 life forms**: (1) submergent, (2) emergent, (3) floating leaf, and (4) floating. **Submergent plants** are rooted in substrate, but the

Table 28.1. Representative vertebrates that use 7 wetland types^a classed as palustrine^b

Wetland type	Description	Flood duration (month)	Vertebrate use
I	Ephemeral ponds	1	Dabbling ducks, shorebirds

stems and leaves are mostly, if not entirely, in water. **Emergent plants** grow with their roots in wet soil part or all of their life, but stems and leaves extend through the water column to above the water surface. **Floating-leaf plants** are rooted in substrate, but extend broad, floating leaves to the surface. **Floating plants** are not rooted and usually remain on the surface of the water.

The composition, distribution, and productivity of vegetation within a wetland are dependent on both biotic and abiotic factors (Whittaker and Niering 1975, Grubb 1977, Bedinger 1979, van der Valk and Welling 1988). Species that potentially occur within a basin are dependent on 2 primary factors. First, **colonization** can occur **via dispersal** of reproductive **propagules** (e.g., seeds, tubers) from outlying areas into the basin. There are many natural dispersal mechanisms that facilitate movement of seeds to new areas. Species such as overcup oak (*Quercus lyrata*) have floating seeds that are easily dispersed by water, whereas willow (*Salix* spp.)

and cottonwood (*Populus* spp.) seeds are light and dispersed via both wind and water (Cronk and Fennessy 2001). In contrast, seeds of other species often attach to, or are digested by, mammals or birds and can be transported great distances from the original source (Collon and Velasquez 1989, Vivian-Smith and Stiles 1994, Mueller and van der Valk 2002).

There also are numerous **human activities** that **facilitate spread** of plant propagules, including automobiles, boats, and farm machinery (Cronk and Fennessy 2001). Human-facilitated dispersal is often cited as the vector responsible for the spread of many invasive species, including zebra mussels (*Dreissena polymorpha*; Johnson and Padilla 1996) and purple loosestrife (*Lythrum salicaria*; Thompson 1989). The other primary source of plant propagules occurs on or beneath the surface of the soil in the wetland basin. Commonly referred to as the **seed bank**, these propagules include **tubers**, **corms**, and other reproductive parts as well as **seeds** that dispersed into or were produced within the wet-

land basin. The **persistence of seeds** in the seed bank **varies by species** in relation to complex physiological requirements involving the interaction of **temperature, light, moisture, and the gaseous environment, as well as seed size** (Baskin and Baskin 1989, Murdoch and Ellis 1992). The soil seed bank rarely reflects the composition of the standing vegetation (Thompson 1992).

Of the potential suite of plant species, **abiotic conditions act as a sieve**, affecting types and densities of species that germinate and survive to maturity (van der Valk 1981). **Recruitment** from the seed bank is partially dependent on the **depth** propagules are buried; only seeds in the upper portion of the soil profile (termed the “active” seed bank) are capable of germination (Simpson et al. 1989). **Other abiotic factors influencing recruitment** are soil temperature, moisture, and oxygen concentrations; photoperiod; quality and quantity of light; and soil and water chemistry (Simpson et al. 1989, Cronk and Fennessy 2001). **Submergent plants germinate under flooded conditions**, whereas **most emergents germinate during drawdown conditions**. In addition, requirements or tolerances exist among different propagules of the same species. Cattail (*Typha* spp.) can reproduce by seed or vegetatively by rhizomes. Optimum seed germination occurs in shallow (~1.25 cm) water or exposed mudflats (van der Valk and Davis 1978, Sojda and Solberg 1993) at soil temperatures ranging from 25° C to 35° C (Bonnewell et al. 1983). Following germination, however, cattail establishment may occur when conditions range from saturated to 15 cm of standing water (Bedish 1967).

In many cases, factors influencing germination of a species are interrelated. Soil temperatures tend to increase with increasing day length, whereas soil oxygen content decreases as soil moisture increases. Likewise, soil temperatures are higher when the surface color is dark rather than light or when there is no residual vegetation. The relationships between other factors are subtler, yet still important. For example, the amount of light that reaches the basin substrate

decreases as turbidity or the amount of residual vegetation increases.

Some common wetland plants are **naturalized** (Table 28.3), but their presence has not significantly compromised wetland values. Annuals such as curltop ladysthumb (*Polygonum lapathifolium*) and common barnyardgrass (*Echinochloa crusgalli*) are abundant in seasonal wetlands managed for **moist-soil plants** and are considered desirable by most managers, yet both species are naturalized. Common millet (*Setaria italica*), another naturalized species, is often planted in wetlands managed for wildlife. In contrast, some native plants such as chufa flatsedge (*Cyperus esculentus*) are classed as noxious by agriculturists, but are important food for wildlife in wetlands.

Unfortunately, numerous plant species with **invasive** characteristics have been introduced into wetlands, particularly during the past 50 years (Table 28.4). For example, in **Hawaii about 55% of plants in wetlands are exotics** (Stemmermann 1981). In some cases, invasive plants have expanded rapidly into wetlands after a major perturbation such as a flood. This appears to have been the case with the spread of tall whitetop (*Lepidium latifolium*) on Ouray National Wildlife Refuge on the Green River in Utah and reed canarygrass (*Phalaris arundinacea*) in floodplain habitats throughout the Upper Mississippi Drainage Basin following the 1993 flood.

Aggressive exotic plants have compromised management because they alter wetland functions and processes. Managers often lack adequate information on effective and reliable techniques to control many invasive species and costs associated with known control techniques can be prohibitive. For example, the distribution and density of saltcedar (*Tamarisk* spp.) throughout the southwestern United States is so extensive that wetland functions and values are compromised, but control and restoration are extremely costly (e.g., nearly \$1,480/ha on Bosque del Apache National Wildlife Refuge in NM). In monotypic stands of saltcedar, the selection of sites for conversion to native species

is based on the potential to duplicate a more natural hydro-period. Once a site is selected, an application of Garlon or Arsenal is applied, and then 2 years are allowed to pass to assure chemical translocation to the roots. Following the herbicide treatments heavy equipment with experienced operators is required to break trees from their root crown and to remove standing undesirable material. Multiple passes with a root rake removes as much belowground biomass as possible. The uprooted woody debris is pushed into piles and burned. Where riparian restoration is the objective, a water delivery and drainage system is developed to create a hydrologic regime that favors the establishment of native plants over exotics during drawdowns. Spot treatments with soil disturbance or herbicides may be used to reduce the area of exotic plant response.

Often, the purpose of implementing management strategies is to manipulate abiotic conditions to favor germination and survival of desirable plant communities or to inhibit exotic and invasive plant species development. In many cases, **desirable is defined based on** cover and food values for target organisms. Regardless of the definition, **understanding plant germination and growth requirements**, as well as other **processes of plant community dynamics**, are **critical for successful wetland management**. **Time and rate of drawdown** not only directly affect the presence or absence of mudflats, but also influence soil temperature and oxygen concentrations. However, many abiotic factors (e.g., time and amount of rainfall, temperature) that directly or indirectly influence propagule establishment vary among years at the same site. Therefore, **implementing the same management action among years** often will **result in** the establishment of **different plant communities**. Thus, the calendar date on which an activity is implemented is not an

appropriate benchmark on which to base management actions. Rather, the **time and type of management activity must be based on the specific conditions** necessary for plant germination, seedling establishment, and growth, as well as existing conditions at the site relative to the organisms of interest (e.g., presence of mudflat during least sandpiper [*Calidris minutilla*] migration). Several handbooks and models that relate common activities (e.g., drawdown time and date) to germination requirements of plant groups common in seasonally flooded wetlands have been developed to provide managers with general guidelines (Fredrickson and Taylor 1982, Fredrickson 1991). However, guidelines are not available for all wetland types or geographic regions. Also, our understanding of factors that influence the establishment and spread of invasive species is limited. Thus, the best option is to develop a monitoring program to collect site-specific information necessary to construct relationships between management activities and plant response.

Van der Valk (1981) developed a model of **wetland plant succession** for prairie marshes. The interactions between plant life-history characteristics and abiotic factors are common to virtually all prairie wetlands and similar models could be developed for other wetland types using the same criteria. In this model, wetland plants are divided into groups based on **life span** (annual, perennial with limited life, perennial with unlimited life), **propagule longevity** (short, long), and **requirements for propagule establishment** (drawdown, surface water). Species can further be classified into **shade intolerant or shade tolerant**.

Annual plants generally have long-lived propagules in the seed bank and, following a drawdown, production of seeds can be large. However, if the wetland remains saturated or flooded for more than a year, the abundance of annuals typ-

ically decreases because they are incapable of germinating in water. In contrast, abundance of perennial vegetation tends to increase because these species propagate by rhizomes as well as seeds, and they can tolerate deeper water. Through time, particularly under **stable water regimes**, **perennial plants** (e.g., cattail, bulrush [*Scirpus* spp.]) capable of **reproducing vegetatively** begin to **dominate** the wetland **plant community**. In many cases, dense, monotypic stands of robust vegetation develop throughout the basin and a decline in biodiversity occurs. In coastal and north temperate wetlands, feeding and house-building activities of herbivores such as muskrats and beaver are extremely important at this stage in the cycle. These activities, in conjunction with **water level fluctuations**, function to create openings in the marsh and facilitate the production of annuals when the next drawdown occurs.

This model illustrates an important facet of wetlands: **abiotic factors controlling germination are dynamic** and result in vegetation changes that influence vertebrate use. Plant communities dominated by annuals normally produce abundant seeds that contain important sources of carbohydrates, vitamins, minerals, and essential amino acids for waterbirds (see Table 28.2). In addition, drawdowns often result in fish mortality; thus, amphibian survival should improve the year following a drawdown due to the absence of predators. In comparison, **seed production will decrease as vegetation shifts to perennial species**, but the stems of perennials **provide vertical and horizontal cover** for seclusion of waterbird pairs and broods, sites for **nest attachment**, food for herbivorous mammals, and **egg attachment** sites for amphibians. In addition, succulent new growth and **rhizomes** serve as **browse for geese**. However, continued flooding for long periods would result in the development of dense, monotypic stands of perennial vegetation throughout the basin. This would likely facilitate development of a fish population, but cause a decline in waterbird diversity

and amphibian survival and breeding success (Weller and Spatcher 1965, Weller and Fredrickson 1974, Werner and McPeck 1994).

Changes in **vegetation composition** represent an important component of natural wetland function. These changes dramatically influence habitat suitability for different vertebrate species. Attempts to consistently provide the same vegetation distribution and composition during consecutive years require implementing management activities to constrain abiotic factors that are inherently dynamic. For example, consistently promoting the growth of specific annuals requires drawdowns to be conducted at roughly similar times (e.g., early spring) every year (Table 28.5). Although this hydroperiod occurs naturally in some wetland types in certain regions, it represents an extreme variation from natural hydroperiods of other wetland types in many regions. In these latter wetlands, implementing this strategy over consecutive years often leads to disrupted wetland function, which can be costly and time-consuming to correct. In these cases, **short-term habitat objectives** to benefit target organisms **must be balanced with long-term objectives** of sustainable productivity.

Macroinvertebrates and Plant Decomposition

Our understanding of **wetland invertebrates** has advanced considerably in the past decade (Batzer et al. 1999). Wetlands provide many habitat niches for invertebrates, which are important foods for waterbirds, amphibians, reptiles, and fish (Mott et al. 1972, Swanson and Meyer 1973, Weller 1988, Eldridge 1990). Many invertebrates are extremely small (1 mm), and their use as food is restricted to a few vertebrates with specialized foraging mechanisms and to large invertebrates. Thus, our focus is on **macroinvertebrate** communities typically associated with different wetland types.

Differences in **invertebrate composition and distribution** among wetland types are **driven by hydrologic regimes**,

Table 28.5. Effect of drawdown date and rate on soil drying and germination of selected moist-soil plants on Mingo National Wildlife Refuge, Missouri

Drawdown date ^a	Rate ^b	Ambient temperature ^c	Daylight ^d	Rate of soil drying ^e	Representative plant germination
Early	Slow	Low	Short	Slow	Smartweed, spikerush, barnyardgrass
	Fast	Low	Short	Medium-slow	Barnyardgrass, willow, chufa
Midseason	Slow	Intermediate	Intermediate	Medium-slow	Rice cutgrass, burhead, barnyardgrass, chufa
	Fast	Intermediate	Intermediate	Medium	Beggarticks, ragweed, panic grass
Late	Slow	High	Long	Medium	Redroot flatsedge, toothcup
	Fast	High	Long	Fast	Cocklebur, aster, crabgrass morning glory

^a Early: prior to 15 May; Midseason: 16 May–1 Jul; Late: after 1 Jul.

^b Slow: >14 days; Fast: <7 days.

^c Low: <16° C; Intermediate: between 16° C and 27° C; High: >27° C.

^d Short: ≤10 hr; Intermediate: 10–2 hr; Long: ≥12 hr.

^e Slow: similar moisture for ≥1 week; Medium-slow: similar moisture for 5–7 days; Medium: similar moisture for 3–5 days; Fast: similar moisture for <2 days.

water chemistry, and vegetation structure (Murkin et al. 1992). The **life-history strategies** of wetland macroinvertebrates have been **shaped by long-term hydrologic cycles**, particularly the type (e.g., backwater, headwater, etc.) timing (e.g., vernal, autumnal), and depth of flooding. Among the most important are morphological or behavioral adaptations to tolerate or avoid drought. **Adaptations** that have evolved due to long-term hydrologic cycles include ≥ 1 of the following: (1) ability to withstand drought in the egg, pupal, or larval state, (2) rapid growth, (3) ability to produce numerous offspring, (4) ability to complete the life cycle within 1 year, and (5) high mobility (Wiggins et al. 1982). Several invertebrate groups, including flatworms (order Turbellaria); fairy, clam, and seed shrimp (orders Anostraca, Conchostraca, and Ostracoda); water fleas (order Cladocera); mayflies (order Ephemeroptera); and mosquitoes and phantom midges (order Diptera) have resistant egg stages that help prevent drought-induced mortality. Aquatic earthworms (order Oligochaeta) may use mucosal secretions to survive drought, whereas bloodworm larvae aestivate in cocoons and fingernail clams (order Telecytoda) burrow into the wet litter layer and rely on their shell to avoid desiccation. Gastropods develop a seal over the operculum and can survive buried in mud for decades. In contrast, aquatic sowbugs (order Isopoda) and sideswimmers (order Amphipoda) have no morphological adaptations to resist drought, but adults aestivate and survive dry seasons by locating suitable conditions in the deeper litter layers.

Many macroinvertebrates that exploit wetlands also have adaptations that enable them to thrive in specific habitats or vegetation types (Euliss et al. 2002). Macroinvertebrate communities can be grouped based on **habitat association** into those that occur primarily in (1) **benthic** substrates, (2) **submergent** vegetation, (3) **perennial** herbaceous vegetation, (4) **annual** herbaceous vegetation, and (5) **leaf litter**. Species that compose each group have life-history strategies that allow them to exploit a particular hydrologic regime (Table 28.6). A wetland invertebrate fauna often exists in the dry substrates of an ephemeral or intermittently flooded wetland. When such sites are flooded, invertebrates initiate life-cycle responses that may result in large numbers and biomass of invertebrates in the flooded basin (Batema 1987, Severson 1987, Fredrickson and Reid 1988a). Further, habitat requirements of some invertebrates change depending on life-cycle stage (Pennak 1978). One habitat may be important for egg laying, whereas a different habitat may be required for feeding.

Although long-term hydrologic cycles and habitat type influence adaptive strategies of macroinvertebrates, other factors affect the spatial and temporal occurrence, abundance, growth rate, and reproduction of individual species. Among the most important are the short-term water regime and physical, chemical, and biological factors (Pennak 1978, Wiggins et al. 1982, Pinder 1986). In wetlands that ex-

Table 28.6. Invertebrates associated with different flooding regimes in seasonally flooded impoundments

Flooding regime	Invertebrates
Late drawdown	Mosquito Pond snail Water boatman (<i>Sigara</i> spp.) Chironomid
Early drawdown	Mosquito Pond snail Water boatman
Autumn–winter	Mosquito Water boatman Chironomid
Long vernal flooding	Fairy shrimp (order Anostraca) Mosquito Water boatman
Short vernal flooding	Fairy shrimp Mosquito

hibit dynamic, short-term flooding regimes, macroinvertebrates that exhibit rapid growth during periods of adequate water and nutrient availability have an advantage. Furthermore, producing large numbers of young and completing the life cycle in 1 year allow for greater success. When water levels decline, species that cannot tolerate drought must avoid dry conditions. Those most successful often are highly mobile and capable of immigrating to suitable sites. Beetles (order Coleoptera) and water boatmen (order Hemiptera, *Sigara* spp.), in particular, respond to drawdowns by aerial dispersal to available wetlands.

Another important factor affecting invertebrate abundance and diversity is **litter type** and availability that forms when plants senesce. Forms of herbaceous litter include stems, leaves, and flower structures, whereas leaves are the primary litter from woody vegetation. Nutrients and organic matter rapidly leach from litter upon initial contact with water and concentrate in the water column (Peterson and Cummins 1974, Yates and Day 1983, Wylie 1985). Fungi, bacteria, and microinvertebrates associated with litter accelerate decomposition and release additional energy and nutrients (Fig. 28.5). Macroinvertebrates also feed on litter conditioned by bacteria and fungi, further assisting in litter decomposition and nutrient cycling. Because they are readily consumed as food, **macroinvertebrates** are an important **functional link in the transfer of nutrients** from detritus to waterbirds, herptiles, and fish (Batema et al. 2003).

Decomposition rate is governed by several factors including **litter type, lignin and nutrient content of the litter, hydrologic condition, and temperature** (Webster and Benfield 1986, Middleton et al. 1992). Under a given set of environmental conditions, herbaceous litter generally decomposes faster than woody vegetation (Fig. 28.6). **Robust**

Fig. 28.5. Litter decomposition pathway in a detrital-based wetland (CPOM = coarse particulate organic matter; FPOM = fine particulate organic matter).

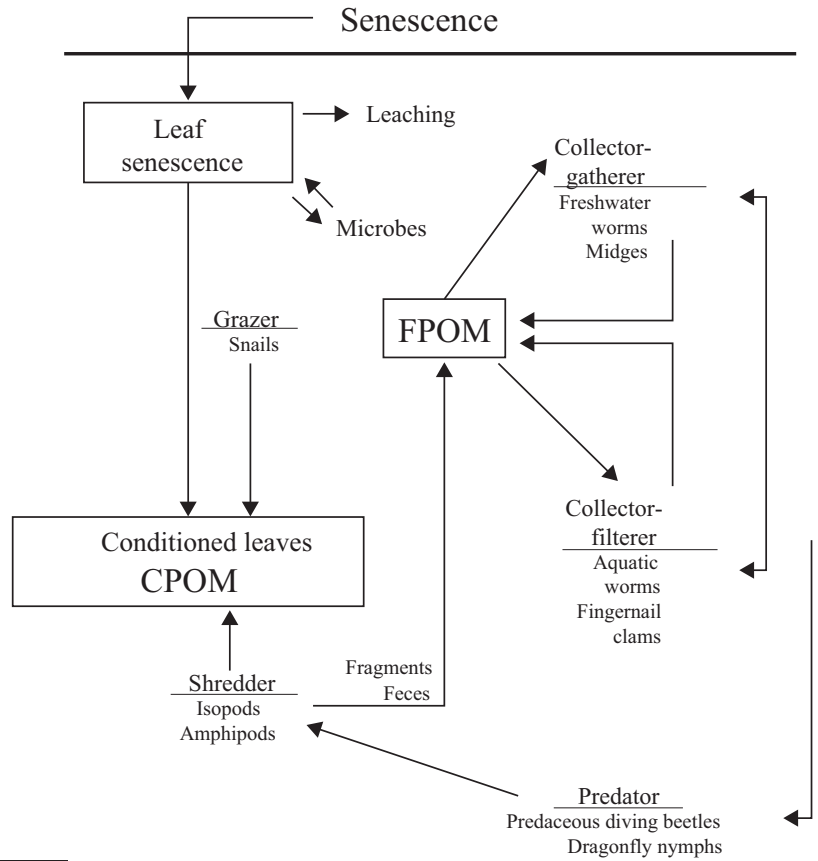

Fig. 28.6. Decomposition rates of litter types. Data from Boyd (1970), Yates and Day (1983), Wylie (1985).

emergents often decompose slower than submergent plants because they contain greater lignin content. Regardless of litter type, decomposition rates generally increase when litter is shallowly flooded and temperatures increase. Deep flooding may result in anaerobic conditions that restrict the faunal community actively associated with the decomposition process (Suthers and Gee 1986). The decomposition process may cause anaerobic conditions, resulting in subsequent

elimination of invertebrate communities. Factors controlling decomposition are changing constantly; therefore, peaks in macroinvertebrate abundance often are dramatic and short lived. This **cycle or "pulsing"** of macroinvertebrate populations, although variable among years and habitat types, is typical of invertebrates that exploit nutrient-rich, **detrital-based systems** that are in a constant state of hydrologic flux.

Vertebrates

Vertebrates have a myriad of life-history strategies that reflect adaptations to the dynamic nature of wetlands. Understanding the temporal and spatial scale of vertebrate use is becoming increasingly important because contemporary **managers are challenged to provide suitable habitat for an increasing array of wildlife within highly modified landscapes**. With this growing responsibility, the need to summarize information related to life-cycle requirements of vertebrates is increasing. Species abundance, chronology and duration of stay, mobility, habitat and nutritional requirements, and sensitivity to disturbance are important aspects to consider when evaluating management options. Unfortunately, detailed scientific information does not exist for many species. Further, there has been little effort to integrate species requirements with general wetland ecology principles (Laubhan and Roelle 2001). Consequently, our ability to provide long-term benefits for multiple vertebrate species is constrained (Fredrickson and Laubhan 1994). However, experimentation and monitoring, personal observations, discussions with local experts, and literature review can often be beneficial.

Our intent in this section is to (1) provide a broad overview of the complexities of life-history strategies of different groups of species, (2) identify important linkages among life-history strategies and wetland habitat dynamics, and (3) emphasize the importance of providing necessary habitat resources at the appropriate time and spatial scale for the target organism. Thus, we do not provide an exhaustive analysis of all species or taxonomic groups. Mammals and fish are not considered in this chapter, but they are important components of wetland ecosystems and should be considered in management decisions.

Waterbirds

Waterbirds are a diverse group that includes **waterfowl** (swans, geese, and ducks), **loons, pelicans, grebes, cranes, rails, shorebirds, and wading birds** among others (Weller 1999). Although not considered waterbirds, many songbirds also are dependent upon wetland resources for breeding, wintering, and migration (Greenberg 1988, Grover and Baldassarre 1995, Yong et al. 1998, Weller 1999, Shutler et al. 2000). Some species, such as willow flycatchers (*Empidonax traillii*), are considered facultative wetland birds and spend as much time foraging in uplands as around wetlands (Weller 1999). Others, such as prothonotary warblers (*Protonotaria citrea*) and swamp sparrows (*Melospiza georgiana*), are obligate wetland species that depend upon wetlands for their entire life cycle (Mowbray 1997, Petit 1999, Hoover 2009). These latter species are not considered further, but information on habitat requirements is available and should be considered in the development and management of wetland habitats.

There are 43 species of waterfowl (Bellrose 1980) and >70 species of other waterbirds that breed, migrate, winter,

or are resident in North America (Laubhan and Roelle 2001). This group of species is probably the most extensively studied of wetland-dependent vertebrates. Numerous books on waterbird ecology and management are available (e.g., Bellrose 1980, Richards 1988, Weller 1999, Kushlan and Hafner 2000, Baldassarre and Bolen 2006, Weller 2009). In addition, the North American Bird Conservation Initiative has compiled regional and national summaries of population status and trends for many waterbird species, as well as identified critical wetland resources for protection. Examples of these initiatives include the United States Shorebird Conservation Plan (Brown et al. 2001) and Waterbird Conservation for the Americas (Kushlan et al. 2002).

Use of wetlands by foraging waterbirds largely is affected by type, quality, distribution, and availability of suitable foods and cover. Considerable research has been conducted on the food habits of waterbirds. This information has been synthesized and published for many taxonomic groups, including breeding waterfowl (Krapu and Reinecke 1992); shorebirds (Skagen and Oman 1996); and herons, rails, and grebes (Laubhan and Roelle 2001). In addition, the **Birds of North America species accounts** provide detailed lists of food items for individual species (Poole et al. 1992–2003). In general, diet varies greatly among species and includes amphibians, reptiles, fish, invertebrates, mammals, and plant foods (e.g., seeds, stems, leaves, tubers).

Waterfowl consume a wide variety of plant and animal foods, including reproductive parts (e.g., tubers, seeds), stems, and leaves of plants, as well as invertebrates and vertebrates, especially fish. However, the proportion of each item consumed **varies among species and annual cycle events** (Krapu and Reinecke 1992). For example, **diets of diving ducks contain a larger proportion of animal foods than diets of dabbling ducks** (Sedinger 1992) and mergansers eat mostly fish (Krapu and Reinecke 1992). The diet of other waterbirds also is diverse. Grebes and herons consume mostly fish, but also forage on invertebrates, reptiles, and amphibians (Laubhan and Roelle 2001). Shorebirds consume primarily invertebrates during all phases of the annual cycle (Helmers 1992), but seeds also contribute to the diet (Skagen and Oman 1996). Rails also consume varied amounts of seeds and invertebrates, but seeds generally constitute a greater proportion of the diet during autumn and winter (Rundle and Sayre 1983, Meanley 1992). Finally, cranes, geese, and some dabbling ducks often consume foods (e.g., agricultural grains) in terrestrial habitats (Tacha et al. 1994).

Food selection also varies within many species (e.g., waterfowl) during different portions of the annual cycle (Fredrickson and Heitmeyer 1988, Plissner et al. 2000). Dietary shifts largely are correlated with different annual cycle events (e.g., migration, breeding) that require different nutrients to complete. **Flight requires large amounts of energy, whereas protein is required for feather molt and egg production**. Therefore, nutritional requirements vary among annual life-

cycle events and many species shift food types to meet these demands (Fig. 28.7). In most cases, dietary changes occur in the relative proportion of proteins and carbohydrates rather than specific food items. Prefledging waterfowl and females of most species increase protein intake by foraging on invertebrates during the prebreeding and breeding periods (Krapu and Reinecke 1992, Sedinger 1992). In contrast, seeds and other plant foods high in carbohydrates are consumed during migration (Drobney and Fredrickson 1979, Fredrickson and Heitmeyer 1988). Although some waterbirds tend to consume certain food types during specific annual cycle events, most species exhibit considerable dietary breadth. For example, >400 genera of invertebrate prey are consumed by 43 species of shorebirds in the western hemisphere (Skaugen and Oman 1996); white-faced ibis (*Plegadis chihi*) consume invertebrates from 13 orders, and Virginia rails (*Rallus limicola*) consume seeds belonging to 14 different families (Laubhan and Roelle 2001).

Dietary differences among species often can be related to differences in **morphology or modes of foraging**. Species with large bodies and long necks (e.g., swans) can acquire foods at deeper depths than species with smaller bodies and shorter necks (e.g., dabbling ducks). In comparison, diving ducks have short bodies, legs that are positioned toward the rear of the body, and large, lobed feet that enable these species to acquire foods at deeper depths than dabbling ducks. Bill morphology also is important. Swans and snow geese (*Chen caerulescens*) have powerful mandibles that can be used to dislodge roots and tubers not accessible to ducks. In contrast, ruddy ducks (*Oxyura jamaicensis*) and northern shovelers (*Anas clypeata*) have mandibles with closely spaced lamellae that enable consumption of plankton and microinvertebrates (Krapu and Reinecke 1992).

Factors influencing availability of foods and foraging efficiency include **water depth, vegetation structure, and**

vegetation distribution (Elphick and Oring 1998, Weller 1999, Bancroft et al. 2002). Many species, including rails, shorebirds, herons, and ibises, forage by standing on a substrate; thus, foraging locations are constrained by water depth (see Fig. 28.4). As a result, leg length (i.e., metatarsus) may affect available foraging habitat for these species. Small waterbirds, such as shorebirds and rails, require shallow flooded habitats; whereas herons are capable of capturing foods in deeper water (see Fig. 28.4). Species capable of swimming also are constrained by water depth. Waterfowl are frequently observed in deep aquatic habitats (e.g., lakes, reservoirs); however, foods must be accessible within the constraints of their body and bill morphology. Water depths must be less than the neck length of swans or dabbling ducks for foods (tubers, benthic invertebrates) to be available for these species. In contrast, grebes are capable of foraging at depths to 6 m because they forage while diving (Storer and Nuechterlein 1992).

Foraging requires expenditure of energy because individuals must search for and capture food items before consuming them. At a minimum, sufficient foods must be obtained to offset these costs. Therefore, factors that hinder the location and capture of food items can influence foraging location. Subtle differences in foraging habitats used exist among species in the same taxonomic group, but some general management rules apply. Optimum foraging habitat for most shorebirds is characterized by 25% cover of short vegetation (notable exceptions include common snipe [*Gallinago gallinago*] and pectoral sandpipers [*Calidris melanotos*] that forage in denser vegetation; Helmers 1992, Holmes and Pitelka 1998). Cranes, herons, and ibises also forage in these habitats, but herons and ibises are capable of foraging in habitats with taller and denser vegetation (Kushlan and Bildstein 1992). Most waterfowl species are capable of exploiting food resources in a wide range of vegetative conditions. In contrast, bitterns prefer to forage in marshes with densely vegetated habitats that provide concealment (Gibbs et al. 1992a, b) and rails prefer dense emergent cover interspersed with openings (Meanley 1992).

Water volume also influences foraging efficiency (items consumed per unit time), particularly when prey is highly mobile. Locating and capturing fish or nektonic invertebrates is more difficult as water volume (depth and surface area) increases. Thus, foraging efficiency of wading birds increases when wetlands are dewatered and food items (fish, macroinvertebrates) become concentrated (Kushlan 2000).

Breeding requirements of waterbirds are complex due to the myriad of activities that occur during this portion of the annual cycle. Suitable nest sites must be located, sufficient foods of adequate quality must be obtained to lay and incubate eggs and, following hatching, suitable foraging habitat must be available for young to survive. Further, many of these activities occur simultaneously. Similar to foraging habitats, **hydroperiod and vegetation** are important components

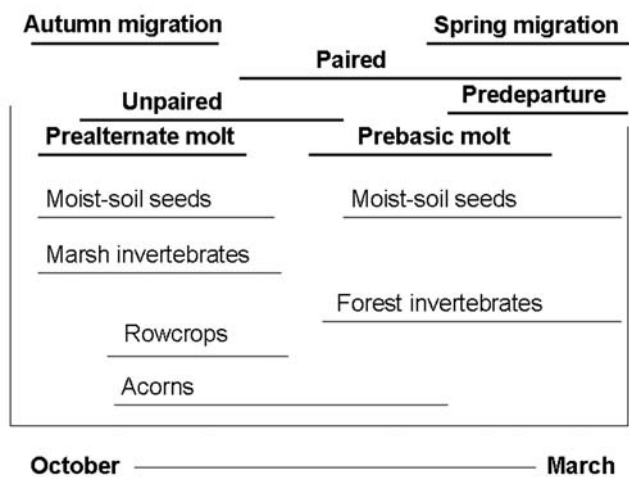

Fig. 28.7. Changes in diets of wintering (Oct–Mar) female mallards undergoing 7 important life-history stages) in the southern United States.

affecting suitability and quality of breeding habitats (Weller and Spatcher 1965, Weller and Fredrickson 1974, Kaminski and Prince 1981, Ball and Nudds 1989). However, numerous factors directly or indirectly influence selection and use of different habitats by individual species. Examples include **weather, predation, food type and availability, and competition**. Relationships among these factors often affect success or failure of individual breeding attempts and, ultimately, population size of a species. However, they often are subtle and may change among years. Waterfowl nesting success often is dramatically different between wet and drought years. Although nest site selection of individuals may not have changed, other factors important in affecting breeding success of the entire population may be different, including amount of wetland habitat available, abundance of predators, or the ability of predators to find nests (Batt et al. 1992).

The primary requisites of breeding habitat for waterbirds include an appropriate interspersed of suitable nesting, brood-rearing, and foraging areas (Laubhan and Roelle 2001). Of the 13 species of shorebirds that breed in the conterminous states, all nest on the ground, typically on elevated areas near water (Helmers 1992). Nest sites are in areas ranging from bare sand and gravel beaches (e.g., piping plover [*Charadrius melodus*]) to vegetation of moderate height and density (Fig. 28.8). If invertebrates are available,

areas suitable for nesting also provide suitable brood habitat (Laubhan and Roelle 2001).

Dabbling ducks also typically **nest on the ground**. However, these species nest in vegetation that provides concealment. Most studies indicate nest densities and nesting success increase with increasing availability of dense grass, forbs, and shrubs (Duebber and Lokemoen 1976, Lokemoen et al. 1984, Sugden and Beyersbergen 1987). For example, **visual obstruction readings (VOR)** of vegetation at nest sites of mallards (*Anas platyrhynchos*) and gadwalls (*A. strepera*) range from about 20 cm to 45 cm, whereas blue-winged teal (*A. discors*) and northern shoveler nests are in vegetation that typically ranges from 10 cm to 20 cm VOR (see Fig. 28.8). A notable exception is the northern pintail (*A. acuta*), which tends to nest in sparser cover than other dabbling ducks (Duncan 1987). After eggs hatch, females typically move young to wetlands with abundant invertebrates and emergent vegetation that provides concealment from predators (Courcelles and Bedard 1979, Pehrsson 1979, Monda and Ratti 1988). Thus, juxtaposition between suitable ground vegetation and water is important and most species tend to nest within 100 m of water (Bellrose 1980).

Grebes, American coots (*Fulica americana*), and most diving ducks generally **nest over water**. Grebes nest in stands of emergent cover or on mats of submerged aquatic vegetation (Terres 1980) surrounded by large expanses of

Fig. 28.8. A range of visual obstruction readings (VOR) at nest sites of breeding birds that use wetland habitats, based on reports in the published literature. Minimum and maximum values may represent mean values, and some measurements were obtained from grasslands adjacent to wetland habitats.

open water (Storer and Nuechterlein 1992). If emergent vegetation is selected, stem densities must be sufficient to support nests. However, there is considerable variability in vegetation characteristics at nest sites within and among species (Glover 1953, Burger 1985). In comparison, nests of diving ducks are restricted to emergent vegetation. Nest site selection and nest success have been shown to correlate positively with amount of vegetative concealment (Hines 1977, Kaminski and Weller 1992). Wetlands used by broods of diving ducks contain a suitable type and abundance of invertebrates (Minot 1980, Talent et al. 1983, Wright and Street 1985). Diving ducks usually move relatively short distances (usually ≤ 1 km) between nest site and brood habitat (Ringelman and Longcore 1982). Further, broods tend to use deeper water than dabbling ducks and are more likely to forage near submerged aquatic vegetation (Monda and Ratti 1988).

Rails and bitterns also nest in flooded areas characterized by tall, dense, emergent cover interspersed with sparsely vegetated sites (see Fig. 28.8). However, least bitterns (*Ixobrychus exilis*; Weller 1961) and clapper rails (*Rallus longirostris*; Eddleman and Conway 1998) also nest in shrubs. Nests are placed in dense vegetation, while young use areas that are more open as foraging sites as compared to those used by adults (Johnson and Dinsmore 1985, Davidson 1992, Eddleman and Conway 1998). Water depth at nests range from saturated soil to 46 cm for rails (Bookhout 1995), whereas American (*Botaurus lentiginosus*) and least bitterns nest in areas flooded from 5 cm to 20 cm and 8 cm to 96 cm, respectively (Gibbs et al. 1992a, b). Most individuals nest in elevated areas with vegetation capable of supporting nests and providing concealment (Laubhan and Roelle 2001).

Other members of the Ardeidae (herons) nest in a variety of habitats, including trees, shrubs, and occasionally emergent vegetation or on the ground. Site selection depends on geographic area and available substrate (Butler 1992, Davis and Kushlan 1994). Nests often occur in single- or mixed-species colonies near or over water; however, specific locations often are influenced by distribution of foraging habitats and predators (Davis and Kushlan 1994). Parents feed young in the nest for a short time following hatching; thus, special habitat requirements for broods are not required.

Most, but not all, members of waterfowl, herons, ibises, cranes, and rails that breed in temperate North America either reside in breeding areas all year or migrate to the southern United States during winter (Ehrlich et al. 1988). In contrast, only a few shorebirds occur in the conterminous United States during winter (Hayman et al. 1986). Many species wintering in the United States exhibit **greater flexibility in selection of winter habitats compared to breeding habitat**. For example, factors important in habitat selection during the breeding season (e.g., location of nest

sites relative to foraging sites and brood habitat) do not constrain use of winter habitats. However, annual cycle events that impact breeding success occur during the winter in some species, including courtship, pair formation, and molt. These activities often require specific habitats and food resources. Other important parameters of winter habitats include suitable roosting areas and habitats that provide protection from extremes in climatic conditions (Laubhan and Roelle 2001). These resources are provided by a variety of habitats, including flooded forests, emergent marshes, scrub shrub, and agricultural fields.

Collectively, waterbirds are highly mobile and many species are migratory. Thus, **habitat selection must be considered from a macro- to microhabitat scale** (Soulé 1991b, Kaminski and Weller 1992) to identify temporal and spatial variability in factors involved (Wiens 1985). Although extensive variability exists among species, **a single wetland usually cannot provide all the habitat needs of a single species, nor can a single wetland provide habitat for all species simultaneously** (Fredrickson and Laubhan 1994). For example, waterfowl in the Prairie Pothole Region require ephemeral, semipermanent, and permanent wetlands in close proximity to nesting areas to successfully complete brood rearing (Afton and Paulus 1992).

Wetland complexes are generally needed to **provide necessary resources within and among seasons** (Plissner et al. 2000, Haig et al. 2002). However, even at the scale of a single wetland complex, numerous factors influence avian use, including size, topographic complexity, and dominant vegetation of individual wetlands (Laubhan and Roelle 2001). Reductions in wetland density or size can influence avian richness and abundance (Shutler et al. 2000), and reduce nest density and success of many species (Brown and Dinsmore 1986, Hunter et al. 1993, Grover and Baldassarre 1995). In addition, changes in land use surrounding wetlands also are important. Floodplain forests typically support a diversity of habitats in close juxtaposition, including vernal pools, seasonally flooded forests and scrub shrub habitats, and permanently flooded oxbows and sloughs. The juxtaposition of forested habitat to wetlands also is important for many amphibian species that breed in wetlands, but spend the remainder of their annual cycle in the forest. Colonial waterbirds often nest in scrub shrub or forested habitats, but may forage in nearby oxbows, sloughs, and flooded swales (Hunter et al. 2002). Trees and shrubs also provide seclusion for mated pairs of waterfowl and thermal cover for waterbirds during periods of inclement weather (Magee 1996). Mast (e.g., acorns, samaras) produced in flooded timber also is a source of carbohydrates, and a distinct macroinvertebrate community often develops after leaf-fall (Batema et al. 2003).

Vertebrates requiring tree cavities also rely extensively on forested habitat. Cavities in large trees that occur in or adjacent to wetlands are particularly important as nest sites for

wood ducks (*Aix sponsa*) and hooded mergansers (*Lophodytes cucullatus*), and also serve as den sites for raccoons (*Procyon lotor*), squirrels, and other mammals (Soullière 1990). Cavities in smaller trees are important for a host of smaller birds and mammals such as prothonotary warblers and golden mice (*Ochrotomys nuttalli*).

Issues of scale are complex, but the **types and interspersed of wetland habitats** are extremely **relevant to development and management activities**. Considering existing wetland features within a landscape context is valuable for identifying missing or degraded wetland types and can assist in prioritizing land acquisitions. This information can be used to identify and develop strategies to correct altered wetland processes caused by past land uses.

Amphibians

Amphibians represent a diverse group of species that have received increased attention during the past decade due to reported **population declines** (Barinaga 1990). Current evidence suggests many species may be experiencing population declines, range constriction, or extinctions at scales ranging from local to possibly global (Wake 1998, Alford and Richards 1999, Gibbons et al. 2000). Potential factors related to suspected declines include **disease, invasive species, chemical contamination, and commercial trade**; however, most biologists agree that **habitat destruction** at local scales is a major factor.

Conservation of amphibians is important not only to preserve biodiversity, but also because they are an integral component affecting wetland functions and processes. Amphibians occupy a variety of positions in the food web and can differentially affect energy flow in wetland systems. During the larval stage, amphibians may regulate primary production through suspension feeding (Dickman 1968, Seale 1980). As adults, they are both predators and a high-quality food source for predators and may heavily influence invertebrate populations, thereby indirectly affecting litter decomposition (Burton and Likens 1975).

Amphibians have **complex life cycles** (Wilbur 1980). Many species are biphasic, spending most of their adult life in terrestrial habitats and using aquatic environments only for mating, oviposition, and larval development. In addition, population sizes naturally undergo wide fluctuations (Semlitsch et al. 1996, Pechmann et al. 2001). Thus, persistence of a species is dependent on the production of large numbers of metamorphs during favorable years, rather than consistently producing some metamorphs every year (Pechmann et al. 1989, Berven 1990).

Breeding adults of some species (e.g., spadefoot toads [*Scaphiopus holbrooki*], wood frogs [*Lithobates sylvatica*]) spend only 1–2 days in aquatic environments, whereas others (e.g., green frogs [*L. clamitans*], gray treefrogs [*Hyla versicolor*]) spend several weeks or months (Semlitsch 2000a). Similarly, the time aquatic larvae spend in wetland habitats

also varies, ranging from 21 days for spadefoot toads to 1–2 years for bullfrogs (*L. catesbeiana*; Semlitsch 2000a). **Abiotic** (e.g., temperature, hydroperiod) and **biotic** (e.g., vegetation, predation) **factors**, as well as **interactions** between these factors, **influence** the rate and success of **larval growth and development** (Wilbur and Collins 1973, Carey et al. 1999, Semlitsch 2000a). Further, these interactions constantly change due to the dynamic nature of wetlands.

Hydroperiod is often considered among the **most critical factors** associated with habitat conditions for amphibians because it directly or indirectly affects other factors known to **influence amphibian populations**. Hydroperiod affects floristic composition and structure, the likelihood of larvae achieving metamorphosis, and influences the distribution and abundance of predators that feed on amphibian eggs and larvae (Schneider and Frost 1996, Wellborn et al. 1996). If wetlands dry prior to metamorphosis, larvae die. Likewise, increased water permanence can also negatively affect larval amphibians by enhancing survival of predators such as fish and salamanders (Morin 1981, Werner and McPeck 1994, Skelly 1995, Wellborn et al. 1996). Consequently, most amphibians occupy wetlands during only a portion of the entire hydrologic cycle (e.g., temporary to permanent; Skelly 1997). Some studies indicate that wetlands with hydroperiods <30 days or >1 year are used by fewer species than wetlands with intermediate hydroperiods (Heyer et al. 1975, Wilbur 1980). Consequently, amphibians are sensitive to altered hydroperiod (Semlitsch 2000a, Paton and Crouch 2002). Filling or draining wetlands, developments to increase water permanency, and urbanization, all can have significant effects on local populations (Orser and Shure 1972, Semlitsch 2000a).

Amphibians are sensitive to changes in temperature and moisture because their skin has a thin epidermal layer. Changes in climatic events (e.g., rain, drought) have been associated with changes in behavior (e.g., Burke et al. 1994, Semlitsch 2000a). Water chemistry also is important in regions with acid or oligotrophic waters, which are avoided by many anurans (Strijbosch 1979). Although some amphibians are able to successfully breed at low pH levels, **acid tolerance** varies among species (Dale et al. 1985). Negative correlations also have been reported between amphibian species richness and chloride, conductivity, magnesium, total hardness, and turbidity (Hecnar and McCloskey 1996a).

Vegetation characteristics can affect local environmental conditions (e.g., temperature [Tester et al. 1965]), as well as the availability of resources required by amphibians. Wood frogs commonly use wooded wetlands, while northern leopard frogs (*L. pipiens*) use deeper wetlands with more open surroundings (DeBenedictis 1974). In Minnesota, wood frogs did not use a recently flooded site because it did not provide appropriate vegetation for egg mass attachment (Fishbeck 1968). Strijbosch (1979) reported differences in breeding site selection among anurans based on underwater

structure of plants. Finally, the proportion of wetland supporting vegetation cover affected the occurrence of anurans in seasonal and semipermanent wetlands (Fischer 1998).

Vegetation structure of terrestrial habitats also is important. Leopard frogs frequently inhabited short grass (15–30 cm) adjacent to wetlands, but avoided heavily wooded and sandy areas that were either bare or had short, sparse vegetation (Merrell 1977). Anurans that are more terrestrial overwinter beneath leaf litter in moist terrestrial habitats (Schmid 1982).

There have been mixed reports on the effects of habitat size and shape on amphibians. A study evaluating the relationships among isolated wetland size, hydroperiod, and amphibian species richness found no relationship between species richness and wetland size, but hydroperiod was extremely important (Snodgrass et al. 2000). In another study, streamside zones 30–95 m in width contained a higher abundance of species than widths 25 m (Rudolph and Dickson 1990).

An extremely important consideration in conservation and management of amphibians is **metapopulation structure** (Marsh and Trenham 2001). A **metapopulation** is a set of local populations among which gene flow, extinction, and colonization may occur. Two primary factors influence metapopulation dynamics: (1) the number of individuals dispersing among ponds, and (2) the dispersal distances and probability of successfully reaching ponds (Gibbs 1993, Semlitsch 2000a). Most pond-breeding amphibians reside in terrestrial habitats that are usually within 200 m of wetlands during the nonbreeding season (Madison 1997). Most individual amphibians cannot migrate for >200–300 m due to physiological constraints, such as desiccation (Schmid 1965, Grover 2000, Semlitsch 2000a). Thus, suitable terrestrial and aquatic habitat, including connecting corridors between wetlands, must be provided over relatively small spatial scales to ensure population persistence (Semlitsch 1998). Distance between wetlands is important because it directly affects the probability of recolonization and, therefore, the chance of preventing isolated local populations from extinction (Skelly et al. 1999, Semlitsch 2000a). As wetlands are actively drained or dry naturally in drought years, the required travel distance between suitable habitats may increase so that dispersal to other wetlands becomes impossible. Thus, the understanding of **amphibian life-cycle characteristics** and needs has **important** implications for **management** that differ from those of more mobile avifauna.

Reptiles

Snakes, turtles, crocodilians, and other reptiles are important components of wetland systems, but they have received relatively little attention. **Reptiles** may be **experiencing** even greater **global declines** than amphibians (Gibbons et al. 2000). The U.S. Fish and Wildlife Service listed 70 species of reptiles as endangered and another 18 species as threat-

ened (Gibbons et al. 2000). In contrast, only 17 species of amphibians were listed as endangered and 9 species were listed as threatened. Ernst et al. (1994) suggested that **if current trends continue, all turtle species** in North America would be **threatened with extinction** in the 21st century.

Factors involved with declines in reptiles are similar to those for amphibians. Habitat loss and degradation, including loss and degradation of wetlands and adjacent uplands, are considered to be major factors affecting declines of reptiles (Gibbons et al. 2000). Invasive species, global climate change, disease, pollution, and unsustainable use are other factors that have reduced reptile populations (Gibbons et al. 2000). Although most threats can be placed into these categories, a different suite of problems may affect each species depending upon its life-history needs. Thus, **conservation and management efforts** must be **developed for individual species** (Ernst et al. 1994).

Wetland-dependent reptiles have diverse life-history strategies and habitat needs. Some species complete their entire life cycle in wetlands, sometimes in a single wetland, whereas other species require a diversity of wetland and/or upland environments to complete their annual cycle (Siegel 1986, Ernst et al. 1994, Rowe 2003). Bodie and Semlitsch (2000) found that habitat use of false map turtles (*Gratemys pseudogeographica*) and slider turtles (*Trachemys scripta*) differed among seasons, gender, and age, but a diversity of habitats, including uplands, were heavily used. In Missouri, the endangered eastern massasauga (*Sistrurus catenatus catenatus*) uses crayfish burrows in prairie areas for hibernation, but is more common in old fields and upland forests later in the growing season (Siegel 1986).

The **protection of hibernacula** for both snakes and turtles is **important for survival** of these species. Many species of turtles overwinter in mud of wetlands and snakes often use crayfish burrows or other burrows and stump holes near wetlands to overwinter (Carpenter 1953, Ernst et al. 1994, Kingsbury and Coppola 2000). In northern climates, water near the ground surface in burrows is critical for overwintering snakes because it provides protection from freezing (Maple and Orr 1968). Some snakes overwinter singly (Kingsbury and Coppola 2000), whereas others overwinter in dense aggregations that can include multiple species of snakes as well as other vertebrate taxa (Carpenter 1953). Hibernacula are not necessarily protected by wetland regulations or by wetland management activities. Burke and Gibbons (1995) found that wetland regulations would not protect any of 93 nest sites of mud turtles (*Kinosternon subrubrum*), Florida cooters (*Pseudemys concinna floridana*), and slider turtles. Wetland regulations also would not protect any of the hibernation burrows of 24 mud turtles. Kingsbury and Coppola (2000) noted that clearing of uplands to the edge of wetland hibernacula would have devastating effects on copperbelly water snakes (*Nerodia erythrogaster neglecta*).

Reptiles are particularly susceptible to road kill (Ernst et al. 1994), and new road construction near wetlands or between wetlands and upland habitats should be avoided. Closing roads on refuges during periods of pronounced movements can also reduce impacts to these species (Siegel 1986). As with amphibians, waterbirds, and other wetland-dependent wildlife, **effective conservation and management requires** an understanding of the **life-history needs** of the organism to provide the necessary **habitat resources at the appropriate time and at an acceptable spatial scale**.

WETLAND PLANNING

Proper planning is critical to maximizing long-term natural resource production regardless of whether activities involve acquisition, protection, creation, restoration, enhancement, or annual management. Unfortunately, planning often is approached as an obstacle that must be overcome to either secure funds or obtain permission to implement actions, rather than as **an integral and necessary component of achieving success**. Consequently, planning often is ignored, completed in haste, or used to validate selected decisions based on subjective information or the desires of a few individuals. In cases where an objective approach to planning is used, common mistakes include making decisions prior to acquiring and synthesizing information from all relevant disciplines and failure to consider the overarching reasons for wetland activities at multiple landscape scales.

Recognizing the different values (positive and negative) associated with wetland resources is important because decisions that historically were made within fish and wildlife agencies years ago are now made with input from citizens that view natural resources from many different, and often competing, interests. In many cases, decisions are often biased in favor of uses that have marketed outputs that results in conversion and exploitation of environmental resources (Barbier et al. 1997). Favoring uses with market output often are advocated because there is a belief that technological advances will allow replacing the wetland functions that will be lost by modifying or destroying the wetland. However, the functions and values lost often are not completely replaced through mitigation procedures, especially with regard to the abiotic and biotic processes necessary to support healthy and sustainable fish and wildlife populations. Therefore, in addition to making traditional land-management decisions, wetland professionals also must create opportunities to educate public officials and lay individuals in order to conserve or restore wetlands for a wide variety of reasons, including value as wildlife habitat. This will require the development of new and interdisciplinary approaches to problem solving, including the use of information from other disciplines (e.g., political, economic, and social) during the decision-making process.

The **lack, or inappropriate use, of planning** is a fundamental **cause of highly variable results** of many wetland projects **because factors** (e.g., soils, hydrologic condition, and social perspectives) that may affect management potential and success **are not considered when making decisions**. Consequently, projects may fail even after considerable resources in time and money have been invested, or require further development and management costs after completion because original designs were based on incorrect assumptions. This has prompted many agencies to establish policies that require resource management planning based on science. The **1997 National Wildlife Refuge System Improvement Act** mandates that management decisions be consistent with the principles of sound fish and wildlife management and available science. In addition, several governmental (U.S. Fish and Wildlife Service, U.S. Geological Survey, Western Governors Association, Association of Fish and Wildlife Agencies) and nongovernmental entities (American Wind and Wildlife Institute, American Wind Energy Association, The Nature Conservancy, Ducks Unlimited) are currently advocating development of new initiatives to stimulate science-based conservation planning at regional scales. A primary reason for many of these initiatives is the recognition that current threats to fish and wildlife habitat are increasing and often are regional, national, or global in scope (e.g., alternative energy development, climate change). In this section we provide an overview of important considerations that lead to better decisions that are ecologically based and sensitive to wetland processes.

Planning Approaches

There are numerous **approaches to planning**. A common feature of most approaches is a **hierarchical framework** that provides an increasing level of detail regarding specific attributes that will be used to **measure success** (Table 28.7). Each tier within the framework is usually denoted by a keyword, such as **mission, purpose, goals, objectives, and strategies**. Agency missions are typically broad statements (e.g., ecosystem integrity), goals are open ended and provide general management guidance (e.g., wetlands to support waterbirds), and objectives are detailed statements that include specific, quantifiable information (e.g., seasonally flooded wetlands with food resources necessary to support foraging shorebirds). The goal is achieved if all objectives pertaining to the goal are achieved. The term strategy is most often used to denote specific actions that will be implemented to achieve objectives. A primary value of this approach in wetland management is that the intent of a project becomes more refined in each successive tier and, ultimately, development and management approaches selected are less likely to conflict with the ecological potential of the site. Also, both abiotic and biotic factors influencing wetlands can be incorporated at the level of objectives. Interrelationships among

Table 28.7. A tiered framework illustrating an increasing level of detail during the planning process, based on U.S. Fish and Wildlife Service guidelines

Framework	General description	Example
Purpose	Specified or derived from law, proclamation, executive order, or other legal document establishing, authorizing, or expanding a refuge.	Migratory Bird Conservation Act, for use as an inviolate sanctuary, or for other management purposes, for migratory birds.
Vision	Statement of what the planning unit should be based primarily on the mission, purpose, or other mandates.	Area is managed to benefit the diversity of plants and wildlife native to the Rocky Mountains.
Goal	Descriptive, open-ended, and often broad statement of desired future conditions that conveys a purpose, but does not define measurable units.	Provide and manage natural and man-made wetlands to provide habitat for migratory waterfowl, shorebirds, wading birds, and associated wetland-dependent wildlife.
Objective	Concise statement that is specific, measurable, achievable, results-oriented, and time-fixed.	Manage 40–70% of available wetland area for dense (>70% distribution) seed-producing plants flooded 30 cm to maximize seed availability for foraging of autumn (Sep–Oct) migrating dabbling ducks (teal, pintail, mallard).
Strategy	A specific action or technique, or combination of actions or techniques, used to meet an objective.	Water-level manipulations (e.g., drawdown), fire, herbivory, mechanical actions (e.g., disk).

From U.S. Fish and Wildlife Service (2003).

and within these factors are important because they form the foundation of effective management.

Use of a hierarchical approach also is important in wetland management because **no wetland can maximize all potential functions**. A given wetland often provides different functions and has different values depending on scale. Thus, the spatial distribution and types of wetlands necessary to support one taxonomic group or wetland function may not be sufficient to support another taxonomic group or wetland function. Migratory avifauna link individual wetlands within a defined flyway, wetlands within a floodplain are linked with respect to floodwater storage or sediment retention, and pond-breeding amphibians may link isolated wetlands within a watershed. Thus, **conservation** efforts designed for **waterfowl** may be **insufficient to ensure floodwater storage** functions of wetlands or to **conserve amphibians** and isolated wetlands. Therefore, **goals and objectives** must be **articulated in** a manner that avoids confusion regarding the **spatial, temporal, and taxonomic scales being considered**. **Identifying the scale is critical** because specific habitat-based objectives must reflect the habitats required and the life-history needs of the species associated with those habitats.

Need and Purpose

A primary reason for **planning** is to establish **specific criteria** that will be used to (1) **define success**, (2) **identify activities** (e.g., acquisition, restoration, creation) and **management procedures** (e.g., levees, roads, water-control structures) that are best suited for achieving success, and (3) develop **monitoring protocols** to evaluate progress. The necessity of defining success in explicit terms may seem obvious, but planning often focuses only on broad goals that focus on de-

fining desirable outcomes (i.e., values) that do not directly incorporate knowledge of wetland functions and the need for long-term productivity. Often, this occurs because wetland projects are linked to agency or programmatic missions that encompass large geographic areas. These types of goals are valuable for prioritizing resources and determining appropriate types and distributions of wetlands necessary to sustain or enhance certain wetland values (e.g., bird populations, floodwater storage along a river) at large spatial scales. However, **success at landscape and continental scales is driven by success at local scales**. Therefore, more specific goals and objectives also must be developed at local scales because the **biotic and abiotic conditions** of individual wetlands **and their temporal availability are critical for** achieving overall conservation **success**. For example, strategic acquisition of wetland areas throughout a flyway may be a critical component of migratory bird conservation. However, if individual wetlands targeted for purchase within the flyway are severely altered with respect to fundamental processes (e.g., hydrology, nutrient cycling), large-scale conservation efforts will fail or be severely hampered. Thus, at local and landscape scales, a more appropriate **definition of success may be total functional area rather than simply the amount of area acquired, managed, or restored**.

After success has been defined, activities (e.g., acquisition, restoration, creation) and management strategies that involve development (e.g., levees, water-control structures, roads) or applications (water management, fire, herbivory) must be identified that are best suited for achieving success. This requires gathering a diversity of information from various scientific disciplines and conducting detailed field evaluations. Often, the information necessary to make decisions varies depending on the intended outcome of the proposed

project; thus, information searches should be conducted for individual projects.

Another important consideration is to **document both historic and current abiotic and biotic conditions** as thoroughly as possible (Table 28.8). **Comparing historic and current conditions** can be **helpful in identifying** important **physical changes** to the landscape **and how wetland processes have been modified**. This information can be used to determine management options most likely to contribute to project success. However, care should be exercised in how this information is used because there is a **threshold beyond which technology and engineering will not be effective in restoring wetland functions and processes**. For example, in some cases success is defined as emulating “historic” conditions. The definition of historic should be clearly defined, because many ecological communities have been extensively disrupted in the 48 contiguous states. Depending on the degree of disruption, it may not be possible to emulate conditions that occurred 100 years ago, or even 15 years ago. In these cases, decisions may be based on restoring specific attributes that may or may not be representative of historic conditions, but will contribute to success of the project. Therefore, regardless of the definition of success, realistic decisions must be made regarding the ability to use “management” to achieve desired results. Sources of historical data include long-term climate and hydrologic data, explorer notes, general land office records, public land survey notes, historic aerial photographs, digital soil maps, digital elevation models of the project site, and analyses conducted by paleobotanists and anthropologists on plants and activities prior to human settlement, respectively.

Finally, social, cultural, economic, and political factors should be considered when evaluating acquisition, restoration, management and other activities (see Table 28.8). For

example, it often is important to provide information on how a wetland project potentially will impact the types and amount of recreational and economic (e.g., jobs, land use) opportunities in the surrounding area. Given the increasing and diverse demands placed on remaining wetlands by society, this information is becoming necessary to gain public support for proposed project design and implementation. Thus, **managers must maintain credibility with the general public** by integrating their concerns and priorities into management decisions. Managers must also **guard against false or exaggerated benefits** of particular projects; **otherwise**, long-term support for wetland **conservation and management activities may be jeopardized**.

The use of scientific information to evaluate the ability to meet project criteria and select appropriate activities and strategies will undoubtedly improve success of wetland projects. However, much remains to be known regarding wetland processes and how wildlife responds to changing conditions caused by natural and anthropogenic agents, both within and outside public land boundaries. Consequently, it is impossible to guarantee that decisions made during planning will result in project success. Thus, **monitoring schemes must be developed and implemented** to periodically check progress and adjust management approaches to unexpected problems or changing conditions (i.e., **adaptive resource management**). In addition, proper monitoring permits an objective review of past actions and greatly improves the ability to make better decisions on future projects.

Monitoring often requires considerable time and funds. In the past, these resources often were considered to be better spent implementing additional projects. This attitude has changed as more interest has been focused on the long-term sustainable productivity of wetlands. However, resources remain limited; therefore, technical guidance should be sought

Table 28.8. Factors important to consider in wetland planning

Category	Factor	Examples
Biological	Historic	
	Geomorphology	Formative process, parent material, soils
	Climate	Precipitation, temp, growing season length, evapotranspiration
	Hydrology	Frequency, time, duration, amount, source (groundwater, surface water), annual and long-term variations
	Plants	Composition and distribution
	Animals	Composition and distribution
Current	Hydrology	Variation from historic conditions (type and extent of modification and related effects on wetland processes)
	Plants	Changes in composition and distribution from historic (e.g., endangered species, nonnatives), life-history requirements (e.g., soil moisture and salinity tolerances for germination)
	Animals	Changes in composition and distribution from historic (e.g., endangered species, nonnatives), life-history requirements (e.g., vegetation composition and structure needed for breeding and migration)
Social	Public use groups	Effects of management on hunters, fishermen, hikers, photographers, birdwatchers
	Local community	Potential changes in farming and ranching practices, time and amount of water use
Economic	Local and regional	Potential effects of management relative to number of jobs, access to land, fees and restrictions associated with use of land for economic gain (e.g., ranching, agriculture)
Legal		Hydrology (e.g., water rights or drainage issues), legal mandates related to land unit (e.g., land purchased under Endangered Species Act, Migratory Bird Conservation Act)

in the design, selection of methods, and implementation of monitoring programs. This will ensure that time and money is used efficiently without sacrificing the types and value of information necessary to implement adaptive resource management (Holling 1978, Walters 1986).

WETLAND MANAGEMENT

Individual wetlands should be evaluated using a hierarchical planning approach to ensure that values at different spatial scales are identified prior to making decisions and initiating management. However, **pristine wetlands** that have retained their inherent hydrologic characteristics and functions **should be protected and passively managed** (Errington 1963, Weller 1988, Fredrickson and Reid 1990). Unfortunately, only a small percentage of wetlands in the conterminous United States and Hawaii have remained unaltered by human activity. In contrast, the hydrologic condition of many wetlands in Alaska and northern Canada remains largely unchanged from historic conditions. Developing a better understanding and protecting the natural hydrologic regimes and land use in northern areas should be a primary management goal.

Wetlands that have been modified or impacted often must be actively managed to ensure long-term sustainable productivity, including consistent provision of resources to wetland wildlife (Fredrickson and Reid 1990). Success often depends on implementing activities that can be broadly categorized as restoration, enhancement, or creation. The goals and objectives of these activities often differ. **Wetland restoration** is defined as returning a disturbed ecosystem to a close approximation of its prior condition (National Research Council 1992). If the site originally was a wetland and the objective is to specifically enhance a selected wetland function(s) that produced a value that originally existed, the most appropriate term describing wetland activities is enhancement (Natural Resources Conservation Service 1999c). According to this definition, some functions may remain unchanged while others may be degraded. In contrast, implementing a wetland project on a site that historically was not a wetland, or on a site that currently is a wetland that will be converted to a different hydrologic regime, vegetation type, or function than originally occurred on the site, is termed **wetland creation** (Natural Resources Conservation Service 1999b).

Many of the **same techniques are used regardless** of whether the project meets the definition of **restoration, enhancement, or creation. Designs that allow wetlands to become self-regulating** and do not require management are often **considered ideal** (Mitsch and Wilson 1996). However, **some type of management** will normally be necessary to **achieve wildlife habitat objectives**. Therefore, design and management considerations are presented collectively in the following section. However, **design, location, specifications, and purpose for constructing physi-**

cal features, as well as management strategies, often differ due to differences in criteria used to define success. We present 3 case studies to illustrate how information in this chapter can be used to make decisions and increase the probability that management will be successful.

Design and Management Considerations

The ability to **sustain wetland productivity** requires an appropriate design based on **emulating wetland processes** necessary to promote desirable habitat conditions **needed by wetland wildlife to survive and reproduce**. A primary challenge often is **to emulate important hydrological parameters** (Weller et al. 1991). A successfully managed wetland contains foods and cover of a type, quality, and distribution that are the same or functionally similar to those found in natural, unmanaged wetlands. Management should provide resources that meet the physiological and behavioral needs of wildlife while **simultaneously** ensuring long-term productivity.

Restoring important hydrological parameters often requires construction and/or **installation of physical structures** (e.g., levees, water control structures, water supply and discharge systems, and pumping systems) that facilitate **control of water inflow**, distribution, and discharge. Water management is necessary **to create soil and water conditions suitable for germination and growth** of desirable plant communities, **control problem vegetation, stimulate invertebrate production, and make resources available for target species** (Fredrickson 1991). Water control is particularly **critical** for providing habitat conditions required by **foraging waterbirds** (see Fig. 28.4). For example, of 81 species of waterbirds using wetlands in the southwestern United States, only 19 successfully forage in water >25 cm in depth, but 10 of these readily use water ≤25 cm. Twice as many species (38) forage in water ≤10 cm deep (Fredrickson and Reid 1986).

Capital investments to achieve hydrologic control **can be large**. However, **costs** can be **reduced** appreciably and wildlife benefits maximized **if developments are designed to complement existing topographic and geomorphic features**. Highways, dirt roads, ditches, and even fencerows often disrupt **sheetflow** of water across the landscape into wetlands. Removing a fence, adding culverts in strategic areas, plugging a ditch, or lowering gravel roadbeds can be inexpensive and simple measures to restore surface water movement. For groundwater-fed wetlands, locating and breaking **drainage tiles** can be a relatively inexpensive and effective technique for restoring hydrologic conditions. In some cases, however, the costs can be large. For example, the U.S. Army Corps of Engineers is currently working to restore the Kissimmee River in Florida, which they channelized several decades ago (Toth et al. 1993, 1995, 1998). Following channelization, two-thirds of the floodplain wetlands were eliminated and waterfowl use of these wetlands de-

creased by 92% (Perrin et al. 1982). Large-scale restoration projects require involvement by numerous stakeholders, policy-makers, and political groups and can be long-term, slow-moving efforts (National Research Council 1999). The ability to conduct some activities can be limited by outside considerations, including social and economic constraints. In the Lower Mississippi Alluvial Valley, removal of flood control levees, reconstructing meanders in channelized streams and rivers, eliminating drainage ditches, and reforesting the floodplain would be necessary to achieve hydrologic restoration. These activities are not likely (King and Keeland 1999). First, this system has been degraded to the extent that current technology and engineering tools available are not capable of restoring historic hydrologic regimes. Second, existing levees are necessary to prevent flooding of urban areas and productive farmland. Thus, levee removal is neither economically nor socially acceptable.

Wetland Configuration

Prior to implementing development or management activities, a prospective area should be assessed to determine potential wildlife use. Food and cover requirements of target species, including migration corridors and connecting habitats, should be considered in relation to existing site conditions within the local area to identify habitats in short supply. In the Prairie Pothole region, extensive loss and fragmentation of grassland habitats adjacent to wetlands has resulted in an increased concentration of predators and low rates of waterfowl nest success because of high rates of nest predation (Greenwood et al. 1987, Sargeant and Raveling 1992). In fact, Beauchamp et al. (1996) noted that waterfowl nest success had declined from about 33% in 1935 to 10% in 1992. Nest success of 15–20% is needed to sustain many dabbling duck populations (Cowardin et al. 1985, Klett et al. 1988). Trapping of predators is an option, but trapping is costly, difficult to implement over a large scale, and may be ineffective in many landscapes (Sargeant et al. 1995). Thus, to achieve a goal of improved waterfowl nesting success, restoration projects must address both grassland and wetland habitats. **One alternative strategy** that has been implemented is to **integrate grassland and wetland restoration over large scales**, thus improving landscape structure and reducing the effects of predators on nest success (Reynolds et al. 2001). Estimated nest success was 46% higher and recruitment rates were 30% higher for 5 species of dabbling ducks following large-scale grassland restoration (1.9 million ha) associated with the **Conservation Reserve Program** in the Prairie Pothole region (Reynolds et al. 2001).

Similar consideration must be incorporated when considering habitat suitability for amphibians. Wetland amphibians are not as vagile as waterbirds, but some species move between wetlands in close proximity. Semlitsch (1998) estimated that 6 species of salamanders were capable of mov-

ing an average of only 164 m, with some individuals traveling 450–625 m. Because amphibians are sensitive to desiccation, many plant communities and land-use types (e.g., agriculture, clearcuts) may be unsuitable for movements by some amphibian species. Thus, the extent and type of **use** a wetland receives **by wildlife is influenced** not only **by habitat conditions** in that wetland, but also **by the condition of adjacent wetland and terrestrial habitats**. Generally, provision and management of a complex of different wetland types in a localized area often increases overall diversity and density of wildlife species (Fredrickson and Reid 1988b). Wetlands ranging in size from **<1 ha to 1,000 ha** can be **important for wildlife if they are managed as a complex**.

If possible within the constraints of existing abiotic and biotic factors, management should be directed toward **providing the most limiting habitats** that historically were present in a physiographic region. Engineering and biological technology exists for **creating or rehabilitating** most wetland types, but successful long-term operation and wildlife use of a wetland will occur only if the **wetland type is correctly matched with local site conditions**. Further, types of wildlife use desired must match the geographic location of the area. For example, habitat for breeding birds often is the focus of management, but the site may be best suited for migrating or wintering birds.

Levees

Levees are an integral component of many degraded, altered, or created wetlands because they permit **control of water levels** and affect the maximum managed water depth. They also may enable water transfer to and from designated wetlands. Although levee dimensions vary depending on wetland type and proposed function (Fig. 28.9), levees should be constructed along natural contours to prevent further disrupting surface water flows (Fig. 28.10). Contour levees also assure the wetland can be completely dewatered if necessary to favor growth of desirable vegetation communities (e.g., annuals adapted to germinate on moist soil), control problem vegetation (e.g., drying, flooding, disking, mowing), reduce the incidence of disease outbreaks, and conform to legal statutes (e.g., mosquito abatement policies).

In contrast, **levees placed perpendicular to natural slopes tend to impede water discharge** and may result in surface water that cannot be removed unless lateral ditches are constructed into the interior of the wetland. Although lateral ditches enable complete dewatering of a basin, they increase development costs, require periodic maintenance, and often reduce the area that can be effectively managed. **Decisions concerning the contour interval** on which to establish levees **should be balanced among construction costs, detrimental effects to existing habitats, and maximizing the area flooded to desired depths**. Construction of levees on 30-cm contours to create a green-tree reservoir may result

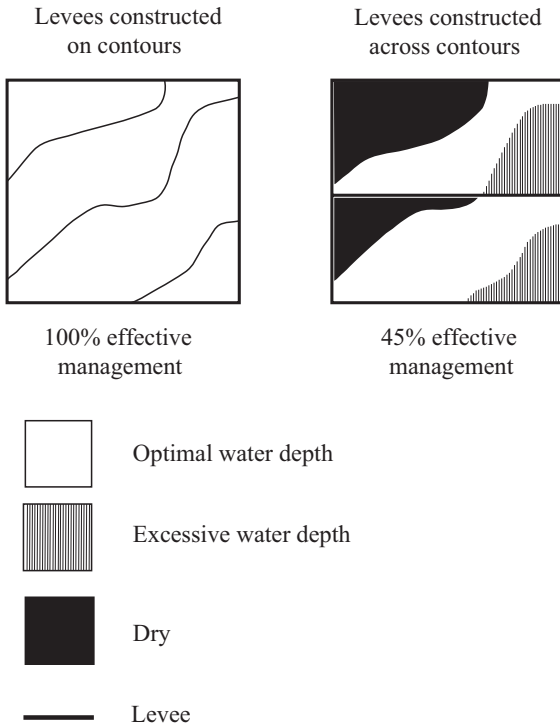

Fig. 28.9. A schematic depicting the importance of levee placement on contours.

in optimum water control, but also may require removal of numerous mast-bearing trees and increase habitat fragmentation. The contour interval selected should maximize the area flooded to desired depths while minimizing removal of valuable bottomland hardwoods (King and Fredrickson 1998).

Levees can be constructed using a variety of methods. The choice often depends on the objective as well as soil type, availability of equipment, and imagination of the technical staff. Commonly used equipment includes laser-controlled dirt scoops, bulldozers, motor graders, rice dike plows, and fire plows. Regardless of construction method, dimensions should be based on engineering criteria. Physical and chemical properties (e.g., organic matter content, texture) of soils influence compactibility and shear strength, and ultimately will dictate the required dimensions necessary to assure long-term levee stability. However, within acceptable engineering standards, levees also should permit accomplishment of normal management operations.

Levees should be **capable of supporting machinery** (e.g., tractor, mower, and disk) necessary to maintain them and manage vegetation. Further, levee **side slopes** should be **gradual to deter potential damage by erosion and burrowing mammals** (see Fig. 28.10). Constructing levees with 4-m crowns and minimum side slopes of 3:1 normally can satisfy these objectives. Most agencies have recognized the value of constructing levees with slopes of $\geq 4:1$ for ease of mowing,

detering burrowing animals, and to reduce erosion associated with wave action. In extreme cases, slopes as great as 10:1 have been used for specific purposes. Levees with more gradual side slopes require an increased volume of material and also impact more wetland habitat, but they may be needed to satisfy ecological or engineering requirements.

Levee height depends on the size of the impoundment and expected depth of flooding. Levees in large wetlands (e.g., >32 ha) or wetlands constructed to simulate permanently flooded habitats are susceptible to wave action and erosion. Consequently, large or deeply flooded wetlands require more substantial levees than seasonally flooded wetlands (see Fig. 28.10). Levee height should be a **minimum of 1 m above the predicted annual maximum flooding depth**. If this is not possible, levee height should be uniform or spillways should be incorporated into the design to permit exchange and equalization of floodwater on both sides of the levee to minimize damage during high water.

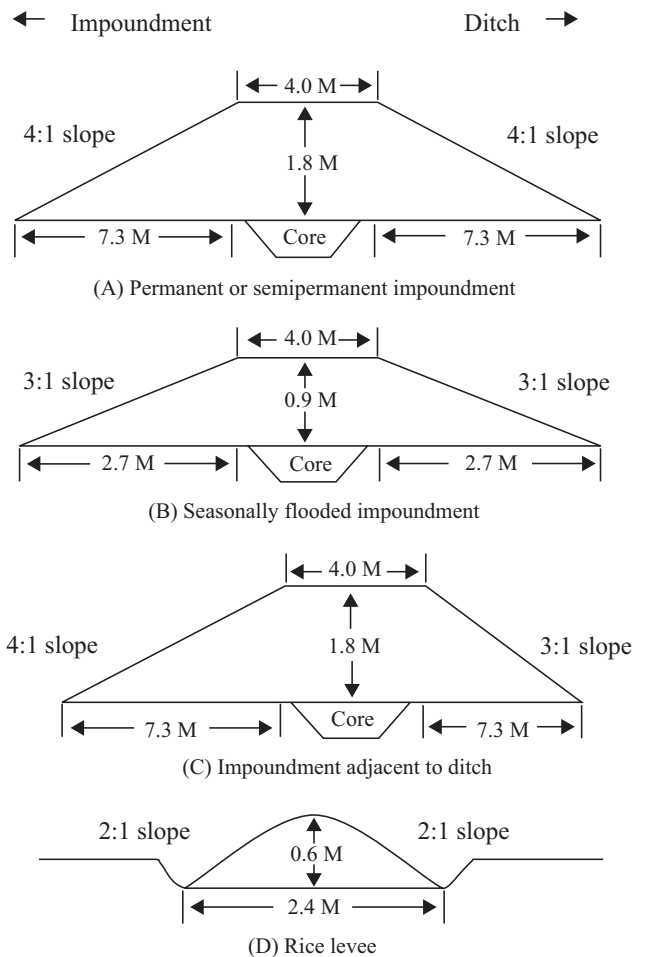

Fig. 28.10. The base specifications of levee types to facilitate wetland management activities.

Water Control Structures

Annual, seasonal, and even daily changes in hydrologic parameters (e.g., depth) are common in most functional wetlands. In modified wetlands, emulation of natural hydrologic regimes commonly requires the installation of permanent **water control structures** that **allow precise water level manipulation, including the complete removal of water from the basin** (Fredrickson 1991). Therefore, selecting the appropriate type and proper location of water control structures with the potential to discharge storm flows is important.

The **proper locations of intake and discharge structures** are the **highest and lowest elevations within the wetland, respectively** (King and Fredrickson 1998). Further, **the same structure should never be used for intake and discharge** (Fredrickson 1991). In areas with high salinities, multiple inlet structures at the highest elevations and multiple drains at the lowest elevations provide the best management options. This design enables complete water discharge necessary to control plant community establishment and permits optimum flooding necessary to make resources available to waterbirds. Additionally, correct placement of water control structures maximizes water circulation within a wetland, which prevents accumulation of soil salts, reduces the risk of disease outbreaks, and facilitates nutrient cycling.

In most situations, **stop-log water control structures** can be used to regulate water input and are ideal for controlling water discharge in increments as small as 5 cm (Fig. 28.11). These structures require less frequent monitoring because stop-logs can be preset at the desired elevation and additional water that enters the wetland is removed from the surface via gravity flow. In contrast, **screwgates** (i.e., sluice gates) require more monitoring because water transfer occurs from the bottom of the wetlands (see Fig. 28.11). Screwgates are frequently used as intake structures, but are not favored as discharge structures because they must be checked and adjusted frequently when manipulating water levels (Fredrickson 1991).

Water-Level Management

Historically, many palustrine wetlands outside of floodplains were flooded as a result of precipitation, groundwater, or a combination of both. Small, localized precipitation events saturated the soil, whereas larger events resulted in surface runoff of water from adjacent uplands that filled wetlands. In arid locations with a deep capillary fringe, rainfall of only 84 mm (0.25 in) may result in extensive flooding. In these systems, all wetlands types were not necessarily flooded every year, but some habitats were available in most years. Maintaining these conditions is especially important for species with limited mobility because they must survive between wet and dry cycles at the site. This is an increasing challenge because **runoff from rainfall**, in many regions of the United States, is **diverted for agricultural or urban uses** and does not reach wetland sites. In addition, **climate change**

Fig. 28.11. Examples of stop-log and screwgate water-control structures.

scenarios predict significant changes that will severely **affect the hydroperiod** of wetlands, including a high confidence of major changes in ecosystem structure and function, and the resilience of many ecosystems is likely to be exceeded this century (Intergovernmental Panel on Climate Change 2007).

In contrast, off-channel floodplain wetlands were historically inundated during flood events. Channelization and diversion of river flows and associated tributaries has resulted in serious hydrologic alterations in many of these systems. Depending on wetland type and location, the effects of these modifications may be manifest in either severe flooding (Belt 1975, Galat et al. 1998) or an almost complete lack of floodwater (Reinecke et al. 1988). In either situation, waterbird use often is limited. Sediments or toxicants also degrade water quality in many rivers (Longcore et al. 1987, Grue et al. 1989).

Wetland development and management must often **rely on alternative sources of water** because hydroperiods have been severely altered across the entire conterminous United States. **Common solutions include** obtaining water from

ditches and rivers, use of wells to transport groundwater to the surface, and construction of reservoirs to capture precipitation and runoff for later use (Reid et al. 1989). **Groundwater and reservoirs** are more reliable sources of good-quality water, but construction of expensive levee or pump systems may be required to accomplish water transport to managed sites. Reservoirs also are disadvantageous because a considerable amount of area often must be converted to deepwater habitats to store sufficient water, and siltation frequently limits reservoir life. **Long- and short-term costs** associated with using groundwater vary, depending on type of pump and power unit and distance to the water table.

It also is important to recognize that **water quality varies among sources**. Thus, use of water from sources that differ from those occurring historically can potentially **influence some wetland processes**. Groundwater often contains more salts than rainwater. If salinity of groundwater is sufficiently high, or salts are allowed to accumulate in the basin over numerous years, a shift in vegetation composition is possible. Thus, types of alternative solutions to obtaining water should be evaluated not only based on costs, but also on the potential to affect project success.

Obtaining water is frequently considered the **most important issue in wetland management**. However **complete discharge of water at appropriate times during the annual cycle also is essential**. It may seem counterproductive to enhance drainage in managed wetlands, but creating conditions necessary for annual plant germination and the ability to control problem vegetation using water or mechanical equipment requires timely and complete removal of surface water.

Case Studies

Intensively managed wetland sites are often concentrated in floodplains. Floodplains are highly variable, thus necessitating a wide range of management approaches. **Success** of any given approach is **dictated by well-defined objectives**, a thorough **understanding of the biotic and abiotic processes** (including their variability) in the system, appropriate **infrastructure**, and well-conceived **adaptive management plans**. Case studies of 3 U.S. Fish and Wildlife Service refuges provide insights into how managers have developed wetland management strategies within floodplains.

Mississippi Alluvial Valley

Bald Knob National Wildlife Refuge is in central Arkansas along the Red River near its confluence with the White River. When first acquired, the 6,000-ha refuge consisted of about 4,047 ha of **rice cropland** and about 1,820 ha of **mature forested wetlands**. At times, the refuge supported as many as 200,000 northern pintails and >400,000 total waterfowl. In addition, rice management on the area provided important habitat for migrating and wintering shorebirds and year-round habitat for wading birds. The original farm was

ideal for rice agriculture because of the lack of topographic relief, a reliable water supply, and infrequent overbank flooding from the river, which enabled water to be managed reliably in most years. The area immediately surrounding Bald Knob was largely nonforested, although an extensively forested wildlife management area, Hurricane Lake, was within 16 km of the refuge.

Bald Knob was a high priority acquisition to help the U.S. Fish and Wildlife Service meet the goals established by the **Lower Mississippi River Valley Joint Venture**. The site was acquired in the 1990s and planning efforts to define long-term goals and objectives were initiated. Decisions regarding development and management were driven by the landscape setting, local biotic and abiotic conditions, and the existing infrastructure.

It was decided that management was **best suited to benefit waterfowl** because of the tradition of Bald Knob National Wildlife Refuge as a **wintering ground** for large concentrations of **waterfowl** and an existing **water management infrastructure** for rice production that was considered **suitable for intensive management of emergent wetlands**. The lack of forested cover on surrounding lands made reforestation a less desirable option because benefits to forest-interior nesting songbirds would be minimal without other large-scale acquisitions. Thus, specific objectives regarding the amount of habitat provided and when it would be available were developed first for waterfowl, second for other waterbirds, and finally for Neotropical migrant songbirds.

Middle Rio Grande Valley

The 23,140-ha **Bosque del Apache National Wildlife Refuge** is located in the Middle Rio Grande Valley 157 km south of Albuquerque, New Mexico. Some 2,763 ha of the 3,683 ha of this **avulsive floodplain** are intensively managed for breeding, migrating, and wintering wetland-dependent species. The refuge was established in 1939, but the infrastructure developed by the Civilian Conservation Corps was in disrepair by the 1980s. In addition the small staff had dilapidated equipment and the management focus was to draw down units early (Feb) to promote plant germination. **Few desirable plants responded**, but these plant communities were mowed in the autumn and then flooded, with little variation in treatments among years. There were extensive **invasions of the exotic saltcedar**, but there was neither the understanding nor the equipment or staff to restore the historic riparian woody community.

By the mid-1980s, biological efforts focused on understanding the herbaceous vegetation response within each unit. This resulted in the **identification of topographic, hydrologic, geomorphic, and other conditions associated with the establishment of each plant community**. This information was helpful in **redesigning the infrastructure** to enhance plant management. For example, maintaining salt grass communities required identifying sites with seasonally

variable groundwater, shallow depth to groundwater, limited seasonal flooding with minimal flow-through water in combination with drying by evaporation. With new management direction, the infrastructure was gradually upgraded. Some units were subdivided and others had improvements in the location and size of inlets or outlets. A major renovation upgraded the drainage and supply of water so that inputs were from higher elevations through multiple inlets and drainage was improved by providing multiple outlet structures at the lowest elevation on each unit. The refuge staff also learned that the floodplain had a diverse and viable seed bank of annuals and some perennials. Management success required creating suitable conditions for plant germination and establishment. For example, bare mineral soil with the appropriate soil moisture and temperature was particularly important for germination of many plant species. Identifying soil conductivity helped predict another layer of management complexity, where one suite of riparian plants proliferated on one site yet another suite dominated on a similar site with slightly different conductivity. As the understanding of each management unit improved, the refuge staff developed confidence to establish objectives for each unit in terms of amount and type of foods produced as well as the number of each waterbird species that could be accommodated.

As herbaceous plant management was refined, there was a management expansion to address the degradation of the woody plant community. Refuge management gradually shifted toward a **systems approach**. After initial plantings of cottonwoods, refuge staff learned that the abiotic conditions necessary for successful establishment of seedlings included appropriate depth to groundwater, soil stratigraphy, and soil salinities. **Water management could create suitable establishment conditions for planted seedlings, as well as conditions necessary for natural regeneration.** Thus, **planting was no longer necessary.** Repetitive observations of annual events provided further insight into the establishment requirements of riparian tree communities. While cottonwood, willow, and saltcedar all have light, aerially dispersed seeds and require bare soil for germination, their conditions for establishment differ and can be controlled to some degree by appropriate infrastructure and management. The removal of dense saltcedar stands and the maintenance of appropriate soil moisture conditions were critical measures to restore native plant communities.

Concurrent with the enhancement of biological understanding, the implementation of management required a **skilled maintenance staff** that understood how equipment could be **used or modified to meet biological objectives.** **Cooperation between the biological and maintenance staff was essential** to success because it led to new innovations, including water management refinement, modernized efficient water-control structures, evaluation of traditional methods and the evolution of more efficient methods

for saltcedar removal, the addition of new and more powerful equipment, equipment modifications to meet management objectives, the refinement of grantsmanship to acquire funding for restoration, enhancement, and management, the establishment of a dynamic refuge support group (Friends of Bosque del Apache), and a well-conceived and well-utilized volunteer program. The concept of teamwork and the sharing of ideas among refuge staff with different skills, intellects, and interests were critical to achieve these goals. The new recognition of the importance of local geomorphic, hydrologic, and soil chemistry conditions to predict potential plant communities would not have been possible without input from biologists, managers, and equipment operators and an appreciation of the unique skills and experiences that each group provides. This collaborative effort improved management success within the refuge as well as outside the refuge boundary within the Middle Rio Grande Valley, and for sites from Colorado to the highlands of Mexico.

Hawaiian Floodplain

The small (371 ha) **Hanalei National Wildlife Refuge** on Kauai, Hawaii, has many of the management challenges common to floodplain wetlands. The geomorphologic setting of the island is unique; Kauai is of **volcanic origin** and has distinct, wedge-shaped watersheds that transport surface water from high, mountainous, interior elevations to the ocean. The porous volcanic rock surrounding the valley also transports water below the surface (i.e., groundwater). Drainages are well developed, and the Hanalei River (length = 25.7 km) is one of the larger river systems in the state. This river, which drains a 49.5-km² area, is on the north shore of Kauai and exhibits features typical of a riverine system (e.g., natural levees, cut banks, point bars, abandoned channels, crevasse splays, and backswamps) as it enters the broad, low valley and begins to meander within the floodplain (Fig. 28.12). Near the ocean, the river cuts through old beach ridges. The lower 3.2 km of the river flows through the refuge and 2 large private land holdings and past taro (*Colocasia esculenta*) farms, small businesses, and residences before emptying into Hanalei Bay. Backswamps and abandoned channels have fine-textured materials, while coarse materials dominate natural levees, point bars, crevasse splays, and old beach ridges. A veneer of fine-textured material with variable thickness is common within the valley. This veneer thins on the buried beach ridges and as one gets closer to the ocean.

Hanalei National Wildlife Refuge is one of the most important sites in Hawaii for **4 endangered Hawaiian waterbirds** including the Hawaiian coot (*Fulica alai*), moorhen (*Gallinula chloropus sandvicensis*), stilt (*Himantopus mexicanus knudseni*), and Koloa or Hawaiian duck (*Anas wyvilliana*). In addition, the endangered Hawaiian goose or Nene (*Branta sandvicensis*) currently nests on the refuge, and there may be the potential to reintroduce the Laysan duck (*A. laysanensis*).

Fig. 28.12. Wetland development within the Hanalei River floodplain in Kauai, Hawaii, in relation to selected geomorphic features.

Thus, Hanalei National Wildlife Refuge has the typical suite of **physical disruptions related to agriculture and flood control including** roads, a channelized stream, an incised stream, levees, ditches (supply and drainage), disruption of surface deposits, and irrigation infrastructure. These physical **disruptions** also **influence natural processes by changing hydrologic conditions, topography, and the amount of river water in the lower floodplain.**

Agricultural activities in the Hanalei River Valley have been present for 1,300 years (Schilt 1980). Thus, this site has a long history of agricultural development, including the infrastructure required for crops that require flooded conditions. Flooded conditions associated with these agricultural practices also attract waterbirds.

The U.S. Fish and Wildlife Service continued to develop wetlands after the refuge was established, but objectives changed from agricultural to conservation. New levees, drains, and water control structures provided opportunities for hydrologic manipulations required to produce the food and cover for meeting the life-history needs of all 5 endangered waterbirds on about 36 ha. These new develop-

ments recognized the need to have similar soil textures within each unit, to have the potential to quickly export excessive rainfall from units, to have independent water delivery and discharge, and to have nesting and foraging sites in close proximity. The suite of conditions at Hanelei National Wildlife Refuge requires managers to address multiple problems:

- A floodplain with physical disruptions to the natural flow of water.
- Changes in the river channel that compromise water intake.
- Alteration of natural process because of physical disruption, changes in water use, and presence of exotic plants and animals.
- A poorly sited infrastructure in relation to geomorphic and hydrologic conditions.
- An infrastructure with inadequate supply, control, and discharge of water.
- Poor understanding of water use on taro and wetland impoundments.

- Cultural issues associated with taro, a food source with nutritional and ceremonial value to native Hawaiians.
- Endangered species, including 4 wetland-dependent birds, about which there is limited knowledge.
- Inadequate knowledge of native plants and their life-history requirements, especially the abiotic conditions that stimulate germination, growth, and seed production.
- Predation and disease potential.
- Permits required to change the infrastructure.
- Funds to implement changes to the infrastructure, management, and research.

Intensive wetland management was preferred **over restoration** because of the extensive abiotic and biotic disruptions, the limited wetland area remaining on Kauai, and the need to recover these species. **Restoration** of a sufficiently large area to support endangered waterbirds was **not practical**; thus, intensive management was a logical choice. Although Hanalei National Wildlife Refuge was considered an important site for all of the endangered waterbirds, surveys indicated limited use by coots, stilts, and moorhens, and counts of Koloa rarely exceeded 25 birds from the time of refuge establishment in 1973 through 2007. Five months after renovation, numbers of Hawaiian stilt approached 200 and Koloa approached 300. During the summer of 2009 numbers of Koloa exceeded 500 and Hawaiian moorhen numbers reached 256. Based on these **immediate responses by endangered waterbirds**, the **manipulation of soil and water was most effective** when abiotic conditions were used to determine the type and location of the management infrastructure.

SUMMARY

Wetlands are dynamic habitats that provide many benefits to wetland-dependent wildlife as well as to society. Understanding wetlands and their benefits is complex and requires information on their abiotic and biotic characteristics. Unfortunately, many societal benefits were not well recognized historically and, as a result, vast areas of wetland habitats were lost or modified in the lower 48 states and Hawaii following European settlement. Many wetlands were either converted to other uses such as agriculture or were influenced by anthropomorphic changes that modified the physical condition or disrupted wetland processes. These changes in wetland area and functions resulted in legislation that led to state and federal programs for wetland management and protection that benefit wildlife and society. Some wetland programs are especially important for wildlife because wetlands provide valuable habitat for a wide suite of species, many of which are either endangered or species of regional or national concern. Thus, management or protection of remnant wetlands is critical to maintain viable populations of many wetland-dependent species. Historically wetland management techniques were applied without recognition of the temporal or landscape setting that characterized a site, and the focus was on migratory birds, especially waterfowl. We describe an approach that identifies the importance of understanding geomorphic setting, climatic conditions, and life-history strategies of plants and animals (including birds other than waterfowl), as well as cold-blooded vertebrates, as the basis for wetland decision-making. Case histories provide insights into the contemporary challenges of making decisions in highly modified environments.

Managing Coastal Wetlands for Wildlife

INTRODUCTION

Description of Coastal Wetlands

COASTAL WETLANDS DIFFER greatly from those inland primarily because of seawater stresses on vegetation and tidal action that make water levels more dynamic. Most coastal wetlands in the United States are **marshes** (i.e., dominated by emergent herbaceous vegetation) rather than **swamps** (i.e., dominated by trees or shrubs), because there are no trees that can tolerate flooding, freezing, and even moderate salinity. **Mangroves** (flood- and salt-tolerant trees) are limited to parts of Texas, Louisiana, and Florida and are rarely managed for wildlife. In contrast, coastal marshes have been managed for wildlife, particularly waterfowl, since the early 1900s. Understanding of the relationships among coastal wetlands, wildlife, and fish has evolved slowly from trial-and-error efforts to attract waterfowl to more sophisticated application of scientific methods and ecological theories to accommodate multiple wildlife and fish species in the face of global sea-level rise and climate change. In this chapter, we summarize the form, function, ecological relationships, wildlife value, and management of coastal wetlands of the United States outside of Alaska and Hawaii.

Regional Variation

Physical features of a coastal region influence development of coastal wetlands. Regions bordered by a broad, flat coastal plain onshore and a gently sloping continental shelf offshore, such as the southeastern United States, contain the greatest expanse of coastal wetlands. Wetlands form along the shoreline when sediment deposited by rivers or the sea fill shallow waters and extend seaward as shoals that gradually accrete from the water bottom to elevations suitable for plant growth (Coleman 1988). Coastlines bordered by mountainous terrain, such as the northwestern United States, usually contain deep water near shore and produce conditions unfavorable for wetland development (Seliskar and Gallagher 1983). Near mountainous coasts, the continental shelf is narrow and steep, curtailing sediment accumulation and accretion necessary for extensive wetland formation; therefore, wetlands develop along the fringes of rivers or shallow bays.

Coastal wetlands comprise **approximately 24,380 km²** in the United States outside of Alaska, Hawaii, and the Great Lakes (Alexander et al. 1986). For perspective, this area is larger than New Hampshire, but smaller than Vermont. Most are along the shorelines of the Gulf of Mexico and the South Atlantic, and are associated with extensive coastal plains and drowned river valleys. Much of the New England

and Pacific coasts have rocky coastlines and contain wetlands only in protected bays.

Gulf Coast

The Gulf of Mexico coastal region contains **approximately 14,190 km²** of wetland, an area that is larger than Connecticut, but smaller than Hawaii, or equivalent to 58% of the total coastal wetlands (Alexander et al. 1986). Much of this (**approx. 9,840 km²**) occurs in Louisiana and developed as deltaic deposits and Chenier Plain deposits of the Mississippi River (West 1977, Penland and Sutter 1989). Marshes border the entire coastline of Louisiana and extend inland up to 80 km in the eastern half of the state, which contains the Mississippi River Deltaic Plain (Chabreck 1988). Tidal swamps are common further inland. Because of the extent of these marshes, waters range from highly saline to fresh, with broad transitional bands in between (O'Neil 1949, Chabreck 1972). In recent decades, mangroves have been expanding into and replacing salt marshes in Louisiana (Perry and Mendelssohn 2009), Florida (K. Krauss, National Wetlands Research Center, United States Geological Survey [USGS], personal communication), and Texas (T. Stehn, United States Fish and Wildlife Service [USFWS], Department of Interior [DOI], Aransas National Wildlife Refuge, personal communication).

The Texas coastline contains **approximately 1,915 km²** of marsh in a narrow band (Alexander et al. 1986), with most located east of Galveston Bay, representing a westward continuation of the Chenier Plain of the Mississippi River. Marshes of the region display the gradual transition from saline to fresh and provide wide habitat diversity (Stutzenbaker and Weller 1989). Westward, along the Texas coast to the Rio Grande River, small marshes fringe lagoons where water salinity reaches 55 parts per thousand (ppt; Buller 1964, McMahan 1968, West 1977). Here too, mangroves appear to be expanding into marshes.

Mississippi, Alabama, and the Gulf Coast of Florida contain **approximately 2,435 km²** of coastal marsh (Alexander et al. 1986). Marshes along the west coast are nourished by freshwater and sediments from the Pearl River. Elsewhere along the coasts of Mississippi, Alabama, and northern Florida, marshes are limited to alluvial pockets along shorelines of protected bays and rivers. The western coast of Florida contains extensive lowlands and large areas of coastal marsh. South of Tampa Bay, however, mangroves dominate coastal lowlands, and marsh occurs only in isolated openings among stands of these shrubs and trees.

Atlantic Coast

The Atlantic Coast contains **approximately 9,815 km²** of marsh (Alexander et al. 1986), an area that is larger than Delaware, but smaller than Connecticut. Three-fourths of the marsh is south of Maryland, principally in North Carolina, South Carolina, and Georgia (Shaw and Fredine 1954,

Reimold 1977). Broad, flat coastal plains slope gently to the shoreline in these states and produce vast lowlands near sea level.

In Virginia and Maryland, coastal marshes are largely associated with Chesapeake Bay and tidal creeks and rivers draining into the bay. In the 1930s, mosquito control agencies dug extensive ditches in many of these marshes (Hindman and Stotts 1989). Delaware and New Jersey contain sizable areas of marsh associated with Delaware Bay. Also, scattered marshes occur as fringes along seashores protected by barrier islands. In South Carolina, many coastal marshes were impounded to grow rice in the 1800s, but most of those impoundments are now managed for wintering waterfowl (Landers et al. 1976). Marshes in New York lie principally along tidal creeks leading inland into Long Island. Most tidal marshes along the east coast of Florida border large rivers and extend inland for great distances, such as along the St. John's River.

Much of the New England coastline is rugged with rock outcroppings. Marshes along the coast are relatively small (combined they occupy approx. 555 km²) and subjected to larger tidal fluctuation (4 m) than most other coastal marshes in the United States (Nixon and Oviatt 1973). They border tidal creeks, bay shores, and other protected waters. Jorde et al. (1989) noted coastal marshes in the northern Atlantic states are threatened by common reed (*Phragmites australis*) as well as purple loosestrife (*Lythrum salicaria*).

Pacific Coast

The Pacific Coast lacks a broad coastal plain; instead, steep mountains parallel the shoreline and slope abruptly to the ocean (Inman and Nordstrom 1971). The continental shelf is narrow and steep, restricting formation of barrier islands and spits; consequently, coastal marshes have developed only in protected bays and fringing the borders of rivers that empty into the Pacific Ocean. Smooth cordgrass (*Spartina alterniflora*), introduced into many of these marshes during the 1970s, now threatens native plant communities (Callaway and Josselyn 1992).

The Pacific Coast outside of Alaska contains only **approximately 375 km²** of coastal marsh (Alexander et al. 1986), much of which is associated with San Francisco Bay. Other significant marshes are associated with Puget Sound, Gray's Harbor, and Willapa Bay in Washington and Tillamook and Coos bays in Oregon. Marshes elsewhere consist mainly of fringe zones along bay shores or in the mouths of rivers containing sandbars that minimize wave action (Sanderson and Bellrose 1969).

Types of Wetlands

Coastal wetlands can be classified based on water salinity, elevation, flooding, plant species, or a combination of these variables. A **classification system based on water salinity** by Cowardin et al. (1979) is commonly used nationwide.

Cowardin et al. (1979) noted the number of years of data needed to estimate average salinity are not commonly collected, and suggested that managers instead use plant species or associations to indicate broad salinity classes. Thus, in practice, the Cowardin et al. (1979) system of classifying marshes by average water salinity has been **based on observations of emergent vegetation** rather than measurement of water salinity. Classification systems **based on elevation** are common within several regions of the United States (Mitsch and Gosselink 2000). Classifying marshes by elevation also has been based on emergent vegetation rather than elevation measurements. These systems complicate communication among regions because different terms are used for similar habitats. For instance, areas dominated by smooth cordgrass that is stunted by flooding can be classified as high marsh in coastal New England, but as low marsh on the Atlantic Coast of the southern United States. Classification systems directly based on emergent vegetation are more straightforward, but still can complicate communication among regions. For instance, areas dominated by marshhay cordgrass (*S. patens*) occur in coastal New England and on the Gulf Coast; however, they are known as salt marshes in New England and brackish marshes on the Gulf Coast. Managers and researchers must be familiar with all of the differing classification systems. Species of emergent vegetation are the key to converting classification between systems, and to communicating with managers and researchers from other regions. Regardless of the variable used as the basis of classification, the boundaries between classes are arbitrary because water salinity, elevation, and plant species form gradients.

Common plant associations have been identified for many regions (Chabreck 1970, Nixon 1982, Zedler 1982, Josselyn 1983, Seliskar and Gallagher 1983, Odum et al. 1984, Teal 1986, Weigert and Freeman 1990). Recently, statistical analyses have been used to identify common plant associations that are more detailed than earlier classification schemes (Visser et al. 2000). For broad descriptive purposes, marsh types often are known as salt (**polyhaline**), brackish (**mesohaline**), intermediate (**oligohaline**), or fresh, reflecting the amount of contact with seawater. These types generally occur in bands paralleling the shoreline. In small rivers the bands can be tens of meters wide and some may not occur, but, because of the great width of marsh along the Louisiana coast, all marsh types are well represented (**salt** = 21%, **brackish** = 31%, **intermediate** = 11%, **fresh** = 31%), and the bands exceed 20 km in some areas (Chabreck and Linscombe 1978).

Botanical nomenclature follows the Integrated Taxonomic Information System (ITIS 2003), but nomenclature changes. Recent changes create potential confusion because one of the most important species to wildlife managers was referred to in many publications as *Scirpus*, following the nomenclature of Radford et al. (1968) and Godfrey and Wooten (1979):

recent publications often refer to this species as *Schoenoplectus*, following ITIS (2003).

Mangrove Swamp

Mangroves (i.e., salt-tolerant wetland trees and shrubs) form extensive swamps only in southern Florida, where killing freezes are infrequent. Florida has ≥ 4 species: black mangrove (*Avicennia germinans*), buttonwood (*Conocarpus erectus*), white mangrove (*Laguncularia rhizophora*), and red mangrove (*Rhizophora mangle*). Mangroves also occur in Texas and Louisiana, but Texas has only black mangrove and red mangrove and Louisiana only has black mangrove. Mangroves are replacing salt marshes in all 3 states, presumably because of a recent lack of killing freezes. Since the 1930s, 34% of the salt marshes in 10,000 Islands National Wildlife Refuge, in southern Florida, have converted to mangrove swamps (Howard et al. 2009). In Louisiana, the number of saline marsh sites with black mangroves doubled between 2001 and 2005 and tree heights exceeded 4 m by 2003 (Michot et al. 2009). Mangrove swamps are not addressed further because they are rarely managed for wildlife, but that situation may change as mangroves continue to replace salt marshes in Florida, Louisiana, and Texas.

Salt Marsh

Salt marsh has the greatest tidal fluctuation of all marsh types and contains a well-developed drainage system. In Louisiana, water salinity averages 18.0 ppt (range = 8.1–29.4 ppt) and soils have a lower organic content (\bar{x} = 17.5%) than types farther inland (Chabreck 1972). On the Gulf Coast, vegetation within this type is salt tolerant and is dominated by smooth cordgrass, seashore saltgrass (*Distichlis spicata*), and needlegrass rush (*Juncus roemerianus*). Mangroves do not dominate because of occasional killing freezes, but provide valuable wildlife habitat, especially for colonial nesting waterbirds, such as the brown pelican (*Pelecanus occidentalis*). On the Pacific Coast, the most saline marshes contain plants such as Virginia glasswort (*Salicornia virginica*), arrowgrass (*Triglochin maritimum*), and native California cordgrass (*Spartina foliosa*) or the nonnative smooth cordgrass (Seliskar and Gallagher 1983, Callaway and Josselyn 1992, Zedler et al. 1999).

Brackish Marsh

Brackish marsh lies inland and farther removed from the influence of saline waters than the salt marsh type, but is still affected by daily tidal action. Average water depth exceeds that of salt marsh. In Louisiana, soils contain higher organic content (\bar{x} = 31.2%), and water salinity averages 8.2 ppt (range = 1.0–18.4 ppt; Chabreck 1972).

Brackish marsh contains greater plant diversity than salt marsh and, in Louisiana, is dominated by 2 perennial grasses, marshhay cordgrass and seashore saltgrass. An important wildlife food plant of brackish marsh of the Atlantic and

Gulf coasts, Olney bulrush (*Schoenoplectus americanus*), grows best in tidal marsh free from excessive flooding, prolonged drought, and drastic salinity changes. Olney bulrush is, however, crowded out by marshhay cordgrass unless stands (of Olney bulrush) are periodically burned (Chabreck 1981). Widgeongrass (*Ruppia maritima*), the dominant submerged aquatic plant of brackish marsh, is a preferred food of ducks and American coot (*Fulica americana*). On the Pacific Coast, brackish marsh contains short and tall forms of Lyngbye's sedge (*Carex lyngbyei*), which appears to be an ecological analog of smooth cordgrass (Seliskar and Gallagher 1983).

Intermediate Marsh

The **intermediate marsh** type lies inland from brackish marsh. Intermediate marsh receives some influence from tides. In Louisiana, water salinity averages 3.3 ppt (range = 0.5–8.3 ppt), water levels are slightly higher than in brackish marsh and soil organic content averages 33.9% (Chabreck 1972). Plant species diversity is higher than in brackish or saline marsh, and the intermediate marsh contains both halophytes and freshwater species used as food by a wide variety of herbivores. In Louisiana, marshhay cordgrass dominates intermediate marsh as it does brackish marsh, but to a lesser extent. Other common marsh plants in intermediate zones are common reed, bulltongue (*Sagittaria lancifolia*), and coastal waterhyssop (*Bacopa monnieri*). This type also contains an abundance of submerged aquatic plants that are important foods for ducks and American coot (Chabreck 1972). Use of “intermediate marsh” is uncommon outside the Gulf Coast, perhaps because this type is rare or because it is known as tidal freshwater marsh. Even in Louisiana (Chabreck 1972), intermediate marsh is the smallest type and occupies only approximately 2,523 km², of which approximately 1,533 km² are emergent wetlands and the remainder is open water (ponds, lakes, etc.).

Fresh Marsh

Fresh marsh occupies the zone between the intermediate marsh and uplands or forested wetlands in the alluvial plain of major river systems. Tidal fresh marsh is normally free from salinity, but periodic periods of salinity prevent conversion to swamps. Water levels can be only slightly affected by tides, as on the Gulf Coast where high tide slows river discharge more than it raises water level, or greatly affected by tides as in the northern United States. In Louisiana, water salinity averages only 1.0 ppt (range = 0.1–3.4 ppt), and water depth and soil organic content (\bar{x} = 52.0%) are greatest in fresh marsh because of slow drainage (Chabreck 1972). In some Louisiana fresh marshes, soil organic-matter content exceeds 80% and the substrate for plant growth is a floating organic mat referred to as “flotant” by Russell (1942).

Fresh marsh supports the greatest diversity of plants and contains many species that are preferred foods of wildlife.

Dominant plants include maidencane (*Panicum hemitomon*), spikerushes (*Eleocharis* spp.), and alligator weed (*Alternanthera philoxeroides*) in Louisiana (O'Neil 1949). On the Atlantic Coast, Odum et al. (1984) identified 8 communities in tidal freshwater marsh with dominant species such as Virginia peltandra (*Peltandra virginica*), annual wildrice (*Zizania aquatica*), and giant cutgrass (*Zizaniopsis mileacea*). This marsh type also contains submerged and floating-leafed aquatic plants of value as wildlife foods. In many areas, tidal freshwater marsh was converted to agriculture, as it was in the delta of the Sacramento and San Joaquin rivers (Herbold and Moyle 1989). As with emergent vegetation, submersed aquatic vegetation is richer and more abundant in fresh marshes than in saline marshes (Chabreck 1971, Yozzo and Smith 1998, Simenstad et al. 2000). Some floating aquatics, such as spatter-dock (*Nuphar luteum*), are sufficiently common that they are the basis of identified communities (Odum et al. 1984), whereas others, such as the exotic water hyacinth (*Eichhornia crassipes*), form dense stands that block waterways and are considered pest plants.

Tides

Water level, in addition to salinity, is a major factor affecting plant and animal communities in coastal wetlands; the tidal cycle is the major factor affecting water levels. The tidal range at any location varies daily, monthly, annually, and regionally. Wetlands bordering the Gulf of Mexico are subject to a daily **tidal range** of 0.6 m (Marmer 1954). In some areas along the coasts of New England and the Pacific Northwest, tides may fluctuate 3.6–4.8 m daily (Hedgpeth and Obrebski 1981, Whitlatch 1982). Tides within a locality also may vary; south of Cape Cod the range is 0.9–1.5 m, whereas north of Cape Cod the range is 3.0–4.0 m (Whitlatch 1982). The elevation of the soil surface relative to water levels differs greatly among wetlands (Fig. 29.1), which can negate attempts to apply water-level management strategies that are successful in one wetland to other wetlands.

Highest tide levels occur in coastal wetlands during the full and new moons. Factors such as wind direction and intensity, freshwater inflow, and barometric pressure also affect the range and level of individual tides at a locality. The velocity and range of tides decrease as water moves inland. The rate of movement decreases because coastal streams become narrower farther inland and carry less water. Moreover, meandering or winding of streams increases the distance that water must travel to move inland. The rate of flow of tidewater moving across the wetland surface also is reduced by dense vegetation.

Channel size and length affect the rate of water exchange; interior wetlands connected to the sea by large channels are influenced more by tides than are wetlands with small drainages. Coastal wetlands that are transversely divided by large, straight **canals** that connect to the sea are exposed to

Fig. 29.1. Elevation (cm) of mean high water, mean water, and mean low water, relative to the marsh surface (0 cm) at various coastal marshes in the United States. ND = no data available. Sites (A) and (B) were dominated by marshhay cordgrass in Louisiana, (C) was dominated by marshhay cordgrass at a created marsh in Florida, (D) and (E) were dominated by smooth cordgrass and needlegrass rush, respectively, in South Carolina, (F) was dominated by common reed in New York, and (G) and (H) were dominated by common reed and smooth cordgrass, respectively, in Connecticut. (A, B) From Nyman et al. (2009); (C) from Anastasiou and Brooks (2003); (D, E) from Morris et al. (2005), J. T. Morris, Baruch Marine Field Laboratory, University of South Carolina (personal communication); (F) from Montalto et al. (2006); (G, H) from Chambers et al. (2002).

greatest tidal action. In such canals, tidal waters can move farther inland, in greater volume, and at a greater rate than through natural streams. Such canals also accelerate drainage of freshwater from interior wetlands during low tides (Gunter 1967).

HABITAT REQUIREMENTS OF SELECTED FISH AND WILDLIFE

Coastal wetlands and associated water bodies are among the most productive habitats for fish and wildlife. Some species spend their entire lives in this habitat, whereas others use the habitat only seasonally or during a portion of their life cycles. This review describes habitat requirements of selected groups that are important because of their commercial, sporting, or recreational qualities. Basic information is provided regarding the effects of management of coastal wetlands on groups of fish and wildlife.

Waterfowl

Coastal wetlands and waters serve as wintering habitat for a large segment of the continental **migratory waterfowl** population. Major groups include dabbling and diving ducks, and geese. These groups have different habitat requirements that

vary considerably even among species within groups (Bellrose 1980).

Dabbling ducks mostly prefer shallow-water areas with depths 45 cm. These birds feed by tipping to reach the bottom of ponds or the surface of flooded marsh. Small species, such as blue-winged (*Anas discors*) and green-winged teal (*A. crecca*), prefer areas with water 15 cm deep (Chabreck 1979). Teal, mallard (*A. platyrhynchos*), and pintail (*A. acuta*) feed mainly on seeds that they pick up on the bottom. Other dabblers, such as gadwall (*A. strepera*) and American wigeon (*A. americana*), feed extensively on leaves and stems of aquatic plants; consequently, they are able to use areas with a greater water depth (Gordon et al. 1989). Brant (*Branta bernicla*) feed heavily on seagrass (*Zostera marina*).

Diving ducks may consume plant or animal materials on reservoir bottoms or aquatic plants growing in the water. Diving ducks may be found in association with dabbling ducks; however, they usually occupy open-water areas much deeper than those used for feeding by dabbling ducks.

Snow geese (*Chen caerulescens*) commonly winter in coastal marshes and prefer areas containing short grasses and sedges having water levels near or below the marsh surface. Snow geese seldom venture into salt marsh along the Gulf Coast, but salt marsh is an important habitat along the Atlantic Coast (Smith and Odum 1981). A preferred habitat is recently burned marshhay cordgrass, which often contains dense stands of Olney bulrush.

Most waterfowl depend on coastal marshes during only part of the year, the nonbreeding season. American black duck (*A. rubripes*), mottled duck (*A. fulvigula*), and Florida duck (*A. f. fulvigula*) nest, as well as winter, in coastal marshes and depend on coastal marshes year-round. Little is known about population trends of Florida duck and mottled duck, but American black duck populations declined in the latter 1900s; loss of habitat and interbreeding with mallards are believed to be 2 of several factors contributing to the decline of black ducks (Conroy et al. 2002). Black ducks use impounded marsh less than tidal marsh and encounter more mallards in impounded marsh than in tidal marsh (Belanger and Lehoux 1994). Restoration of tidal flow to impounded marshes on the northeastern United States might increase black duck populations.

Coots, Gallinules, and Rails

The **American coot** is a winter resident of coastal wetlands and concentrates in large flocks on ponds and lakes (Lowery 1974a). It is equally at home on shallow ponds with dense growth of aquatic plants for food or deeper lakes with small fishes available as food. The American coot occupies shallow-water areas and tolerates widely ranging water salinities, but limits its use of deepwater lakes to freshwater systems.

Gallinules and rails are less gregarious than coots and prefer marshes with readily available, dense escape cover.

The common moorhen (*Gallinula chloropus*) is a year-round resident of Gulf Coast marshes, whereas the purple gallinule (*Porphyrio martinica*) breeds in the area and migrates during winter. Gallinules occupy freshwater marshes and prefer feeding areas along shorelines of small ponds.

Several species of rails are present in coastal marshes. Clapper rails (*Rallus longirostris*) occupy saline marshes, whereas the king rail (*R. elegans*) occurs in fresh marshes. Rails prefer moist soil conditions, and are driven from marshes by prolonged flooding.

Wading Birds and Shorebirds

Shorebirds include sandpipers, dowitchers (*Limnodromus* spp.), etc. Shorebirds do not nest in wetland vegetation, but feed in shallow ponds and tidal channels common in coastal wetlands. Most shorebirds use shallower water (5 cm deep) than do waterfowl (>10 cm deep; Isola et al. 2000). **Wading birds** include herons, egrets, ibises, and similar birds; they are abundant throughout the coastal wetlands, but most species nest in shrubs and trees. These birds feed in shallow ponds by slowly walking and capturing fishes and other small animals. They also use shallower water than waterfowl. Their wide-ranging foraging and low site fidelity allow them to quickly respond to changing environmental conditions; changes in their abundance are a good measure of habitat condition, but not of population changes (Melvin et al. 1999). In the Pacific Northwest for instance, wading birds may be losing foraging areas as shallow-water areas are replaced by nonnative smooth cordgrass, but it is not known whether wading bird populations have been affected. Shallow water is an essential part of their habitat and birds often concentrate around small pools to capture fishes trapped by receding water (Lowery 1974a). A mix of unmanaged ponds that drain naturally and managed ponds that rarely drain provide foraging habitat across a wide range of conditions (Spiller and Chabreck 1975). If ponds with different water depths cannot be provided, as in former agriculture fields, managers should be able to provide feeding habitat for more species with shallower water than deeper water (Safran et al. 1997).

Passerines

Many **songbirds** use coastal marshes and a few are limited to these marshes during part or all of the year. Some are species of concern such as sedge wren (*Cistothorus platensis*) and seaside sparrow (*Ammodramus maritimus*), whereas one, the Cape Sable seaside sparrow (*A. m. mirabilis*) is endangered. These songbirds forage for spiders and insects and require relatively short, open vegetation such as smooth cordgrass, marshhay cordgrass, and sand cordgrass (*Spartina bakeri*). On the northeastern Atlantic Coast, restoration of smooth cordgrass to areas invaded by common reed should increase habitat for seaside sparrows and saltmarsh sharp-tailed spar-

rows (*A. caudacutus*) because they are less abundant in marshes dominated by common reed (Benoit and Askins 1999). Even areas dominated by suitable plant species may be unsuitable for dependent songbirds if the vegetation is too thick or too sparse. Managed marshes where marshhay cordgrass is vigorous support fewer seaside sparrows and Nelson's sharp-tailed sparrows (*A. nelsoni*) than unmanaged marsh where salinity stunts marshhay cordgrass (Gabrey et al. 1999). At the other extreme, marshes that burned the previous winter had too little vegetation and supported fewer marsh wrens (*Cistothorus palustris*), Nelson's sharp-tailed sparrows, seaside sparrows, and sedge wrens than marshes that had burned earlier (Gabrey et al. 1999). In addition to vegetative structure, patch size influences habitat suitability for songbirds that depend on coastal marshes. Density of saltmarsh sharp-tailed sparrows, seaside sparrows, and willets (*Catoptrophorus semipalmatus*) is greater in larger patches than in smaller patches of otherwise suitable habitat (Benoit and Askins 2002).

Fire might be a useful tool in managing coastal marshes for some dependent songbirds. On the Atlantic Coast of Florida, fire favors the expansion of sand cordgrass, which is critical habitat for the endangered Cape Sable seaside sparrow, at the expense of needlegrass rush (Schmalzer et al. 1991). Marshes should be managed to ensure that vegetative stands in different stages of recovery from fire are present simultaneously rather than being managed for large tracts on the same burning schedule.

Unlike wading birds, many songbirds do not respond quickly to changes in habitat. Jenkins et al. (2003) reported that some Cape Sable seaside sparrows remained in unsuitable habitat that was formerly suitable, and that areas of suitable habitat lacked birds. Thus, the high site fidelity of this endangered species complicates its management.

Fur-Bearing Mammals

Fur-bearing mammals are common inhabitants of coastal marshes and waterways and occupy a wide variety of habitat types, ranging from fresh to saline. Major species include muskrat (*Ondatra zibethicus*), nutria (*Myocastor coypus*), raccoon (*Procyon lotor*), mink (*Neovison vison*), and river otter (*Lontra canadensis*). Muskrats and nutrias are herbivores and feed on a wide assortment of plants; however, certain plant types will support greater population densities than others (O'Neil 1949, Palmisano 1973). Muskrats prefer marshes where Olney bulrush is abundant (O'Neil 1949) and are more specialized than nutria, which causes recently burned brackish marsh to support greatest muskrat densities (Palmisano 1972). Nutrias eat a wider variety of plants than muskrats and reach greatest density in fresh marshes (Palmisano 1973).

The raccoon is usually omnivorous, but coastal marshes often lack plant foods used by raccoons; consequently, they feed largely on animal materials. The mink is carnivorous

and feeds mainly on fishes, crustaceans, small mammals and birds, snakes, and frogs. The river otter also is a carnivore and feeds heavily on fishes and crustaceans (Lowery 1974b).

The river otter ranges over an area of several square kilometers and spends a major portion of its time in or near water. Prolonged drought adversely affects the species; however, the impact of drought is less severe if water is available in deeper channels. Nutrias, raccoons, and mink also are affected by excessive marsh drying, but excessive flooding also may cause the animals to abandon an area, particularly when protective cover becomes submerged (Lowery 1974b).

American Alligators

The **American alligator** (*Alligator mississippiensis*) occurs in the southeastern United States and occupies coastal marshes and water bodies with salinities ranging from fresh to slightly brackish. Alligators are opportunistic feeders, consuming both vertebrates and invertebrates; prey size varies with size of the alligator (Wolfe et al. 1987). Marsh water depths are critical in limiting populations and affecting nesting effort, nest flooding, egg desiccation mortality, and predation on alligator eggs and young (Nichols et al. 1976).

Freshwater Fisheries

Ponds, lakes, bayous, and canals in freshwater marshes of coastal areas are highly productive habitats for freshwater fisheries. Major families found in these habitats include sunfishes (Centrarchidae) and catfishes (Ictaluridae), and contain both foraging and predacious species. Important variables regulating productivity of aquatic habitats are suitable water depths, favorable water quality, adequate nutrients to supply primary producers, and low abundance of undesirable plants such as the exotic water hyacinth (Meador 1988).

Estuarine Fisheries

Estuarine fisheries are those that support species that use a **brackish marsh environment** as a part of their life cycle, mainly during postlarval and juvenile stages. These include important commercial or sporting species such as Gulf menhaden (*Brevoortia patronus*), Atlantic croaker (*Micropogonias undulatus*), white shrimp (*Litopenaeus setiferus*), and blue crab (*Callinectes sapidus*). These species breed in offshore waters and young move inland as larval or postlarval forms. Young that reach favorable nursery areas, such as tidal ponds and bayous, grow rapidly. Favorable nursery areas are those having suitable water salinity and temperature and an abundance of available food. The major food source is derived from detritus or fragments of wetland plants that have been carried into the tidal ponds by tidal currents. The young remain in the wetland systems for several months and then gradually make their way to deeper water, en route to the sea (Gunter 1967).

Crawfish

Crawfish (*Cambarus* spp., *Procambarus* spp.) are an important component of tidal swamps and freshwater marshes, but occasionally occur even in marshes dominated by marsh-hay cordgrass during times of prolonged low salinity (J. A. Nyman, personal observation). Crawfish are important as predators of fish and vegetation, and as prey for many other species of fish and wildlife. Crawfish can be voracious consumers of wetland plants, particularly seedlings (Nystrom and Strand 1996). Some species such as the red swamp crawfish (*P. clarkii*) provide a commercial and recreational resource for man. Summer drying of wetlands is essential for completion of certain life stages. Summer drying also reduces predators, which would otherwise feed on the crawfish once water is returned to the wetland (Perry et al. 1970). The red swamp crawfish is native to the southeastern United States, but is threatening native flora and fauna where it was introduced elsewhere in the United States and throughout the world (Lodge et al. 2000, Smart et al. 2002).

COASTAL ALTERATIONS AND WETLAND LOSS

With a better understanding of how wetlands are affected by hydrological processes, coastal wetland managers (1) can better evaluate the effect of changes in water level or salinity and thereby prevent or restrict undesirable wetland changes, and (2) more accurately compare cost and effectiveness of management or restoration options. Small-scale direct alterations, such as those associated with the extensive ditch construction in Atlantic Coast marshes during the early 1900s (Bourn and Cottam 1950, Dale and Hulsman 1990) and accelerating development of most coastal areas in the late 1900s (Culliton et al. 1992), directly alter hydrological conditions in managed wetlands. In addition to direct alterations, water levels and salinity have been altered indirectly by human activity. An example of human activity that indirectly affects wetlands estuarine-wide is the deepening from 15 m to 40 m of the Calcasieu Ship Channel in Louisiana, which probably increased water depths 40 cm in adjacent wetlands such as in the Sabine National Wildlife Refuge (Suhayda et al. 1989). Another example is the dredging of the Cooper and Santee rivers in North Carolina, which lowered salinity in adjacent wetlands.

Global sea-level rise and **regional subsidence** have increased flooding and salinity in many coastal wetlands. This combination is called **submergence** and along most of the United States coast it averages 0.25–0.30 cm/year (Titus 1996). In North America, submergence is slower in the far north because the earth's crust is still rebounding following the last ice age. Submergence also is faster where geologically recent sediments are deeper, such as in the channels eroded by rivers during the last ice age, which subsequently

filled with sediments. These deposits are common in all drowned river valleys, but are most extensive in the deltaic plain of the Mississippi River, where submergence exceeds 1.0 cm/year (Penland and Ramsey 1990). Subsidence and associated wetland loss also is accelerated by groundwater withdrawals (Stevenson et al. 2000). Global sea-level rise has been relatively slow since the end of the last ice age, but the rate began accelerating in the 1800s (Church and White 2006). Submergence requires that wetlands increase in elevation by vertically accreting new layers of soil over former soil surfaces, or that wetlands migrate inland and upslope over former uplands.

On the Pacific Northwest and the Gulf coasts, faulting causes marsh loss by lowering the elevation of the marsh surface, which causes flooding stresses that even wetland plants cannot tolerate. **Faulting** is caused by earthquakes in the Pacific Northwest (Kelsey et al. 2002), by the extraction of hydrocarbons in Texas (White and Morton 1997), and by the migration of fluids and gases within ancient and modern deposits of the Mississippi River in Louisiana (Kuecher et al. 2001). Faulting lowers the elevation of the marsh too rapidly to be offset by vertical accretion; thus, managing marsh loss resulting from faulting requires creating new marshes. In the Pacific Northwest, new marshes likely will develop naturally where earthquakes reduce the elevation of uplands. In Louisiana until the early 1900s, new marshes developed naturally as the Mississippi River built new deltas, but current management of the river virtually prevents delta building (Coleman 1988). Some delta building occurs in Atchafalaya Bay (Coleman 1988), and delta building has been reestablished on a small scale at the mouth of the Mississippi River (Boyer et al. 1997).

Coastal wetland managers must manage at different **spatial scales**. Small-scale hydrologic management activities can effectively counter undesirable **small-scale hydrologic conditions**. In Connecticut coastal marshes, for example, restoring tidal exchange in the 1970s and 1980s reduced coverage by common reed, which had increased following impoundment that had been initiated to counter excessive drainage caused by ditch creation (Fell et al. 2000). The effectiveness of small-scale hydrologic management is limited because it can alter hydrological conditions only within the constraints imposed by **larger scale hydrological conditions**. The altering of larger scale hydrological processes, such as those resulting from navigation and flood control projects, requires participation with governmental and private organizations in estuarine- and watershed-level planning activities. Plans have been developed and initiated for many coastal wetlands in the United States. Those plans were summarized (Restore America's Estuaries 2002), but are continually evolving. Managing to accommodate global sea-level rise and faulting likewise requires large-scale planning to accommodate creation of new wetlands. Even when managing and restoring small wetlands, landscape position can in-

fluence success. Landscape position can be critical when coastal wetland restoration or management tools are used in the management of estuarine-dependent fish or migratory shorebirds (Skagen et al. 1999, Simenstad et al. 2000).

VERTICAL ACCRETION

Vertical accretion results from formation of new soil on a wetland's surface. Without vertical accretion, submergence (i.e., the combination of global sea-level rise and local subsidence) would soon drown vegetation of coastal wetlands. **Submergence rates** vary regionally because subsidence rates vary regionally. For instance, submergence during the late 1900s in coastal North Carolina averaged 0.30–0.33 cm/year (Kemp et al. 2009) whereas submergence in coastal Louisiana averaged 1.17 cm/year (Penland and Ramsey 1990). Vertical accretion during gradual submergence can be self-regulating because tidal delivery of mineral sediments increases as flooding increases; soil organic matter also decomposes more slowly as flooding increases (Mitsch and Gosselink 2000). This process prevents wetlands from converting to either permanently flooded habitat or to uplands. Where submergence is rapid, vertical accretion may not maintain the wetland soil surface in the **intertidal zone** (DeLaune et al. 1983a, Hatton et al. 1983). Without adequate accretion, flooding stresses vegetation (DeLaune et al. 1983b, Mendelssohn and McKee 1988), the vegetation eventually dies, and the wetland converts to a shallow pond (DeLaune et al. 1994). The most rapid accretion recorded, 0.98 cm/year, was in a portion of the Mississippi River Deltaic Plain that was submerging even faster (Nyman et al. 1993b).

Costal wetland soil is composed of mineral and organic matter; thus, vertical accretion results from their accumulation. Mineral matter remains after burning, whereas organic matter is consumed (Ball 1964, Davies 1974). Mineral and organic matter accumulation are related because clay sediments can supply plant nutrients (DeLaune et al. 1981) and because vegetation promotes sedimentation by reducing water velocity and biologically trapping sediments too fine to settle from the water column (Stumpf 1983). Thus, plant biomass and soil mineral content are positively correlated in marshes dominated by marshhay cordgrass and smooth cordgrass (DeLaune and Pezeshki 1988, Nyman et al. 1994). It is widely concluded that accretion is inadequate if mineral sedimentation is inadequate and that fate of coastal wetlands primarily depends on mineral sediment accumulation (Hatton et al. 1983, Stevenson et al. 1985, Reed 1989, Nyman et al. 1990b). However, accretion in many tidal freshwater marshes (Neubauer 2008) and some New England and Louisiana brackish and saline marshes depends on organic matter accumulation via vegetative growth (McCaffrey and Thomson 1980; Hatton et al. 1983, Bricker-Urso et al. 1989; Nyman et al. 1993b, 2006; Callaway et al. 1997; Neubauer 2008).

Box 29.1. SLAMM: SEA LEVEL AFFECTING MARSHES MODEL

Vertical accretion can be self-regulating when flooding is moderate (Mitsch and Gosselink 2000) but global sea-level rise began accelerating in the 1800s (e.g., Lambeck et al. 2004) such that sea-level rise during the last half of the 1900s averaged 0.16 cm/year (Domingues et al. 2008). How will coastal wetlands respond to faster sea-level rise? One of the most commonly used models to answer this question is SLAMM (Sea Level Affecting Marshes Model; Clough et al. 2010). SLAMM has been applied to Florida (Glick and Clough 2006), the Pacific Northwest (Glick et al. 2007), Chesapeake Bay (Glick et al. 2008), and Georgia (Craft et al. 2009), with each region being the focus of a different version. The following advice is based on version 6 (Clough and Fuller 2009), which is not regionally constrained.

In the absence of site-specific vertical accretion data, average values are used for different wetland types, such as salt marsh or tidal freshwater marsh, in the region being modeled. Managers should provide modelers with site-specific vertical accretion data so that regional averages are not used. Managers should realize that estimates of vertical accretion based on several years of accretion (e.g. feldspar marker horizons or Surface Elevation Tables [SETS]) probably are less realistic than estimates based on several decades of vertical accretion because of decadal cycles in sea level. Measuring accretion is not something that most managers can do; instead, such tasks probably should be outsourced to people familiar with appropriate techniques (i.e., ^{137}Cs dating and ^{210}Pb dating. Note that ^{137}Cs dating will not work in some areas of the southeastern Atlantic Coast because the type of clays there [see Nyman et al. 1993a]).

Vertical accretion rates did not change over time in older SLAMM. This appears unrealistic because accretion is controlled partly by flooding. Thus, older SLAMM predicted what would happen if sea-level rise accelerated but accretion remained the same. SLAMM(6), however, allows accretion to accelerate to a theoretical maximum, which is more realistic given that accretion is faster where subsidence is more rapid (e.g., Nyman et al. 2006). Managers should work with researchers to determine the maximum rate of accretion for different wetland types in different regions. Currently, the maximum average rate of accretion reported is 0.98 cm/year (Nyman et al. 2006) but that rate might not apply to other coastal wetlands.

Previous versions of SLAMM assumed that elevation of mangroves, salt marsh, and brackish marsh varies predictably only with mean tide and spring tide, but SLAMM(6) is more realistic and assumes that habitat types also vary with salinity. Managers should provide modelers with site-specific elevation and salinity data for different wetland types so that regional averages are not used.

SLAMM requires identifying the elevation that separates uplands from wetlands. SLAMM previously referred to this elevation as mean high spring tide; SLAMM(6) refers to this as salt elevation. Both generally defined this as the elevation expected to be flooded at least once per month. Managers should recognize that when SLAMM modelers request the elevation of the spring tide, or the elevation that is expected to flood at least once per month, they are requesting the elevation that separates wetlands from uplands. The elevation that separates wetlands from uplands probably is a measurement that many managers can provide.

SLAMM previously assumed that “When land is protected by a dike, the accretion or sedimentation is assumed to be zero” and “Enclosed wetlands are assumed to be maintained in their initial condition until there is greater than 2 meter inundation, at which time small dikes are assumed to fail” (Clough et al. 2010:18). SLAMM(6) apparently retains this assumption. This probably is accurate where accretion depends upon mineral sedimentation, but accretion via vegetative growth is more complex. This assumption probably is valid where drawdowns are deep and brief or shallow and persistent. However, this assumption probably will be inaccurate where drawdowns are rare, shallow, and short enough to maintain accumulated soil organic matter, and flooding is persistent enough to stimulate accretion via vegetative growth. Managers should have site-specific elevation data and vertical accretion data for impoundments if they want SLAMM modelers to alter this assumption for impoundments.

The relative amounts of mineral and organic matter cannot be used to identify which of the two, if either, limits accretion; nor can the relative amounts of N and P be used to identify which of the two, if either, limits plant production. Simple correlations between accretion and mineral sedimentation or between accretion and organic matter accumulation should not be used to infer which of the two limits accretion. Controlled experiments to identify which one limits accretion are impractical because it takes decades to accrete several millimeters of soil. Several teams (McCaffrey and Thomson 1980, Gosselink et al. 1984) used logic to conclude that sedimentation controlled soil bulk density (g/cm) and that organic matter accumulation controlled accretion (cm/yr). Several teams (Nyman et al. 1993b, 2006; Turner et al. 2000; Neubauer 2008) used multiple regression analysis to show that accretion is unrelated to mineral sedimentation and positively related to organic accumulation.

Mineral Sediments

Mineral sediments originate from either oceanic sources that are carried landward by coastal currents (Meade 1969), river sediments deposited directly by rivers (Frazier 1967), or river sediments discharged into near-shore coastal waters that are subsequently deposited by coastal currents. Sediment quality and quantity varies seasonally and among years. During **low discharge years**, riverine sediments are greatest shortly before or coincide with maximum river discharge (Mossa and Roberts 1990). During **high discharge years**, riverine sediment concentrations are greatest well before maximum discharge as the riverbed is scoured to accommodate increased flow (Mossa and Roberts 1990). Tides deliver mineral sediments to southeastern Atlantic Coast marshes (Stevenson et al. 1988). Storms, however, deliver more sediments than tides in Louisiana and New England marshes (Stumpf 1983, Reed 1989). Different wetland types apparently require different amounts of mineral matter to accrete (Table 29.1).

Wetland managers should promote mineral sedimentation where it controls accretion, where plant biomass varies with soil mineral content, or where the role of mineral sediments in accretion and plant growth is unknown. Levees

and spoil banks can prohibit sedimentation (Cahoon 1994) and fixed-crest weirs can reduce mineral sedimentation in streamside marsh, but not the marsh interior (Reed et al. 1997). In managed wetlands with levees and water control structures, managers should open structures when sediment availability is greatest in adjacent water bodies.

Organic Matter

Coastal wetland soils need continual additions of soil **organic matter** because soil organic matter continually decays. Even where there is no submergence, soil surface elevation declines when more soil organic matter decays than is produced by emergent vegetation. The amount of soil organic matter needed varies among wetland types (see Table 29.1) because soils contain different amounts of organic matter, and soil organic matter in different wetland types decomposes at different rates. Field and laboratory studies indicate that soil organic matter decays slower in marshes dominated by marshhay cordgrass than in those dominated by maidencane or smooth cordgrass (Smith et al. 1983, Nyman and DeLaune 1991). In addition to origin of soil organic matter, coastal wetland managers should consider soil aeration and soil temperature. Soil aeration greatly controls soil organic matter decay (Nyman and DeLaune 1991). Permanent wetland **drainage** accelerates soil organic-matter decay and can cause loss of several meters of elevation. Permanently lowered water levels also can cause wetlands to lose elevation. Ditch creation permanently lowered water levels and reduced soil elevation up to 10 cm in a Delaware marsh (Bourn and Cottam 1950). Tidal restriction permanently lowered water levels and reduced soil elevation in Long Island Sound marshes (Roman et al. 1984). Unfortunately, the effects of **drawdowns** (which are 2–3-month-long drainage events used to promote establishment of annual vegetation in drained ponds) on elevation have seldom been studied. Extended low waters in Gulf Coast marshes during 1996 reduced soil surface elevation in an unmanaged marsh (Weifenbach and Clark 2000). Elevation loss was greater in a managed marsh that had been managed with a drawdown (Weifenbach and Clark 2000). Temperature greatly controls decomposition, with fastest decay occurring during summer. The interaction of temperature and aeration probably cause prolonged low water, such as occurs during a managed drawdown or natural drought, and reduce soil elevation more during late summer than a similar event during spring.

Wetland managers should promote organic matter accumulation where accretion varies with organic matter accumulation, or where the role of organic matter in vertical accretion is unknown. Organic matter accumulation depends on interactions among plant production, soil organic-matter decomposition, and litter accumulation. Soil strength also varies with live root content of the soil rather than mineral sediments in some coastal wetlands (McGinnis 1997). Thus,

Table 29.1. Estimates of the amounts of mineral and organic matter required for vertical accretion depending on the submergence rate (x). Requirements vary with marsh type and submergence rate (cm/yr).

Marsh type	Mineral matter (g/m ² /yr)	Organic matter (g/m ² /yr)
Fresh	424 x	1,700 + 269 x
Brackish	1,052 x	553 + 583 x
Saline	1,798 x	923 + 601 x

Estimates are from Nyman et al. (1990b).

wetland managers should maximize live root biomass to slow erosion around ponds.

VARIABLES AFFECTING PLANT ESTABLISHMENT AND GROWTH

One of the most striking aspects of coastal wetland vegetation is predictable change in vegetation types across **elevation and salinity gradients**, or for several years following a disturbance. The apparent predictability of vegetation types implies that managers can manipulate disturbance and stresses of flooding and salinity to change vegetation. Common emergent plant species rarely are valuable wildlife food plants. Wetland managers often attempt to increase the carrying capacity for resident wildlife or use-days by migrant wildlife by increasing the abundance of preferred or important food plants. This management involves trade-offs when common plant species are valuable for vertical accretion, soil strength, and wildlife cover. Submerged aquatic vegetation (SAV) species generally are valuable wildlife food plants. Wetland managers, therefore, generally seek to promote growth rather than to alter species composition within the SAV community. Exotic species are an important exception to this generalization. The potential to increase the abundance of SAV and emergent food plants decreases as salinity increases. Stress and disturbance are the primary variables that constrain and create management opportunities. For emergent vegetation, the primary stressors are salinity and flooding;

the primary natural disturbances are from fire, ice, storms, and herbivory. Turbidity and the above variables, except fire, also control establishment and growth of SAV. Wetland managers cannot control these factors, but can influence some of them.

Salinity

Seawater is a complex solution of dissolved salts, dominated by sodium chloride. The salt concentration in seawater is **36 parts per thousand**; thus, 1,000 g of seawater contains 36 g of salt. Salinity in coastal wetlands ranges from fresh (1 ppt) to greater than oceanic (36 ppt) with a gradient existing between marine and fresh waters. Annually, salinity changes relatively little in some wetlands, whereas other wetlands range from fresh to oceanic. During high tides, seawater flows inland through channels and is gradually diluted with freshwater. Tides generally intrude into rivers further upstream than salinity, which creates tidal, freshwater marshes and swamps. Examples abound from the Atlantic Coast (Pasternack et al. 2000), the Gulf Coast (Holm and Sasser 2001), and the Pacific Coast (Simenstad et al. 2000). Nearer the coast, evaporation can concentrate salts until salinity exceeds that of seawater. This is especially true where evaporation exceeds rainfall and wetlands flood infrequently. Examples occur on the Gulf Coast (Hedgepeth 1947) and Atlantic Coast (Weigert and Freeman 1990).

Water salinity strongly controls vegetation composition (Fig. 29.2) and productivity because salinity stresses vegeta-

Fig. 29.2. The relationship between marsh type and average annual salinity, in parts per thousand (ppt). Values are approximate only, after Odum et al. (1984); terminology based on Cowardin et al. (1979).

tion (DeLaune et al. 1987). Emergent vegetation in tidal, fresh wetlands generally is richer and has more complex patterns than in saline wetlands (Chabreck 1970, Pasternack et al. 2000). Similarly, SAV in tidal nonsaline wetlands generally is richer and more abundant than in saline wetlands (Chabreck 1971, Yozzo and Smith 1998, Simenstad et al. 2000). Richness declines as salinity increases because few species can tolerate salinity. Species that can tolerate saline water actually thrive in freshwater, but the reverse is not true. Salt-tolerant plants rarely occur in freshwater wetlands because they are outcompeted by salt-intolerant plants for root space, sunlight, or other unknown factors when salinity is low. For example, smooth cordgrass grows best at 0 ppt in the absence of competition (Parrondo et al. 1978), but in Louisiana, it is restricted to marshes where average salinity exceeds 15 ppt (Chabreck 1970). On the Gulf Coast of the United States, the terms fresh, intermediate, brackish, and saline (Chabreck 1970) reflect the perception that salinity is the primary cause of species associations.

Average salinity may be less important than salinity peaks in controlling species composition, but more important than salinity maximums in controlling productivity. Salinity in the pore-water of the soil, which is the salinity environment experienced by emergent vegetation, is often different from that in floodwater on the wetland surface or in adjacent ponds, lakes, bayous, and canals. In regularly flooded wetlands, pore-water may reflect long-term salinity. In irregularly flooded wetlands, pore-water exceeds salinity of floodwater because evaporation from the soil surface concentrates salts. Seawater trapped in coastal lagoons or slightly elevated marshes, where high evaporation and low freshwater occur, may contain salt levels much greater than sea strength. These waters, such as in the Laguna Madre of Texas and Mexico (Hedgepeth 1947), are described as **hypersaline** and contain salt concentrations that few plants can tolerate.

Human activity has altered salinity in some coastal wetlands sufficiently to change one wetland type to another. Small-scale examples abound on the Atlantic Coast of the United States, where roadways restrict freshwater drainage and maintain a body of water that dilutes incoming tides (Roman et al. 1984). These changes may be helping the spread of common reed on the Atlantic Coast (Chambers et al. 1999). Whereas roads across streams and rivers can "freshen" coastal wetlands, navigation channels within streams and rivers can increase salinity. A large-scale example occurs in southeastern Louisiana, where construction of a navigation channel (Mississippi River Gulf Outlet) accelerated drainage of freshwater and replacement by marine waters over thousands of hectares of baldcypress (*Taxodium distichum*) swamp and low-salinity marshes. Even where navigation channels cause only periodic salinity incursions, emergent vegetation has been altered (Holm and Sasser 2001). Coastal wetlands also can be affected by the damming of rivers. Dams on rivers flowing to the Texas coast exacerbated

hypersaline conditions in the Laguna Madre (Stutzenbaker and Weller 1989). Attempts to counter large-scale salinity increases with local restrictions on tidal exchange have been unsuccessful (Chabreck et al. 1979, Bourgeois and Webb 1999). Total impoundment of a wetland where rainfall exceeds evaporation can maintain nonsaline conditions. An example is a 26,000-ha impoundment in Sabine National Wildlife Refuge in southwestern Louisiana, which is the only freshwater marsh remaining between Sabine Lake and Calcasieu Lake (Gosselink et al. 1979).

Flooding

Some coastal wetlands flood daily, whereas others rarely flood. Flooding strongly controls vegetation composition and productivity because it deprives plant roots of oxygen. The resulting stress can kill plants (Mendelssohn and McKee 1988). **Flooding stress** is probably more related to length than to frequency of flooding events. Several classification schemes are used to classify coastal wetlands on the basis of flooding. In areas where water levels result primarily from solar or lunar tides, such as the Pacific and northeastern Atlantic coasts of the United States, these classification schemes are feasible because flood frequency and duration can be predicted from tide charts and measurements of soil elevation. Coats et al. (1989) illustrated the usefulness of such data in planning wetland restoration and management in San Francisco Bay. In areas where tides are dominated by winds, such as Chesapeake Bay and the Gulf Coast of the United States, these classification schemes are of little use to wetland managers because of a lack of long-term hourly data needed to calculate flood duration. In practice, most coastal wetland managers classify wetlands based on species composition of emergent vegetation rather than flooding. On the northeastern Atlantic Coast of the United States, classifying wetlands as regularly or irregularly flooded reflects the perception that flood frequency is the primary cause of differences in species associations. Within most coastal wetlands, emergent vegetation is taller and more productive adjacent to creeks and bayous than in the wetland's interior because these soils regularly drain. This generally applies whether the streamside wetland is lower (Fig. 29.3) or higher (Fig. 29.4) than interior wetland.

Fire

Fire is the primary disturbance factor in many tidal, nonsaline marshes, but is less common in saline marshes. Plant species richness is generally greatest in the growing season immediately following a fire. After several growing seasons, species richness declines as a few species regain dominance. Fire has been occurring in coastal marshes since before European settlement (Frost 1995). Fires start naturally via lightning and by spontaneous combustion (Viosca 1931). Native Americans and initial European settlers regularly burned coastal marshes, but their activity may have been irrelevant

Fig. 29.3. A possible zonation pattern found in a brackish Pacific Northwest tidal marsh. LW = low-water mark; HW = high-water mark. After Seliskar and Gallagher (1983).

Fig. 29.4. A possible zonation pattern found in a southeastern Atlantic tidal saline marsh, showing sedimentary development. After Weigert and Freeman (1990).

in the southeastern United States because fire compartment size and frequency of lightning were great (Frost 1995). On the Pacific Coast, however, burning by Native Americans probably was important in governing vegetation structure because size of fires was smaller and lightning was less frequent (Frost 1995). Prescribed burning decreased by the early 1900s, at least on the Gulf Coast of the United States, but returned by 1926 (Hoffpauer 1968). By the 1930s, wildlife managers concluded that periodic burning prevented wildfires and increased abundance of important wildlife food plants (Arthur 1931, Griffith 1940, Lynch 1941, Smith 1942, Uhler 1944, O'Neil 1949). Many marsh managers on the Gulf and Atlantic coasts burn marshes regularly (Nyman and Chabreck 1995, Stevenson et al. 2000). However, some burning apparently is done because of tradition rather than to achieve clearly stated, measurable goals.

Hurricanes

Hurricanes regularly affect wetlands on the Gulf and southeastern Atlantic coasts. Although coastal wetlands slow inland movement of storm-driven floodwaters, hurricanes may be the most destructive force affecting wetlands and wildlife populations. Harris and Chabreck (1958) noted removal of

sod that was 0.3 m thick and up to 1.5 m in diameter by a hurricane and noted a 140% posthurricane increase in vegetation openings. Chabreck and Palmisano (1973) also noted a 118% increase in openings in the emergent vegetation following a hurricane. In 2002, tropical storm Isadore and/or hurricane Lilly virtually eliminated SAV from >100 km of coastal Louisiana (J. A. Nyman, personal observation). Hurricanes have reduced white-tailed deer (*Odocoileus virginianus*), muskrat, nutria, rabbit (*Sylvilagus* spp.), and raccoon numbers by 60–70% (Ensminger and Nichols 1957, Harris and Chabreck 1958). Wetland managers can do little to manage such damage.

Hurricanes push high-salinity water over normal impediments and into nonsaline wetlands, where high salinity levels may be maintained for weeks or months. Vegetation may be stressed or killed if the storm surge is much saltier than normal waters and higher salinity is maintained in the wetland. One of the dangers of using levees to manage coastal wetlands is the threat of storm tides pushing high-salinity water over levees and the resulting long period of flooding. Some managers of wetland impoundments in coastal Louisiana have removed portions of levees following hurricanes to reduce flooding because they have concluded that it is

better to lose water control for several years than it is to flood with high-salinity water for several weeks.

Herbivory

Wildlife managers face conflicting goals regarding **herbivory**. A common management goal is to increase availability of food plants for geese, muskrats, nutria, or cattle. Conversely, herbivory by geese, muskrats, and nutria can be sufficient to denude coastal marshes of vegetation and cause emergent marsh to convert to shallow open water (Lynch et al. 1947). In the ideal situation, plant mortality caused by herbivory is compensatory to other forms of mortality. Thus, no need would exist to increase food plant abundance because herbivore populations would be limited by a factor other than food availability.

In situations where food limits herbivore populations, increasing abundance of food plants would increase herbivore populations. This was a common situation and management objective before the 1990s when pelt prices of nutria and muskrat were sufficiently high to support commercial trapping. Currently, populations of nutria and muskrats are adequate to support the limited commercial trapping and there is little need to encourage growth of food plants for furbearers.

Herbivores may consume plants faster than plants can replace themselves eliminating vegetation and destroying habitat for many species. Such denuding of vegetation has been called an “**eatout**” and such incidents occur on all North American coasts (e.g., Lynch et al. 1947, Smith and Odum 1981). In these situations, herbivore populations are limited by a variable other than food availability until vegetation is denuded. After vegetation is reduced, animals starve or migrate to adjacent areas. Species causing the most “eatouts” are muskrats, nutria, and geese (Lynch et al. 1947, Smith and Odum 1981).

Turbidity

Water clarity, measured as **turbidity**, is the most important variable limiting submersed aquatic vegetation in coastal ponds because it controls the amount of sunlight available for photosynthesis. Silt, clay, and phytoplankton can cause high turbidity. Fish can indirectly cause high turbidity by constantly disturbing loose bottom sediments. Sedimentation can be sufficiently rapid to bury emergent and SAV. Commercial culture of Pacific oysters (*Crassostrea gigas*) can reduce and eliminate SAV beds in the Pacific Northwest by increasing sedimentation rates (Everett et al. 1995). Limiting the inflow of surface waters that carry river-borne or marine silt and clays can reduce turbidity. **Drawdowns** also are used to reduce turbidity by causing bottom material to cement together and by removing fish (Chabreck 1960).

Competition and Succession

Much of the variation in vegetation across a wetland results from stress gradients (flooding or salinity) because stresses influence **competition** among plant species for light and nu-

trients. Managing stresses generally requires manipulating water exchange between wetlands and adjacent water bodies. Restoring tidal exchange to remove common reed is an example of increasing salinity stress to achieve a management goal (Fell et al. 2000).

Variation in vegetation over time is the result of **succession** following disturbances (fire, ice, hurricanes and, on the Pacific Coast of the United States, vertical land movement). Robust, perennial plants that are unimportant wildlife foods such as cordgrasses, maidencane, or common reed usually dominate an undisturbed marsh. Most important wildlife food plants, such as the flatsedges (*Cyperus* spp.), spikerushes, and barnyard grasses (*Echinochloa* spp.), are annual plants and require disturbance to create open, exposed soil for germination and growth. Small seedlings are unable to compete with larger plants and, to survive, must take advantage of openings created by disturbances that kill other plants.

The primary tool that wetland managers use to disturb emergent vegetation is fire. Managers also can drain ponds to initiate the establishment of annual vegetation on exposed bottoms, as is common in moist soil management of inland wetlands (e.g., Anderson and Smith 2000). The goal of drainage, or drawdown, is to promote growth of annual species that are abundant seed producers. Drawdowns are harder to achieve in microtidal than in regularly flooded or seasonal wetlands because continuous levees and pumps generally are needed. In regularly flooded wetland, gravity drainage is sufficient to achieve drawdown.

PLANNING HABITAT MANAGEMENT IN COASTAL WETLANDS

Restoring a coastal wetland to its original condition is costly and, in most cases, extremely difficult. Coastal wetlands are **dynamic systems** and, if it were possible to completely restore a wetland, it could be restored to only one stage in its frequently changing past. Thus, management goals generally focus on maximizing productivity, quality, and diversity. Ecological processes in coastal wetlands are complex and involve the action and interaction of numerous factors. All plants have a range of tolerance for disturbance and for water salinity, quality, and depth; generally, plants will grow as long as the conditions are within this range (Penfound and Hathaway 1938, Chabreck 1972). Whenever conditions exceed the tolerance range for an extended period of time, plants unable to tolerate the changed conditions will die and other species, whose requirements have been met due to the change, will dominate the area. Managers manipulate these processes to produce the desired plant and animal communities. Achieving management goals may require changing conditions; whereas, achieving other management goals may require protective measures to maintain existing conditions. Regardless, the only practical tools for extensive areas of wetland are manipulation of water levels, water salinities, and frequency of disturbances such as fires, floods, and

drawdowns. With such manipulations, the wetland manager can manage wildlife habitat quality by encouraging **desirable plants** and discouraging **undesirable plants**.

Wetland management is costly and benefits gained depend upon the amount invested, the skill with which the program is planned, and the recognition of opportunities and restraints provided by regional hydrologic patterns. Unfortunately, management frequently has been initiated to correct problems that were not fully understood or to achieve vague goals. This is a problem on the Atlantic (Perry et al. 2001), Gulf (Chabreck 1988), and Pacific coasts (Williams and Farber 2001). Planning by persons familiar with a problem and the ecological processes operating in the area will reduce the cost of the program and increase its effectiveness.

In planning a wetland management project, careful consideration should be given to several factors. There should first be an evaluation of **environmental conditions** present in the area, such as major plant communities, drainage patterns, water quality, water levels, soils, and existing structures. This **evaluation** should consider the area to be managed, as well as the estuary and watershed level. Second, animal communities in the area should be identified and target species selected for management. The objectives should be clearly stated, site specific, measurable, and long term (Restore America's Estuaries 2002). Third, habitat conditions including plant communities, water quality and levels, soils, disturbance regime, and other factors necessary to produce the target animal communities should be identified. Fourth, the optimal growth requirements to produce the desired and undesired plant communities should be identified. Fifth, management procedures available for producing the habitat conditions required by target animal communities should be evaluated to develop specific management guidelines. Sixth, acquisition of data that can be used to evaluate the management effectiveness must be planned. Management activities implemented without subsequent data collection can be neither defended nor criticized objectively. Regular collection of **postmanagement data** is needed to guide management improvement. Coastal wetland managers should consider collaborating with a few dedicated volunteers who, in some cases, have provided critical data over years (e.g., Erwin and Beck 2007). Objectively evaluating wetland management requires data from a similar unmanaged area or from a suite of unmanaged areas (Brinson and Rheinhardt 1996). Simply comparing the managed area before and after management is initiated or altered is unlikely to be useful because of annual variability in hydrological conditions and in plant and animal abundance (Neckles et al. 2002, Restore America's Estuaries 2002).

CREATING COASTAL WETLANDS

Created coastal wetlands generally have broad goals, but some have been created to benefit several fish species (Simenstad et al. 2000) or a single bird species (Zedler 1993). Some

created coastal wetlands are virtually identical to natural coastal wetlands, whereas others are not. The inability to fully replicate natural wetlands is a valid critique of wetland mitigation projects, which often are required by the **Clean Water Act** to offset development of natural wetlands. However, created wetlands that are not part of a mitigation program contribute to a net gain in wetlands and wetland wildlife habitat. Even when created to mitigate for wetland losses under the Clean Water Act and unequal to natural wetlands, created coastal wetlands can provide suitable habitat to multiple wildlife species (Brusati et al. 2001, Armitage et al. 2007, Desrochers et al. 2008).

One challenge to creating a new coastal wetland is obtaining an appropriate **surface elevation**. An appropriate surface elevation will be low enough to create flooding stress that eliminate upland plants species, but not so low that even wetland plant species will be eliminated. Guidance regarding elevations is available only for a few regions (e.g., Montalto et al. 2006, Nyman et al. 2009).

Young, created wetlands generally lack flora and fauna of old, natural wetlands, which is especially problematic when the goal is to create habitat for an endangered species (Zedler 1993). Many differences between natural and created wetlands arise from lower amounts of soil organic matter in created wetlands (Craft et al. 2002). The resulting differences in soil chemical environment cascade up the food web and alter communities of emergent vegetation, soil annelids and insects (Levin and Talley 2002), and fish (Chamberlain and Barnhart 1993). **Dredged material wetlands** create benthic and avian communities similar to natural wetlands if the created wetlands have water levels and circulation patterns that mimic those in natural wetlands and if the created wetlands are near natural wetlands (Brusati et al. 2001). There appear to be fewer differences between created and natural wetlands when tidal or riverine energy, rather than dredging equipment, deposits the sediments. This may occur because tidal and riverine waters cannot elevate the sediments higher than is found in natural wetlands.

The ability of created coastal wetlands to vertically accrete probably depends upon the same accretion processes occurring in natural wetlands in the region, but data are needed to test this assumption. If natural wetlands in the region naturally accrete via vegetative growth, then it is likely that the created wetland will begin to vertically accrete after emergent vegetation establishes and the wetland floods enough to stimulate root production at the soil surface (Nyman et al. 2006). If natural wetlands in the region naturally accrete via mineral sedimentation, then it is likely that the created wetland will begin to vertically accrete after tides and storms flood the wetland enough to deliver available mineral sediments.

Excavating Uplands to Create Coastal Wetlands

Uplands can be converted to coastal wetlands by excavating upland areas to reduce their elevation while also connecting

them to adjacent tidal water bodies. This is referred to as **restoration** when the site is a former wetland and the material being excavated was placed there to fill the wetland (e.g., Armitage et al. 2007). Migrating birds use such wetlands at rates similar to natural wetlands (Armitage et al. 2007, Desrochers et al. 2008) or even more frequently (Havens et al. 1995), but breeding birds do not (Armitage et al. 2007, Desrochers et al. 2008). Reduced breeding bird use has been attributed to a lack of the unvegetated habitat preferred by shorebirds (Armitage et al. 2007), a lack of short vegetation (Desrochers et al. 2008), and a lack of the expansive marsh areas preferred by songbirds (Havens et al. 1995). Havens et al. (1995) made several recommendations, including creating a more natural microtopography, but also regarding soils, vegetation, and habitat complexity. Wallace et al. (2005) recommended excavating larger creeks and leaving unplanted corridors, especially in the higher elevation areas where creeks are less likely to develop on their own.

Wetlands created by excavating uplands have different soils and vegetation than natural wetlands, but those differences decline over decades at rates similar to naturally, newly created wetlands (Krull and Craft 2009). Managers excavating uplands to create coastal wetlands should, therefore, allow 1–2 decades for benthic, plant, and wildlife communities to approach those found in older, natural wetlands. Such development might allow vegetation and breeding bird use of this type of wetland to approach that of older, natural wetlands.

Placing Dredged Material in Open Water

Sediment dredged from navigation channels can be used to create emergent wetlands if the dredged material is placed to create an **intertidal surface**. Sediments generally originate as a byproduct of dredging to maintain depth of **navigation channels**, in which case projects often are referred to as “beneficial use of dredged material” projects. Dredging solely to obtain sediments for creating wetlands (i.e., “dedicated dredging”) is less common. Goals of projects to create wetlands on dredged material are to optimize use of the material, expand area of wetlands, and slow erosion. Studies of coastal wetland creation on dredged spoil primarily have been conducted by the U.S. Army Corps of Engineers. Early studies were in North Carolina (Woodhouse et al. 1972), while others dealing with dredged material and shoreline stabilization were along Chesapeake Bay (Garbisch et al. 1975), Galveston Bay (Dodd and Webb 1975), and San Francisco Bay (Knutson 1976, Josselyn and Buchholz 1984).

Creating coastal wetlands on dredged material generally has been successful at creating new habitat for emergent vegetation, but success varies. In areas with **firm substrates**, success is greater than in areas where the substrate is poorly consolidated. Without a firm base for support of deposits, the dredged material rapidly subsides and sinks below the

surface of the water (Chabreck 1989). Substrate composed of fine clays and silts may remain in a slurry state for a significant period after placement and require a retaining structure for containment. The final elevation when such substrates dry is much more difficult to predict than when substrates are composed of sandy material that lose water and dry quickly (Chief of Engineers 1986). Wetlands created from dredged material have different soils and vegetation than natural wetlands, but those differences are expected to decline over decades (Edwards and Proffitt 2003). Nonbreeding shorebirds have been observed to use natural and dredged wetlands similarly, but breeding birds have not (Brusati et al. 2001, Erwin and Beck 2007). Failure of successful breeding-bird reproduction on this type of created wetland has been attributed to predators (Erwin and Beck 2007), but factors related to sediment quality and topography probably apply to this type of created wetland, as they do to wetlands created by excavating uplands. If similarity in nonbreeding birds use between natural and dredged wetlands was a consequence of similar benthic invertebrate communities as Brusati et al. (2001) hypothesized, then dredged areas that have finer sediments and fewer benthic invertebrates than natural areas, such as in the one described by Bilodeau and Bourgeois (2004), will not support birds in the same way as will natural wetlands. It is possible that such differences will decline over time as finer sediments in created areas are removed by tidal and storm energy. Managers using dredged material to create coastal wetlands should, therefore, try to obtain sediments similar to that in areas with high wildlife use and should allow years or decades for benthic, plant, and wildlife communities to approach that found in natural areas.

The **hydraulic pipeline dredge** is most commonly used for projects involving dredged material. Hydraulic pipeline dredges can push material through 5–8 km of pipeline without intermediate booster pumps. With long-term planning, wildlife managers can work with navigation managers (i.e., the U.S. Army Corps of Engineers) to create coastal wetlands from dredged material that otherwise is deposited offshore or piled on uplands. Such wetlands will need to be within 10 km of a navigable waterway unless wildlife managers can provide the additional funds needed to pump sediments further.

Establishment of wetland plants on dredged material should not be left to natural invasion because erosion can be very substantial during the time required for natural invasion to fully vegetate shorelines, even in tidal freshwater areas. Planting marshhay cordgrass is recommended for sites in intermediate and brackish marshes along the Gulf of Mexico (Eleuterius 1974). A large seed source makes plantings unnecessary in San Francisco Bay (Williams and Farber 2001). In saltwater areas, smooth cordgrass should be planted below mean high tide, and marshhay cordgrass above mean high tide (Allen et al. 1978, Landin 1986). Plant

spacing of 45 cm and 90 cm was tested (the 45-cm spacing required 4 times more plants). The 45-cm spacing had lower plant survival, but produced stands with greater density. Fertilization of plantings has not increased survival (Allen and Webb 1983).

Using Rivers to Create Coastal Wetlands

River flow can be used to create wetlands. This often is possible in floodplains where preexisting wetlands have subsided and been replaced by agricultural impoundments or shallow, open water. Such agricultural impoundments were commonly constructed before the 1900s in the tidal portions of many rivers, such as the Sacramento River in California and the Cooper River in South Carolina. Cycles of wetland creation, subsidence, and rebuilding also are natural to river deltas worldwide (Coleman 1988). Constructing openings in natural or artificial levees permits water confined in river channels to enter adjacent shallow-water areas where the unconfined water spreads and slows. Water deceleration allows sediment to be deposited, thereby creating deltas (Chabreck 1988). Such projects are often called sediment diversions even though they may be restoring river flow. Sediment diversions in the lower Mississippi River have created wetlands at a rate of 4.7 ha/year (Boyer et al. 1997). Wildlife use of wetlands created in this manner is assumed to be virtually the same as in natural wetlands because sediment deposition in these created wetlands is assumed to lead to sediment quality, water quality, channel density, and microtopographic structures typical of that in wetlands created by unmanaged sediment deposition by rivers, but data are lacking. Wetland managers employing sediment diversions should anticipate years to decades between opening the levee and the development of emergent vegetation. Frequently, sediment elevation rapidly increases, but then remains static for years at an elevation too low for emergent vegetation, but too high to accommodate sufficient river flow to deliver additional sediment. Such pauses appear to be broken by unusually large spring floods that add the final few centimeters of sediment needed to allow emergent plants to establish.

Using Tides to Create Coastal Wetlands

Tidal flow can be used to create wetlands. This often is possible where preexisting wetlands have subsided and been replaced by agriculture, salt production ponds, or shallow open water. Some refer to these projects as restoration because they create wetlands in areas where wetlands formerly occurred (Williams and Farber 2001). Restoring tidal flow to impounded, former wetlands is common on the Atlantic and Pacific coasts (Chamberlain and Barnhart 1993, Able et al. 2000), but not on the Gulf Coast, where tidal energy and sediment availability are so low that breached impoundments remain shallow open water. Some of these efforts have specific goals such as creating wading-bird habitat

(Fell et al. 2000) or creating fish habitat (Simenstad et al. 2000), but some are accidental (e.g., Byers and Chmura 2007). Success of these projects at recreating coastal wetlands depends on the availability of sufficient sediments in adjacent waters and the tidal energy to carry sediments into the restoration. Success appears to increase with surface elevation at time of restoration, sedimentation rate, and range of tolerance by colonizing vegetation (Byers and Chmura 2007). On the Atlantic Coast, Perry et al. (2001) recommended grading sites to favor low marsh rather than high marsh prior to reestablishing tidal exchange, to reduce coverage by common reed.

Building Terraces to Create Coastal Wetland Edge Habitat

Terrace construction has been described as creating only edge habitat (Fig. 29.5). **Terraces** are constructed by dredging shallow open-water areas and piling the dredged material in 5–20-m-wide rows to form a linear, **intertidal surface**. Emergent vegetation, such as cordgrasses, generally is planted on the edges to accelerate the establishment of rooted vegetation, which reduces erosion. Terraces are used in coastal Louisiana and Texas to slow the erosion of adjacent, preexisting wetlands. It is assumed that 1 ha of terrace (10 m × 1,000 m) provides more fish and wildlife habitat than 1 ha² (100 m × 100 m) of created wetland because of the tremendous ratio of edge to area in terraces. It also is believed that terraces promote sedimentation by slowing

Fig. 29.5. Aerial view of marsh terraces constructed in Louisiana coastal marsh ponds. Terraces generally are constructed in pond areas created by wetland loss, to slow erosion of remaining wetlands and to increase habitat quality for fish and wildlife by providing abundant edge habitat. This image shows 4 different terrace designs; large terrace fields containing straight terraces surround the points indicated by (A) and (B). Smaller terrace fields containing curved terrace are adjacent to the points indicated by (C) and (D).

wave and wind energy in the ponds (Turner 1999). Unlike spoil banks, which are continuous and rise above normal tides, terraces are discontinuous and flood at high tide. Constructing terraces gained popularity as a restoration and mitigation technique following reports that terraces near the Calcasieu Ship Channel on Sabine National Wildlife Refuge reversed shoreline erosion and created almost 7 ha of salt marsh with an interface of almost 1,525 m (Steyer 1993). Terraces also increase submersed aquatic vegetation and, hence, waterfowl, fish, and invertebrates (La Peyre et al. 2007, O'Connell and Nyman 2010). The effectiveness of terraces at slowing erosion of adjacent wetlands remains unknown, primarily because of the newness of the technique and the long time required for differences in erosion to become measurable.

Wave Dampening Fences

Since 1989, discarded Christmas trees held in place by fence materials have been used in coastal Louisiana to slow wetland erosion and create wetlands. Fike and Wicker (1992) described projects constructed in coastal Louisiana through 1992 and made recommendations to improve planning and construction. Bahlinger (1996) examined 6 Christmas tree projects and documented effects ranging from marsh creation, to increased coverage by submersed aquatic vegetation, to reducing depth of ponds and channels. Nyman (1997)

concluded that 8 of 29 Christmas tree projects in coastal Louisiana appeared to slow erosion and/or create emergent wetlands. Scarton et al. (2000) and Boumans et al. (1997) likewise reported that although Christmas tree fences caused sediment accumulation in adjacent ponds, they had little effect on marsh creation and emergent vegetation.

MANAGING EXISTING COASTAL WETLANDS

Managing existing habitats generally involves **trade-offs** because habitat needs for some wildlife species are mutually exclusive with other species of wildlife, some fish species, or some plant communities (Table 29.2). Thus, management efforts can provoke conflict among affected interests. For example, managers of coastal wetlands and managers of estuarine-dependent fisheries have disagreed over the acceptability of reducing channelized tidal flow in coastal wetlands caused by navigation canals. If effective management programs are to proceed, then concessions must be made with the best interests of the sustainability of all resources in mind.

Salinity Management

Tidal Restoration

Coastal wetlands that were converted to hay farms or freshwater impoundments, as used to be common in New Eng-

Table 29.2. Compatibility of various coastal wetland management goals with various techniques for managing existing coastal wetlands. Exceptions undoubtedly exist and compatibility may be reversed in some regions. For these reasons, this table is offered as a list of relationships to be considered by wetland managers rather than as predictions of how a particular technique on a particular coastal wetland will affect a particular management goal.

Management goal	Management technique						
	Salinity management		Water-level management			Succession management	
	Tidal restoration	Freshwater reintroduction	Impoundment	Impoundment and semi-impoundment	Fire	Drawdown	Timber harvest
Breeding waterfowl	o ^a	x ^b	xo ^c	xo	o	x	o
Migrating waterfowl	o	x	xo	xo	x	x	xo
Breeding wading birds	x	x	xo	xo	o	x	o
Migrating wading birds	x	x	xo	xo	xo	x	xo
Migrating shorebirds	x	x	xo	xo	xo	x	xo
Breeding passerines	x	o	xo	xo	x	o	xo
Migrating passerines	x	o	xo	xo	x	o	xo
Mammals	o	x	xo	xo	x	x	xo
American alligator	o	x	xo	xo	xo	x	xo
Freshwater fish	o	x	xo	xo	xo	x	xo
Estuarine fish	x	x	o	o	xo	xo	xo
Marsh vertical accretion	x	x	xo	xo	x	x	xo

^a "o" indicates that a technique and a goal generally are incompatible.

^b "x" indicates that a technique and a goal generally are compatible.

^c "xo" indicates that a technique and a goal can be compatible or incompatible depending upon how the technique is implemented, or that different species in the target group will respond differently.

land, offer opportunities to restore wildlife habitat. Such hay farms are considered agricultural wetlands because they are dominated by marshhay cordgrass. Restoring tidal exchange by breaking dikes replaces the passerine bird community of hay farms with waders, waterfowl, shorebirds, and gulls (Slavin and Shisler 1983). The increase in waterbird use is attributed to the replacement of dense vegetation with non-vegetated areas. Coastal wetlands that were **impounded** to increase waterfowl habitat by reducing salinity can be restored by breaking dikes or installing culverts. Such management increases the number of saltmarsh sharp-tailed sparrows, seaside sparrows, semipalmated sandpipers (*Calidris pusilla*), and least sandpipers (*C. minutilla*) presumably at the expense of less salt-tolerant waterbirds (Brawley et al. 1998).

Freshwater Reintroduction

Diversion of freshwater into marshes is currently used at several locations along the lower Mississippi River to restore deteriorating marshes; it is being considered in other areas where feasible. These actions, commonly called **river diversions**, restore spring floods prevented by flood protection levees. **Culverts** and **siphons** are used to allow river water to pass through or over levees during flood stages. Water flows through the marsh, adding sediment and nutrients, lowering water salinity (Lane et al. 1999), increasing SAV and nekton abundance (Rozas et al. 2005), and increasing emergent (DeLaune et al. 2005) plant growth. The added sediment and increased plant growth may contribute to vertical accretion and slow land loss. Reducing water salinity and adding nutrients promotes plant growth, increases plant species diversity, and increases habitat quality for numerous fish and wildlife. A major handicap of this type of restoration is that it can only be used in wetlands adjacent to the freshwater source. Freshwater reintroduction into an estuarine basin will change salinity regimes and enhance vegetation growth; however, concern has been expressed regarding other impacts associated with water salinity changes. Harvestable resources such as eastern oysters (*Crassostrea virginica*) and brown shrimp (*Farfantepenaeus aztecus*) become more accessible as saltwater encroaches into formerly freshwater or low-salinity habitats closer to urban areas. Unfortunately, industrial and domestic pollution also are more severe in these areas and may affect these resources (Chatry and Chew 1985).

Water Control Structures

Dikes and levees have been used to increase habitat quality for waterfowl by holding freshwater and excluding saline water from saline marshes. The resulting impoundments will freshen if rainfall and freshwater inflow exceed evaporation, and diversity and production of waterfowl food plants increases. Many such impoundments were constructed on the Atlantic Coast throughout the early 1900s, but tidal action was restored during the late 1900s to some such wet-

lands to increase habitat quality for waterbirds that prefer more saline conditions (e.g., Brawley et al. 1998).

Managers sometimes attempt to reduce water salinity across thousands of hectares of wetlands with levees, culverts, **flashboards**, **weirs**, etc., to offset regional increases in salinity across hundreds of square kilometers caused by channelized tidal exchange in navigation channels. Even where rainfall and freshwater inflow exceed evaporation, such attempts merely moderate extreme salinity without affecting mean salinity if **fixed-crest weirs** are used (Chabreck et al. 1979), but mean salinity can be lowered if levees are combined with versatile water-control structures such as **gates** and **variable-crest weirs** (Miller 2003; Sharp and Billodeau 2007a, b). This type of management can interfere with the ingress and egress of estuarine nekton from the marsh (Hoesse and Konikoff 1995), which can lead to conflicts with agencies charged with promoting estuarine fisheries that benefit from channelized tidal flow.

Water-Level Management

Levees, culverts, flashboards, weirs, etc., have been used in coastal wetlands since the mid-1900s to create water levels that favor growth of desired vegetation and/or provide water depth needed by different species of waterbirds (Griffith 1940, Landers et al. 1976). The term **drawdown** refers to drainage for several months in spring and summer to establish annual vegetation by converting pond areas to mud flat areas. When reflooded, the ponds provide abundant seeds for waterfowl (Landers et al. 1976). This type of management mimics that of moist soil management that is common in inland wetlands, and it is generally successful in coastal fresh marshes but fails in coastal saline marshes. Even in marshes dominated by marshhay cordgrass where salinity averages 5 ppt, exposed pond bottoms generally fail to develop stands of annual vegetation (J. A. Nyman, personal observation). Water-level management can be classified as (1) permanently flooded to provide water for waterbirds and to promote submersed aquatic vegetation, (2) occasionally drawn down to promote annual vegetation, reduce lateral erosion, or create water depths shallow enough for target waterbirds, or (3) managed to provide habitat for waterbirds when ponds otherwise would be drained by unnaturally low tides. Wading birds require shallower water than waterfowl (Isola et al. 2000).

Impoundments have been criticized because they reduce tidal exchange that may provide an energy subsidy that can increase plant production (Odum et al. 1983), reduce mineral sedimentation that can be important to vertical accretion (Reed et al. 1997), and reduce access to the wetland by estuarine-dependent fish and crustaceans (Hoesse and Konikoff 1995). However, studies on the Gulf and Pacific coasts found that plant production increases in response to tidal restriction if it reduces salinity or flooding stress (Zedler et al. 1980, Flynn et al. 1999). A problem for wetland managers is

that some wetland impoundments can fail to reduce flooding stress as intended (Flynn et al. 1999).

Engineering and Hydrology of Impoundments

Impoundments are constructed in coastal wetlands by enclosing an area with a continuous levee system or by using levee systems in conjunction with elevated ridges or uplands to form a closed system (Ensminger 1963). Water control structures are an important part of an impoundment. **Spillways** allow drainage of surplus water associated with rainfall or hurricanes, and stop-logs are used to vary drainage levels. Increasingly, flap-gated culverts are combined with stop-log structures (Fig. 29.6). Facilities also must be provided for completely draining and flooding impoundments. **Gravity drainage** may effectively remove water through gated culverts in areas with extreme tidal fluctuation. However, in many areas, gravity drainage is inadequate and wetland managers must use pumping units to remove water.

Rainfall is the primary water source for most impoundments, particularly freshwater systems. If rainfall is not adequate, ample water may be unavailable to meet management requirements and pumps may be needed. Some wetland managers use one pumping system, with appropriate control structures, to either drain or flood an impoundment. Pumping also may be used to flood brackish water impoundments. In some areas, water can be added by opening control gates on high tides and closing them as tides fall. This process can be facilitated with structures having flap gates that are opened and closed by water pressure (Neely 1960, Williams 1987).

Permanently Flooded Impoundments

Permanently flooded freshwater impoundments received high use by waterfowl, but also can develop large populations of sunfish and largemouth bass that are heavily used by fishermen (Turner 1966). Permanently flooded freshwater impoundments are usually inland and have minor tidal influence. Water-level manipulation in this type of impoundment is minimal and operational costs likewise are minimal. Freshwater marshes permanently flooded by impounding usually have greater water depths than nonimpounded, tidal freshwater marsh. During periods with unusually abundant rainfall, water may be as much as 1.2 m deep. Marsh soils typically have low mineral content because of a lack of sediment in floodwater and because decomposition is slower in flooded soils. In permanently flooded freshwater impoundments, organic matter accumulates at a greater rate and marsh elevations increase above that of natural marsh. Emergent vegetation can colonize scattered floating mats of organic material that often develop on the water surface. Lack of disturbance also allows perennial species to dominate emergent vegetation and spread vegetatively into shallow open-water areas. Over time, shallow open water can be replaced by dense stands of emergent vegetation and only deep water remains. This type of succession is common (van der Valk 1981). Drainage and herbivory generally are the factors that disturb such wetlands (van der Valk 1981), but coastal wetland managers have an additional tool: salinity. At Rockefeller Wildlife Refuge in southwestern Louisiana, saltwater is introduced every 30–40 years to kill emer-

Fig. 29.6. Side and top views of a flap-gated culvert with stop-logs. The stop-logs are inside the managed marsh and can be removed to allow water to drain in the managed marsh, or stacked to prevent drainage. The flap-gate is outside the managed marsh and can be raised to allow the entry of outside water, or left flapping out. When flapping out, the flap will close when the outside water is higher than inside water, but will open when outside water is lower than inside water. Stop-logs are removed and the flap gate is left flapping out to draw down a marsh. After L. J. Broussard, U.S. Soil Conservation Service, Department of Agriculture, Alexandria, Louisiana.

gent vegetation that comes to dominate ponds and, thereby, restore interspersion of pond and emergent vegetation.

Permanently flooded brackish water impoundments are usually managed to produce widgeongrass and dwarf spikerush (*Eleocharis parvula*) to attract ducks (Chabreck 1960, Gordon et al. 1989), but they also produce large populations of shrimp and blue crabs (Strange 1987, Davidson and Chabreck 1989). A survey of marsh impoundments in South Carolina disclosed that permanently flooded brackish water impoundments were used most often (Morgan et al. 1975). Although these impoundments are described as permanently flooded, temporary drainage at 2–3-year intervals to remove fish, consolidate bottom material, and reduce water turbidity was necessary for best widgeongrass growth (Chabreck 1960, Joanen and Glasgow 1965). In Louisiana, brown shrimp were introduced in February and white shrimp were introduced in July by opening water control structures at high tide when postlarval shrimp were present (Davidson and Chabreck 1989).

Manipulated Impoundments

Water levels can be **manipulated** to affect plant growth in coastal wetlands in a manner very similar to most soil management common in inland wetlands. If the manipulated impoundment contains a freshwater wetland, then the similarity to moist soil management is striking in that impoundments are drained during the growing season to encourage germination and growth of annual plants. The major species produced by drying are grasses and sedges (Chabreck 1960, Baldwin 1968), such as coast cockspur (*Echinochloa walteri*), fall panicum (*Panicum dichotomiflorum*), and fragrant flatsedge (*Cyperus odoratus*). Other plants often found in this type of impoundment are bulltongue, California bulrush, and spikerushes. Impoundments can be reflooded when seedlings are about 15 cm tall. Water depths are usually maintained at low levels (10–50 cm) during winter to make the areas attractive to dabbling ducks. Crawfish provide food for many forms of wildlife, and are produced in abundance by this management system and (Perry et al. 1970).

If the manipulated impoundments contain brackish marsh, then draining during the growing season and reflooding throughout the remainder of the year can encourage growth of sturdy bulrush (*Bolboschoenus robustus*) in the emergent marsh, but the greatest effects occur in the drained ponds where, upon reflooding, the growth of SAV will be encouraged (Neely 1960, Landers et al. 1976). Impoundments of this type comprised approximately 10% of the total area of marsh impoundments in South Carolina (Morgan et al. 1975). These areas are flooded to a depth of 25–30 cm during autumn and winter to provide habitat for ducks. If water salinity exceeds 15 ppt, growth and seed production of sturdy bulrush will be adversely affected (Gordon et al. 1989). Impoundments may increase plant stress where they increase flooding duration (Bourgeois and Webb 1999).

Whether in fresh or brackish marsh, drawdowns can stop and reverse lateral erosion in ponds that are shallower than the depth of live roots in the adjacent marsh; natural droughts have a similar effect (McGinnis 1997). Neither drawdowns nor natural drought affects erosion around ponds that are deeper than live roots in the adjacent marsh (McGinnis 1997).

Whether in fresh or brackish marsh, plant production during drawdown can be 3–4 times greater than in unmanaged marsh, but impoundments can fail to drain as planned and, thereby, reduce rather than enhance plant growth (Flynn et al. 1999). Drawdowns in saline marsh and some brackish marsh can kill vegetation because oxidation of marine soils can reduce soil pH below 2; the resulting conditions are known as acid-sulfate soils or cat clays (Neely 1962, Moore et al. 1999). Problems with acid-sulfate soils rarely develop in the United States, but continue to develop where mangrove swamps are drained for rice or shrimp production. Drawdowns in any marsh might reduce marsh elevation by accelerating oxidation of soil organic matter, and increase flooding stress on emergent vegetation when normal water levels return.

Drawdowns can be counterproductive if they oxidize enough soil organic matter to reduce surface elevation or to create acid-sulfate soil (i.e., cat clay) conditions. The resulting flooding stress and/or acidic soil stress would reduce species composition and productivity of plant and wildlife communities. Minimizing the frequency and duration of drawdowns may slow lateral erosion without losing centimeters of elevation that took decades to accumulate.

Weirs, Sills, and Flashboards

Water control structures in marsh drainage systems can be used to counter human-induced increases in tidal exchange and prevent undesirable, unnatural drainage of marsh ponds. Initially, sod was used to restore waterfowl habitat quality impaired by mosquito ditches (Bradbury 1938), but sheet pilings and rocks are now more commonly used to restore more natural hydrologic conditions (Fig. 29.7). The term “**weir**” is common on the Gulf Coast, whereas “**flashboard**” or “**sill**” is common on the Atlantic Coast. These structures resemble low dams that have the top or crest set 15 cm below the elevation of the surrounding marsh to allow water to flow back and forth across the structures. These structures have long been used on the Atlantic and Gulf coasts to counter the effects of ditches and canals (Smith 1942, Chabreck and Hoffpauir 1962). These structures reduce tidal exchange and establish a basin of water behind the structure that cannot recede below the crest; consequently, complete drainage of most ponds at low tides is prevented (Chabreck and Hoffpauir 1962). Constructing weirs and flashboards in unwanted artificial channels is a less costly alternative to filling the channels with sediments. Flashboards are used in Chesapeake Bay marshes to prevent complete drainage of

marshes that were ditched to control mosquitoes in the 1930s (Hindman and Stotts 1989). Weirs are used in coastal Louisiana to counter tidal action and unnatural drainage caused by canals and navigation channels. Most importantly to waterbirds, weirs prevent ponds from completely draining during winter cold fronts; these weir-managed ponds are preferred by wintering waterfowl (Spiller and Chabreck 1975). Weirs with fixed crests have increased the abundance of submersed aquatic vegetation (Nyman and Chabreck 1996) and decreased mineral sedimentation (Reed 1992), but have not altered emergent plant communities (Nyman et al. 1993a) or marsh loss rates (Nyman et al. 1990a). Weirs, sills, and flashboards might affect marsh loss rates where vertical accretion depends on mineral sedimentation. It is unlikely these structures affect soil water-logging unless they alter flood duration on the marsh surface, because marsh soils rarely drain even when adjacent channels drain (Agosta 1985, Nyman et al. 1994).

Cattle Grazing

Cattle grazing can be used to advantage in marshes managed for wildlife (Chabreck 1968, Neely 1968). Carefully regulated grazing can create favorable conditions for some species by opening dense stands of vegetation. Marshes managed for maximum fur-animal production should not be grazed (O'Neil 1949). Grazing will reduce available cover, and cattle trample dens and underground tunnels and compete with wild herbivores for food.

Grazing, which can be easily controlled, is usually beneficial to ducks. Grazing will not only remove dense stands of vegetation, but it also sets back plant succession and increases food production (Stutzenbaker and Weller 1989). Certain

low-value plants, such as marshhay cordgrass, decrease with grazing, whereas some high-value plants, such as seashore paspalum (*Paspalum vaginatum*), increase with grazing. To improve grazed marshes for ducks, cattle should be removed from the marsh during July through September to permit annual grasses and sedges to grow and produce seeds. Marshes should be **flooded** (10–15-cm depth) from October through February to attract ducks and make the seeds available.

Snow geese are attracted to marshes where dense stands of mature vegetation have been removed; consequently, moderate grazing usually benefits snow geese (Chabreck 1968). Geese will feed on new sprouts, plus roots and rhizomes of marsh grasses and sedges. Common snipe (*Gallinago gallinago*) also benefits from cattle grazing. This species prefers areas with exposed mineral soil and no overhead cover; largest concentrations of snipe are usually found on overgrazed marsh range.

Food Plantings

One of the first procedures generally considered when improving wetlands for wildlife is to plant vegetation to produce food. **Food plantings** often fail to meet the objective because they are usually made without site preparation. Usually, the absence of natural food plants in a wetland is a result of unfavorable soil and water conditions or excessive competition from less desirable plants. These conditions will cause failure of plantings in the same wetland area. Plantings in a wetland cannot substitute for regulating water levels and salinities to produce natural foods. Only with application of agronomic techniques have favorable results been achieved with artificial plantings (Neely 1968).

Fig. 29.7. Side and top views of a fixed-crest weir. Increasingly, stop-logs are used to vary the crest of the weir. After L. J. Broussard, U.S. Soil Conservation Service, Department of Agriculture, Alexandria, Louisiana.

Because Olney bulrush is a choice food plant of muskrats and snow geese in coastal marshes of the southeastern United States, considerable interest has been generated in managing marshes for this species. Procedures for establishing or reestablishing Olney bulrush through planting have been intensively investigated (Ross and Chabreck 1972, Palmisano 1973, Hess 1975). These studies disclosed this species could be established by transplanting rootstock. However, plantings must be made within certain water and salinity levels, and protection must be provided against excessive competition from other plants and animal herbivory.

Control of Undesirable Vegetation

Chemical control of undesirable plant species in wetlands has been used on a limited basis partly because undesirable species generally return within a few years (Rollings and Warden 1964, Wood et al. 1996). Herbicides may gain emphasis in the future as management efforts become more intensive. Also, herbicides are being developed that are more effective and can be applied more economically. As with other management techniques, a wetland manager should consult a specialist in this field before attempting widespread applications of herbicides.

Where an undesirable plant species is outcompeting desirable vegetation, the cause often is ongoing succession because of a lack of fire, or habitat change because of a reduction in salinity and **sulfide stress**. Sustainable management in such situations requires restoration of more natural fire regime or restoration of tidal exchange; these management techniques are addressed in the following sections.

Prescribed Fire

Fire appears unimportant in mangrove swamps and coastal wetland forests, but fire is a natural, regular disturbance in many coastal marshes. Natural fires are common in large expanses of coastal marsh during later summer when lightning strikes initiate fires that burn thousands of hectares, and Native Americans regularly burned coastal wetlands. Early Europeans considered such burning barbaric, but prescribed fire has been used in coastal marshes since the early 1900s (Nyman and Chabreck 1995). Prescribed as well as natural marsh fires can be classified as cover burns or peat burns (Lynch 1941, Smith 1942, Uhler 1944, O'Neil 1949). Water levels present during the burn control the type of fire that occurs and water levels following the fire control plant regrowth. Some managers have used mowing as a mechanical disturbance to simulate fire where social concerns regarding smoke are an issue, but mowing is not practical over large areas or in most organic soils. Much of the following information is summarized from Nyman and Chabreck (1995).

Peat burns are those that actually burn marsh soil; they occur when a marsh with peat soil is drained and the soil is dry. The depth of the burn depends on the depth to which

the soil is dry. Peat burns lower surface elevation, can convert marsh to ponds, and are most common in coastal Louisiana. They are not normally used as a management tool, but could be if the goal was to increase pond area at the expense of emergent vegetation and if the peat burn could be prevented from spreading to adjacent areas. Peat burns also have been used unsuccessfully to reverse the spread of cattails (*Typha* spp.) and common reed (Ward 1942, Uhler 1944). Peat burns are rare, but low water levels in Gulf Coast marshes, a lack of local rainfall, and lightning resulted in thousands of hectares of peat burns in coastal Louisiana during the drought of 2000 (T. J. Hess, Jr., Louisiana Department of Wildlife and Fisheries, unpublished data). Peat burns should be uncommon in prescribed fires and can be avoided by burning only when the marsh is flooded by a high-water event.

Fires that remove standing biomass and litter without killing plant roots are classified as cover burns. They result from fires that occur when there is moist soil to several centimeters of water on the marsh surface. Plant communities can quickly recover from cover burns because living roots and seed banks are not destroyed if the marsh is not flooded after the fire. If the marsh remains flooded following a cover burn (whether prescribed or natural), all vegetation can be killed by flooding stresses (Hoffpauer 1968). A successful cover burn can be achieved by burning when the marsh is flooded by a high-water event and before predicted periods of low water. In microtidal areas such as the northern Gulf of Mexico, such conditions coincide with the approach and passage of winter cold fronts that first flood the marsh for several days and then drain the marsh for several days. Most prescribed fires there should be set during the 2–3 days as the cold front approaches and south winds flood the marshes. Northerly winds that prevail for 4–6 days following frontal passage ensure that plant stems remaining after fires are not flooded. In regularly flooded tidal areas such as the Atlantic Coast of the United States, such conditions coincide with the passage of spring tides and the arrival of neap tides, especially during June and December because of the solstices. Most prescribed fires there should be set on, or just after, the highest spring tide to ensure the remaining burned plant stems are not flooded.

Cover burns are valuable and widely used on Gulf and Atlantic coasts because they increase the abundance of wildlife food plants (Arthur 1931, Griffith 1940, Lynch 1941, Uhler 1944) and prevent shrubs from dominating. Cover burns are used primarily in marshhay cordgrass-dominated marshes when marshhay cordgrass forms nearly monotypic stands. In the first or second year following a cover burn, Olney bulrush and other valuable food plants can become more abundant. As succession continues for 3–5 years, marshhay cordgrass again creates nearly monotypic stands. In areas with low salinity, shrubs can dominate after 5–10 years. Such dominance appears to be permanent in some areas because

the shrubs produce too little fuel to sustain a cover burn. In areas with high salinity, marshhay cordgrass will dominate until the next cover burn. Natural fires are common in large expanses of marsh during later summer, when lightning strikes initiate fires that burn thousands of hectares. Prescribed cover burns should be limited to autumn and winter, however, because spring and summer burning can destroy nests or kill young wildlife. Another danger of late-summer fires, whether natural or prescribed, in the southeastern United States, is the possibility of tropical storm surges causing flooding of recently burned areas with saline water for days or weeks.

Root burn is a category of fire described by O'Neil (1949) that has not been confirmed. Root burns were probably cover burns that occurred in late summer just before tropical storm surges or in early autumn just prior to high vernal equinox tides. Such a tide killed about 500 ha of burned marshhay cordgrass marsh on Rockefeller Wildlife Refuge in Louisiana in the 1950s (R. H. Chabreck, personal observation). After the water receded, it appeared the vegetation was killed by a root burn.

Little is known about the effects of fire on vertical accretion or on organic matter export to adjacent estuaries. Stevenson et al. (2000) feared that fire management at Blackwater National Wildlife Refuge in Maryland contributed to marsh loss by reducing organic matter accumulation. A prudent plan would be to burn only as frequently as needed to prevent unplanned burns. Ending prescribed burning would not eliminate fire as a disturbance because large accumulations of litter develop, and lightning can still ignite that fuel.

SUMMARY

Coastal wetlands vary regionally in the United States because of variation in slope, tidal range, and riverine discharge. Within regions, coastal wetlands vary from saline with large tidal ranges to tidal, freshwater wetlands where tides cause an ebb and flow of water rather than a rise and fall. Water

level, water salinity, and fire often are manipulated in coastal wetlands to improve habitat quality for waterfowl, furbearers, wading birds, or American alligators. Mangrove swamps occur in nonfreshwater areas that lack freezing temperatures, such as the South Florida coast. They rarely are managed for wildlife and are not addressed.

Management to improve habitat for waterfowl and furbearers in tidal, nonsaline wetlands, particularly those dominated by marshhay cordgrass, began in the mid-1900s and continues to be common on the Gulf and Atlantic coasts. In the mid-1900s, some saline marshes were freshened via impoundments to improve waterfowl habitat; this management is not currently undertaken. Many earlier efforts are being reversed to restore saline habitats for shorebirds and estuarine fish. In the late 1900s, coastal marsh management to improve anadromous fish habitat began on the Pacific Coast.

Unlike inland wetlands, coastal wetlands must gradually increase in elevation (i.e., vertically accrete) to survive global sea-level rise and local subsidence. Accretion depends on accumulation of mineral sediments from tides and storms, organic matter from emergent vegetation, or a combination of both. Where accretion depends on mineral sediments, levees and water control structures used to manipulate hydrological conditions may inadvertently slow accretion and eventually drown emergent vegetation. Where accretion depends on organic matter, drawdowns used to promote annual vegetation may inadvertently reduce soil elevation and eventually drown emergent vegetation. Evaluating the effects of management on accretion is a recently recognized challenge facing coastal wetland managers.

Management goals should be clearly documented and measurable. Management practices generally must be developed via trial and error to accommodate site-specific soil and hydrologic conditions. Regardless of the locale, one of the most valuable practices is the systematic collection of hydrologic, vegetation, and wildlife data that can be used to evaluate management efficiency and guide changes in management practices.

Managing Farmlands for Wildlife

INTRODUCTION

AGRICULTURAL LAND USE and associated technologies have dramatically changed over the past century, contributing to sweeping alterations of the natural flora and fauna. Natural resource agencies have been challenged to develop habitat programs to counter the negative effects of these changes on wildlife.

Wildlife management programs that succeed in farmlands are generally linked with soil and water conservation initiatives. These initiatives are driven by federal farm legislation that allocates resources and sets the rules framing conservation opportunities. Public support for programs that maintain and enhance wildlife in addition to other natural resource goals is strong. In recent years, public policy has more directly addressed issues concerning the sustainability of farming and natural resources, with new programs that specifically integrate wildlife conservation with agriculture. We emphasize a systems approach to addressing farmland habitat needs and opportunities. There are numerous habitat management guides that provide technical information on the development and long-term maintenance of specific habitat types (e.g., Newman et al. 2003).

CHALLENGES TO MANAGING WILDLIFE IN FARMLANDS

Herein, we recognize **6 challenges** to managing wildlife in farmlands. They are: (1) goals of wildlife management and agriculture have tended to diverge, especially in recent decades; (2) farm conservation programs, widely promoted for wildlife benefits, are often spatially dispersed and temporally insecure, making it difficult to show sustained progress toward wildlife management priorities; (3) reliable knowledge about results of wildlife habitat initiatives is lacking; (4) wildlife agencies need to redouble efforts to communicate the importance of wildlife in critical ecosystem functions; (5) wildlife managers must address both the positives and negatives of interactions between humans and wildlife; and (6) wildlife managers must facilitate access to private lands to meet the public's need for sporting and other recreational wildlife activities.

Divergent Goals

Many wildlife species thrived during agricultural settlement in the late 1800s and early 1900s when farm landscapes comprised small, **diversified farms** that practiced field rotations of grains, forage grasses, and legumes (Leopold 1933). Subtle

variations in the nature and timing of farming disturbances over time and space largely were correlated with trends in the abundance of many upland wildlife species. **Modern agricultural systems**, by comparison, show reduced diversity in terms of vegetation structure and the spatial arrangement of vegetation types (Fig. 30.1). **Cropping practices** now

include **mechanical and chemical disturbances** that occur rapidly and extensively on farmland, causing habitat conditions to have deteriorated in many respects. As a system, farmland has the capacity to provide for broader **ecosystem services**, such as **carbon sequestration and wildlife habitat**, than are currently being realized (Box 30.1).

Fig. 30.1. Expansion of intensive row-crop agriculture near Flagg Center in Ogle County, Illinois, between 1957 (left) and 2007 (right). The transition from small, diversified farms to large-scale row-crop enterprises occurred throughout many of the most intensively farmed regions of the United States during this period.

Box 30.1. ECOSYSTEM SERVICES IN AGRICULTURAL LANDSCAPES

Ecosystem services are defined as the processes and conditions by which natural ecosystems and the species they contain sustain and fulfill human life (Daily 1997). Four main types of ecosystem services have been identified (Millennium Ecosystem Assessment 2005): (1) provisioning services (e.g., production of food, pharmaceuticals and energy), (2) regulating services (e.g., water purification, crop pollination, disease and pest control, carbon sequestration), (3) support services (e.g., seed dispersal, nutrient cycling), and (4) cultural services (providing recreational opportunities, cultural inspiration, scientific discovery).

Agriculture is best known for providing provisioning services (e.g., food, fiber, and fuel), but farmers also help maintain other supporting services such as pollination, biological pest regulation, and soil nutrient regulation (Swinton et al. 2006). Agriculture also could provide a host of other services (water purification, water flows, and biodiversity protection) that are poorly captured by current markets. Agriculture may have more potential to expand its production of currently nonmarketed ecosystem services than other more natural ecosystems because (1) much is known about the input–output relationships of agricultural systems; (2) agricultural systems have precedent for payments that could induce the provision of additional ecosystem services; and (3) agricultural systems have shown strong capacity to provide goods and services in response to economic incentives (Swinton et al. 2006). Although the opportunity to provide ecosystem services from agricultural lands is high, indications are that agricultural landscapes are losing their ability to provide ecosystem services (Björklund et al. 1999). As a result, a greater understanding and appreciation of the services provided by agricultural lands is needed.

Robertson et al. (2004) outline a systems approach to addressing environmental issues in agricultural landscapes, which has good potential for incorporating ecosystem services. Traditionally, agricultural research has been focused on problems at small scales and conducted within narrow disciplinary boundaries (Robertson et al. 2004). This approach has worked to provide solutions to a number of environmental problems, but limitations of the conventional narrowly focused problem-response approach become apparent when solutions developed to solve one problem create problems elsewhere (Robertson et al. 2004, Swinton et al. 2006). A systems approach as proposed by Robertson et al. (2004) provides better opportunity to exploit synergies between problem solutions and other benefits, such as ecosystem services, and also may better predict the effects of specific management interventions. Such an approach would provide expanded opportunities for incorporating currently nonmarketed ecosystem services, such as climate regulation and wildlife conservation, into agricultural policy.

Changing Farm Conservation Programs

Since the **New Deal** era of the 1930s, farm policies and programs have strongly influenced agricultural land use in the United States (Schlebecker 1975, Brady and Hamilton 1988) and have provided **incentives** for farmers to adopt conservation practices (Langner 1985, Jahn 1988). Conservation-related aspects of farm programs have the potential to affect large-scale changes in habitat conditions and, therefore, are of critical importance to wildlife managers (Haufler 2007). The voluntary nature of most programs can result in widely dispersed practices that make it difficult to measure landscape-scale changes in wildlife populations. Although programs have been effective in establishing habitat, incentives are often lacking to properly manage those habitats, resulting in gradual degradation and reduced wildlife benefits. Lands enrolled in conservation programs typically revert to cropping when contract periods end, creating new wildlife conservation crises.

Lacking Reliable Knowledge

Although wildlife agencies monitor and predict year-to-year trends in the relative abundance of selected farmland species, especially game animals and other economically important species, the mechanisms that cause these trends are often poorly understood. Only rarely have agricultural practices been carefully documented relative to the population ecology of a target species. Land use changes have occurred too fast and with so many confounding factors that reliable knowledge is often lacking, especially given the minimal time and resources directed to these questions (Warner 1992b; Table 30.1). Moreover, there are many species (e.g., reptiles and amphibians) for which little at all is known about their population ecology or status in farmland settings (Corn and Peterson 1996, Hecnar and McCloskey 1996b, Maisonneuve and Rioux 2001).

Table 30.1. Typical sources of errors in planning and assessing effects of habitat programs for upland wildlife species in intensively farmed areas

Animal response	Response detected	Sources of errors	Biological explanation
Yes	No	Evaluation period too short	Lag effects Development of vegetation Demographic responses
Yes/No	Yes/No	Measurement techniques	High variability in animal responses and/or census techniques inappropriate
Yes	No	Limited spatial scale	Dispersal

From Warner and Brady (1994).

Communicating Importance of Wildlife in Ecosystem Functions

The **ecological and economic values** of wildlife in agricultural settings should be better communicated to society (Pimentel et al. 1987, Daily 1997). **Conservation initiatives** in farmland settings typically cater to the needs of landowners and hunters of farmland wildlife—small segments of the population. One of the greatest failures of wildlife professionals has been their inability to translate research findings of management practices into ecological and **socio-economic benefits** that resonate with an urban public and policy-makers.

Addressing Positive and Negative Human–Wildlife Interactions

As wildlife issues become more prominent, biologists should expect that landowners and the general public will have varied and, often contradictory, perceptions of wildlife management initiatives. Wildlife managers are increasingly responding to perceived problems, such as to species that are declining and in need of immediate habitat interventions or to species that cause problems for humans. Given that some species considered as successes of wildlife management interventions (e.g., white-tailed deer [*Odocoileus virginianus*]) are now frequently perceived as causing problems, maintaining credibility is a challenge. In efforts to promote habitat management, wildlife managers should anticipate responding to the wildlife-related problems espoused by their clients. Biologists have too often downplayed these problems.

Facilitating Access to Private Lands

Since 1940, individual farm operations in the United States have nearly tripled in size, while the **number of farms has decreased by about 70%**. Meanwhile, the proportion of **Americans living on farms has decreased from 23% to <2%** (National Agricultural Statistics Service 2009). As a result, access to wildlife resources on private lands has become increasingly difficult to obtain by an urban public with few ties to agricultural communities. Furthermore, perceptions of liability and property damage, and increasing demand by outsiders, have led many landowners to curb access. Convincing landowners to allow **access** to wildlife resources on their land requires creative solutions (Box 30.2).

IMPACTS OF FARMING PRACTICES ON WILDLIFE

Rotation Farming

Prior to the early 1960s, **rotation farming** characterized the most intensively farmed landscapes of North America. Corn was usually planted the first year, followed by small grains. These small grains served as a nurse crop for hay (typically forage grasses and/or legumes) that typically persisted for

BOX 30.2. PUBLIC HUNTING ON PRIVATE LANDS: NEW SOLUTIONS BY STATE WILDLIFE AGENCIES

A common human-dimensions issue faced by natural resource agencies is facilitating access by the sporting public to wildlife on private lands. Nearly 20 states have instituted private-land access programs, typically offering landowners a lease payment and liability protection in exchange for allowing public hunting on their property. Funding to support these programs may come from a variety of sources, including hunting license and access program fees, Federal Aid to Wildlife Restoration Funds, and contributions from private conservation organizations.

The combination of vast lands enrolled in the Conservation Reserve Program, strong populations of upland game, an influx of nonresident hunters, and little public hunting land have prompted “walk-in” programs in several Great Plains states. These programs have been popular with landowners and hunters. The Kansas Walk-In Hunting Access (WIHA) began with about 4,000 ha enrolled in 1995 and had grown to include 400,000 ha of private land by 2004. In neighboring Nebraska, a partnership between the Nebraska Game and Parks Commission and Pheasants Forever created the CRP-Management Access Program (CRP-MAP), where landowners receive payments for the combination of habitat improvements and public walk-in access to fields enrolled in the Conservation Reserve Program. The Kentucky Dove Field Lease Program is one of the few examples from an eastern U.S. state, with the Kentucky Department of Fish and Wildlife Resources providing incentives for landowners to establish and manage sunflower or another crop on fields for public-access dove hunting. A different model, not based on a lease agreement or small game hunting, is the South Dakota Volunteer Deer Hunter Program. The South Dakota Game Fish and Parks hosts a list of hunters willing to harvest antlerless deer, enabling landowners to contact hunters directly. An often-repeated theme among states is that ethical behavior of hunters is critical for the continued participation of landowners in these programs.

2 years. Hay fields pastured livestock and maintained soil fertility.

The rotation farming system provided a spectrum of habitat needs for upland wildlife (Warner 1994). For instance, grain fields supported abundant and diverse food resources that included an understory of weedy plants during the growing season (in the absence of herbicides) and waste grains during autumn and winter (Warner 1984, Warner and Etter 1985). Hay fields provided permanent (year-round) cover and prime nesting habitat for many grassland bird species. Due to the relatively small sizes of fields, a variety of cover types occurred in close proximity. **Ecotones** (e.g., permanent vegetation along **field borders**) allowed wildlife to move freely between patches of cover. In addition, the farmland matrix during this era was interspersed with permanent cover such as wetlands, wood lots, and riparian areas.

Modern Farming Practices

Changes in agricultural practices in recent decades have profoundly affected habitat conditions and altered the nature and **juxtaposition** of landscape elements (Noss et al. 1995) in farmland settings. Larger farm equipment has led to larger fields and farms, resulting in a dramatic loss of field borders (Best 1983, Baltensperger 1987). Since World War II, increased applications of **synthetic fertilizers** have reduced the need for crop rotations that include legumes to fix nitrogen in the soil. Production of row crops, especially soybeans, has ex-

panded. Livestock are primarily raised in large confinement operations, resulting in the elimination of semipermanent fields of forage grasses and legumes. These changes have produced a farmland matrix dominated by highly disturbed **monocultures**, with little connectivity among landscape elements. The collective impact of intensive farming practices has been to decrease the likelihood that farmlands will offer the complexity of life-sustaining resources wildlife need (Oldfield and Alcorn 1987, Power and Follett 1987, Turner 1987, Woolhouse and Harmsen 1987). This has led to a general decrease in wildlife traditionally common within farmland settings (National Research Council 1982; Figs. 30.2, 30.3).

The nature and timing of **farm disturbances**, in particular, are increasingly hazardous to wildlife (Freemark and Boutin 1995, Dailey 2002). Modern agricultural practices have reduced the temporal diversity of farm disturbances by increasing their rapidity and intensity across the landscape. The uniform maturation of modern crop cultivars allows tilling, planting, and harvesting to be increasingly synchronous. These physical disturbances often coincide with critical periods of wildlife reproduction, maturation, and dispersal (Warner and Etter 1989, Bollinger et al. 1990, Frawley and Best 1991, Warner et al. 2000). For example, the cutting of hay happens earlier and progresses more rapidly during the nesting season (Warner and Etter 1989, Bollinger et al. 1990, Frawley and Best 1991). Likewise, increased autumn

Fig. 30.2. Changes in the hunter harvest of selected upland game species in Illinois and the Crop Production Index (CPI), Illinois, 1956–2000. The CPI measures the productivity of agriculture by multiplying yearly production by season average prices, and then dividing by the same value for 1977 (the yr the index was developed). The trends portray that agricultural practices were compatible with habitat needs of upland wildlife until recent decades. Data from the Illinois Department of Agriculture and the Illinois Department of Natural Resources.

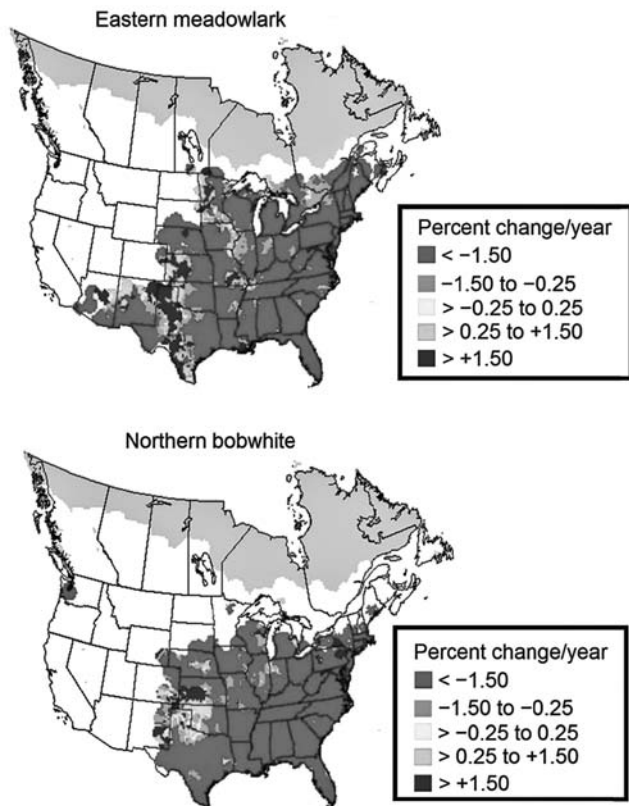

Fig. 30.3. Population trends from the North American Breeding Bird Survey (1966–2003) for 2 characteristic farmland birds, the eastern meadowlark (*Sturnella magna*; top) and northern bobwhite (*Colinus virginianus*; bottom). Percent changes per year of 1.5–2.5%, typical of these and other farmland birds, suggest overall population declines of 40–60% during the 37-year period. From Sauer et al. (2008).

tillage in some areas has reduced availability of crop stubble as forage and cover for wildlife during autumn and winter (Warner and Havera 1989), challenging wildlife to disperse in the context of radical landscape changes, often for long distances and at significant mortality risk (Warner et al. 1999, 2000).

Frequent **chemical disturbances**, from the applications of fertilizers, pesticides, and herbicides, have significant on-farm and off-farm effects on wildlife. Persistent organochlorine pesticides and their metabolites have destroyed many bottomland lakes (Bellrose et al. 1983, Judy et al. 1984), adversely affected the fish community in a substantial portion of the waters of the United States (Flather and Hoekstra 1989), and caused problems like eggshell thinning in bald eagle (*Haliaeetus leucocephalus*) and other birds. Since the 1970s, more acutely toxic, but less persistent, organophosphates and carbamates have been the most commonly used agricultural insecticides. These chemicals vary in toxicity to fishes, birds, and mammals, but may reduce wildlife populations by limiting availability of invertebrate prey (Benton et al. 2002). Herbicides are typically less toxic to wildlife, but affect habitat availability and condition in and near cropland. More than 70% of the nitrogen and phosphorus causing hypoxia (the “dead zone”) in the Gulf of Mexico comes from agricultural sources (cropland and livestock) in the Mississippi River watershed (Alexander et al. 2008).

Some 240 million acres of crops genetically engineered for resistance to pesticides or insects were planted worldwide within a decade of their availability beginning in the 1990s (International Service for the Acquisition of Agri-biotech Applications 2004), including nearly 90% of the soybeans grown in the United States in 2005 (Fernandez-Cornejo and Caswell 2006). The effects of **genetically modified crops** on wildlife have not been evaluated, though genetically modified crops are associated with less tillage of cropland, reduced pesticide use, and use of herbicides less toxic to humans (Fernandez-Cornejo and McBride 2002).

Source–Sink Paradigm

One way of conceptualizing the effects of farming on wildlife follows the “**source–sink**” paradigm, which describes how a species fares in a particular setting (Pulliam 1988). The focus of this paradigm is the net effect of births (b), deaths (d), and movement (immigration i and emigration e) on numbers of a given species in a defined area (Donovan et al. 1995, McCoy et al. 1999). In some settings, production of young exceeds annual mortality; $b + d$ is positive, and the setting is a source. In others, young do not replenish the loss of adults, and $b + d$ is negative, indicating a habitat sink. Movement of individuals between populations ($i + e$) is influenced by connectivity of habitats.

Over the past century, agricultural landscapes have tended toward fewer, smaller, structurally, and florally simpler, more isolated, and more disturbed habitat patches that are less likely to attract an abundance and diversity of breeding species. This has caused a decrease in the portion of settings that are sources. In addition, attractive areas will be sinks unless wildlife agencies provide guidance or incentives to encourage farmers to minimize field disturbances during critical periods. Even in regions where attractive patches of cover abound, the intensity and timing of disturbances cause most settings inhabited by wildlife to be sinks (Burger 1978, Best 1986, O’Neil and Carey 1986).

MANAGING LANDSCAPES FOR WILDLIFE

In accordance with the source–sink paradigm, habitat management within farmlands should strive to increase the number of settings attractive to targeted wildlife and the portion of settings that foster high rates of reproduction and survival. Managers should be cognizant of improvements that can be made on as many landscape elements as possible, increasing the likelihood that farmland settings inhabited by target species will be sources. In farmlands, the major **landscape elements** are habitat patches, corridors, and the surrounding farmland matrix (Forman and Godron 1981, Forman 1995b).

The following guidelines are useful for developing habitat management plans that emphasize the ecological functions of landscapes and spatial relationships between key elements:

- Manage for self-sustaining wildlife populations in densities that are suitable and achievable for the setting, given ecological, socioeconomic, and political considerations.
- Preserve, enhance, or restore the structure and function of existing patches and corridors.
- Create new patches or corridors to replace lost habitat.
- Minimize negative effects and maximize positive habitat attributes of the matrix.
- Restore or mimic natural disturbance regimes (Natural Resources Conservation Service 1999a).

Habitat Patches

Habitat patches are areas of natural or restored native vegetation. In farmlands these consist primarily of woodlots, wetlands, and a few scattered prairie remnants (typically on slopes too steep to cultivate). These habitat patches are typically the focus of management efforts to enhance vegetation and other cover for wildlife (Roseberry and Klimstra 1984, Walk and Warner 1999). **Biological conservation strategies**, in particular, often emphasize management of natural (unfarmed) habitats for rare and endangered plants and animals. However, most habitat patches in farmlands tend to be small and isolated (Herkert 1994), and the extent to which they are connected by permanent **field edges** and other corridors has been reduced. Furthermore, they are primarily edge. Hence, game and other edge-adapted species are often the primary benefactors of small natural areas, not species that typically require interior habitats (Noss 1983). Nonetheless, attention should be focused on characteristics of the land that can preserve or enhance its biotic integrity.

The following principles provide a useful framework when managing habitat patches for wildlife:

- Large patches are better than small patches.
- Connected patches are better than separated patches.
- Unified patches are better than fragmented patches.
- Several patches are better than one patch.
- Proximate patches are better than separate patches.
- Structurally diverse patches are better than simple patches.
- Patches with native plants are better than patches with introduced plants (Natural Resources Conservation Service 1999a).

Corridors

Corridors are linear strips of permanent or semipermanent vegetation such as field borders, fencerows, roadsides, drainage ditches, and riparian areas. Corridors are important because they help sustain flora and fauna in the region by connecting habitat patches (Stamps et al. 1987, Chapman and Ribic 2002). They deter movement of soil and water. By facilitating dispersal of organisms between habitat patches, corridors tend to dampen population fluctuations within patches, reduce the risk of extinction of subpopulations within patches, and increase the probability of recolonization of unoccupied patches (Noss 1983, Stacey et al. 1997). Even narrow field borders such as hedgerows and fences are important in the daily activities of vertebrates in farmland settings and, therefore, deserve management attention (Arnold 1983, Best 1983).

The following principles provide a useful framework when managing corridors for wildlife:

- Continuous corridors are better than fragmented corridors.
- Wider corridors are better than narrow corridors.

- Natural connectivity should be maintained or restored.
- Introduced connectivity should be studied carefully.
- Two or more corridor connections between patches are better than one.
- Structurally diverse corridors are better than simple corridors.
- Corridors with native plants are better than corridors with introduced plants (Natural Resources Conservation Service 1999a).

Farmland Matrix

Row crops, small grains, pasture, and hay characterize the **farmland matrix**. Wildlife may make extensive use of this matrix and are affected, both directly and indirectly, by farming disturbances thereon (Herkert et al. 1996, Kershner 2001, Walk 2001). Therefore, agricultural practices are an important consideration for optimizing habitat conditions for farmland wildlife (Dahlberg 1992, Brady 2007). For example, use of pesticides is an important consideration relative to the abundance and diversity of plants and invertebrates (Potts 1986) available to wildlife as food sources.

Management strategies for enhancing the farmland matrix for wildlife can be linked with soil conservation efforts. Soil-conserving measures tend to improve cover in farmlands. For example, **conservation tillage** leaves some or all of the crop residues (cornstalks, wheat stubble) on the soil surface rather than turning them under. Leaving residue on the surface reduces soil erosion and also provides some useful habitat for wildlife (Basore et al. 1986, Best 1986). Similarly, **contour-strip cropping** uses interspersed strips of close-grown crops (hay and small grains) on the contour between strips of row crops to control erosion. These **alternating strips** of corn, oats, and hay can provide the juxtaposition and configuration of cover types important for enhancing landscape diversity and food webs (Brady 1985). Implementation of these techniques not only improves habitat for terrestrial wildlife, but also improve water quality for

aquatic wildlife by reducing the amount of agricultural pollutants reaching waterways. However, managing for **structural diversity** and the **optimal juxtaposition** of cover are of little value if agricultural disturbances continue to occur during critical periods, such as mowing of legumes and agricultural grasses during the nesting season.

FARM PROGRAMS AS A CONTEXT FOR HABITAT MANAGEMENT

Through much of the 1900s, farm programs diverted cropland from production to adjust commodity production and prices, and to promote conservation. These “**set-aside**” programs have been important because they can potentially establish **early successional cover**, which is at a premium in farm landscapes. They also reduce the hazards of farming disturbances at critical times for wildlife (e.g., the nesting season).

Most programs diverting land from production have fallen far short of their potential for improving habitat conditions on farmland (Kammin et al. 2009). These programs affect millions of hectares of cropland in the United States annually (Fig. 30.4); therefore, influence should be brought, where possible, so that farmers will be encouraged to provide quality habitat for wildlife while meeting the guidelines of agricultural programs. Biologists working in farmland settings should be well informed of these programs in their region, and should strive to optimize the management guidelines that govern these programs. Familiarity with conservation programs (which are perpetually changing) will enable biologists to make informed recommendations to landholders, which in turn establishes credibility and facilitates landowner participation (i.e., getting more and better habitat on the land).

Early Set-Aside Programs

The **Agricultural Conservation Program (ACP)** of the 1930s and 1940s, the **Soil Bank Program** of the 1950s, and the

Fig. 30.4. Farmland diverted from production in the United States, 1956–2002. These “set-aside” programs have been important elements of farm conservation initiatives since the New Deal era.

From Dahlgren (1988), Osborn et al. (1995), Farm Service Agency (2002).

Set-Aside Acres Program of the early 1960s were important for moderating the negative effects of increasingly intensive farming on wildlife (Berner 1984, Edwards 1984, Jahn 1988). Most of the land diverted as part of these programs was seeded with forage grasses and legumes, and fields of forage legumes and grasses already in place were often idled. With minimal farm disturbances, these habitats were immediately attractive to upland wildlife. These set-aside programs, in conjunction with rotation farming, produced upland game densities of historic proportions.

Conservation Reserve Program

The **Conservation Reserve Program (CRP)** emerged in the mid-1980s and has accomplished significantly more for wildlife populations compared to other programs in recent decades (Jones-Farrand et al. 2007). At the program's peak, >14.6 million ha (36 million acres) were enrolled (Fig. 30.5). Through this program, environmentally sensitive farmland is idled for 10–15 years to reduce soil erosion, improve water quality, and provide wildlife habitat (Table 30.2). Specifically, these initiatives protect highly erodible soils and establish permanent grass and/or woody vegetation along land–water interfaces to improve water quality. Landowners receive annual payments based on local land-rental values and up to 50% cost-share for establishing permanent vegetation. Additional cost-share arrangements and technical support are often available through state or local agencies and private conservation organizations.

In 2009, 12.6 million ha (31.1 million acres) remain enrolled in the program. However, 7.5 million ha (18.6 million acres; about 60%) are scheduled to expire from 2010 to 2013. Populations of pheasants in the Great Plains and nesting ducks in the Prairie Pothole Region, at their highest levels in many decades, are in jeopardy, as are a number of nongame species that stabilized or rebounded in large part

due to the CRP (e.g., Henslow's sparrow [*Ammodramus henslowii*]; Herkert 2007).

Whereas early enrollments in the CRP were accomplished through a bidding process during general sign-up periods, the CRP increasingly has offered targeted or continuous enrollment options with additional incentives. The **Conservation Reserve Enhancement Program (CREP)** is a joint state–federal program that addresses specific, local environmental needs. CREP is similar to CRP in contract length, approved practices, and cost-sharing, but additional financial incentives and cost-share resources may be available through state or local agencies and private conservation organizations. CREP in Maryland is well known for its efforts to improve water quality in the Chesapeake Bay watershed. As part of this cleanup effort, Maryland has committed to restoring up to 40,000 ha of streamside property, including 28,000 ha of riparian forest and 4,000 ha of wetlands (Maryland Department of Agriculture 2002). The CREP in Iowa also provides an example of how these programs can benefit wildlife (Box 30.3).

Practices to install filter strips and riparian buffers (CP 21, 22) to reduce soil erosion and improve water quality have had limited benefits for wildlife (Henningsen and Best 2005, Clark and Reeder 2007). In contrast, initial assessments show the field borders practice (CP33) has had the intended benefit of increasing abundance of northern bobwhites (*Colinus virginianus*; Evans et al. 2009). CP 38, the **State Acres for Wildlife Enhancement**, gives state the flexibility to target locations and practices to address high-priority wildlife issues, such as those identified in **State Wildlife Action Plans (SWAPs)**.

Other Contemporary Farm Programs

Contemporary farm programs offer considerable opportunities for addressing habitat needs at farm and regional scales.

Fig. 30.5. Distribution of Conservation Reserve Program, by percent of county enrolled, in the United States in 2008. Data from Farm Service Agency (2009b).

Table 30.2. Wildlife-related conservation practices available under the Conservation Reserve Program

Conservation practice	Description	Contract length (yr)
CP1	Introduced grasses and legumes	10
CP2	Native grasses	10
CP3	Tree plantings	10
CP3A	Hardwood tree plantings	10–15
CP4B	Permanent wildlife habitat–corridors	10–15
CP4D	Permanent wildlife habitat	10
CP5A	Field windbreaks	10–15
CP8A	Grass waterways	10
CP9	Shallow-water areas for wildlife	10
CP10	Previously established grass	10
CP11	Previously established trees	10
CP12	Wildlife food plot	10
CP15A	Permanent contour grass strips	10
CP15B	Permanent contour grass strips on terraces	10
CP16A	Shelterbelts	10–15
CP17A	Living snow fences	10–15
CP21	Filter strips	10–15
CP22	Riparian buffers	10–15
CP23	Wetland restoration	10–15
CP24	Permanent vegetation for cross-wind trap strips	10
CP25	Rare and declining habitat	10–15
CP27	Farmable wetland program—wetland	10–15
CP28	Farmable wetland program—buffer	10–15
CP29	Marginal pasture buffers—wildlife	10–15
CP30	Marginal pasture buffers—wetland	10–15
CP31	Bottomland hardwood trees	15
CP32	Hardwood trees (previously expired contracts)	??
CP33	Upland bird habitat buffers	10
CP36	Longleaf pine initiative	10–15
CP37	Duck nesting habitat initiative	10–15
CP38	State acres for wildlife enhancement	10–15

Farm Service Agency (2009a).

These are voluntary easement **Wetland Reserve Program (WRP)**, **Grassland Reserve Program (GRP)**, and **Healthy Forest Reserve Program (HFRP)** programs for protecting and enhancing habitat on private lands. The **Conservation Stewardship Program (CSP)** encourages producers to address resource concerns in a comprehensive manner by undertaking additional conservation activities and improving, maintaining, and managing existing conservation activities. The **Wildlife Habitat Incentive Program (WHIP)** and the **Environmental Quality Incentives Program (EQIP)** are optimized at local and regional levels by interagency agreements and on-the-ground cooperation. Landowners are offered annual lease payments and other incentives to enroll in these programs, often at rates that offer an attractive financial alternative to producing crops on the land.

The goals of WHIP are to develop upland and wetland habitat for wildlife, fish, and threatened or endangered spe-

Box 30.3. IOWA CONSERVATION RESERVE ENHANCEMENT PROGRAM: HELPING LANDOWNERS PROTECT IOWA'S NATURAL RESOURCES

The Iowa Conservation Reserve Enhancement Program (CREP) is a major state–federal initiative to develop strategically located wetlands and remove nitrate from tile-drainage water in cropland areas. The program is being implemented in cooperation with the Farm Service Agency (FSA) and Natural Resources Conservation Service (NRCS) of the U.S. Department of Agriculture to provide US\$38 million in funding during 2002–2004 to construct and restore up to 3,600 ha of wetlands and buffers. Financial incentives are provided to private landowners to develop and restore wetlands that intercept tile drainage from agricultural watersheds. Landowners receive annual land payments over 15 years and reimbursements for costs of wetland and buffer establishment. Easements to maintain the wetlands and buffers are required for a minimum of 15 years beyond the CREP payments, for a total of 30 years. Additional one-time, up-front incentive payments are used to encourage participating landowners to enter into perpetual easements.

Research at Iowa State University has confirmed that strategically located and designed wetlands under the program requirements will remove 40–90% of the nitrate and >90% of the herbicide in tile-drainage water from croplands. The Iowa CREP is available in the 37 counties in the tile-drained region of north-central Iowa and will specifically target the North Raccoon River Watershed. This watershed is noted for some of the highest nitrate loads in the Mississippi River Basin. Over the next decade, the Iowa CREP could develop wetlands in the program area with the capacity for removing over 5,000 metric tons of nitrate–nitrogen annually. In addition to reducing nitrate loads to surface waters, the wetlands will provide wildlife habitat and increased recreational opportunities.

Iowa Department of Agriculture and Land Stewardship (2002).

cies. Landowners develop wildlife habitat plans with Natural Resources Conservation Service personnel. WHIP offers technical assistance and 75% federal cost-share, with up to 25% cost-share by state or local agencies and private conservation organizations, for 5–10-year agreements. Sample projects include restoring native grasslands, controlling exotic species, stream bank stabilization, and cave closures for bat (Chiroptera) habitat.

EQUIP offers financial and technical assistance to farmers and ranchers for installing or implementing structural or management practices on agricultural land. Examples include integrated pest management and improved grazing practices. EQUIP provides federal support at 75% cost-share (90% in limited cases) and annual payments for up to 3 years.

OPTIMIZING FARM PROGRAMS FOR WILDLIFE: STEPS TOWARD PROGRESS

Wildlife managers can readily use farm programs to affect farm-scale changes to the satisfaction of individual landowners. Strategically applying farm programs to achieve specific or landscape-scale changes in wildlife habitat is considerably more challenging. The success of farmland habitat programs is associated with how well managers are able to accommodate the ecological, political, economic, and social contexts in which these habitat initiatives must occur. **State Wildlife Action plans** provide a useful new framework for guiding farmland wildlife priorities, including targeted species, habitats, and geographic areas.

Identifying Target Species and Ecological Communities

Biologists should consider the **community (ecosystem) approach** to habitat development, a perspective that implies appraisal of the potential effects of management on the number and relative abundance of wildlife species regionally. A community perspective does not preclude emphasizing one or several species in habitat initiatives at localized scales, but ensures the impact of management at larger spatial scales is at least considered. A management program that focuses on relatively common species, such as upland game, should avoid altering prime habitats of uncommon, rare, or endangered species in larger tracts or remnant patches of native vegetation. Large, permanent tracts of habitat in predominately agricultural settings are now uncommon. Where large tracts are present, managers should beware of maximizing edge, a practice that does not benefit area-sensitive species, and may facilitate penetration of cover by predators and by brood-parasitic birds (Winter and Faaborg 1999, Winter et al. 2000).

Identifying Physiographic Characteristics

Once identified, the target region should be examined to assess significant **physiographic features** from which to build

a habitat management plan (Risser et al. 1984, Swanson et al. 1988). Experienced biologists often perform this assessment informally, but it is important to review this process and document criteria used. What are the natural features that give definition to the region (Noss et al. 1995)? What was the natural vegetation prior to settlement: prairie, savanna, forest? What are the significant habitat features that define the wildlife community, including forests, wetlands, riparian corridors, intensive grain cropping, and livestock grazing? Are there remnant patches of natural vegetation or other significant semipermanent vegetation (such as trees along a stream) from which to start? What life-history needs of target species are being fulfilled in the existing agricultural matrix? What life-history requisites are lacking? These are the kinds of questions that generally define the resident fauna and should guide habitat management strategies.

Regional habitat strategies should permit development of corridors connecting important landforms and natural areas (Flather and Sauer 1996). The physical dimensions of corridors and how these corridors are managed will affect the reproduction and survival of wildlife at local and regional scales. River and stream corridors, their riparian vegetation, and quality of water that flows through them merit special consideration. In addition to upland erosion control, emphasis should be placed on the land–water interface, including near- and in-channel processes. Vegetative buffers, riparian forests, and wetlands represent opportunities to mitigate nonpoint-source pollution from agricultural lands. Further, expanded riparian green-belts provide additional perennial wildlife cover.

Recognizing Issues of Spatial Scale

Agricultural land use affects wildlife habitat at all **spatial scales**. Wildlife agencies usually develop habitat at the **patch or field scale**. These sites are readily affected by ecological phenomena occurring in nearby cover types (e.g., interactions at the farm scale). Likewise, **regional phenomena** influence responses by wildlife at farm and field scales. Regardless of the extent of control over local conditions brought about by habitat initiatives, the response of wildlife is affected by habitat conditions at larger scales where physiographic and land use factors are similar.

Temporal Factors

The goal of intensive habitat efforts is generally to improve reproduction and survival of target species on a regional basis (Dumke et al. 1981). The resources needed to enhance the demographics of target species often are poorly understood, and habitat programs may require several years of development before responses by wildlife are apparent. For example, successful intensive ring-necked pheasant (*Phasianus colchicus*) management programs typically require efforts for 5–10 years on a high percentage of farms over a region that is a township or larger in size.

Planning and Coordinating Management Plans

Biologists are prone to underestimate and understate the time needed for different facets of a management plan. They need to carefully consider the time needed to plan, develop support from key agencies and groups, coordinate and implement the initial habitat work, evaluate and refine the approach, and maintain or rejuvenate habitat over the long term.

We recommend **resource planning** as a method for the comprehensive management of the resource base (soil, water, and related plant and animal resources) within intensively farmed landscapes. Management toward multiple natural-resource objectives is a widely supported approach, but is difficult to accomplish on private lands (Jahn 1988). It requires considerable “front end” efforts by biologists that may seem counter to getting habitat in the ground. One problem is that it requires multidisciplinary expertise and interagency cooperation. In the absence of interagency cooperation, only the most persistent landholders will contact the agencies responsible for delivering independently derived plans for wildlife management, soil erosion control, woodland management, and commodity marketing.

Effective **coordination** is a major effort, and one of the most important aspects is to form an advisory group (Phipps 1972). Just as the wildlife biologist evaluates habitat conditions for selected species and provides technical guidelines for management, other professionals provide similar information from their areas of expertise. Members should represent targeted groups (landowners, renters, and farm managers), the community, public agencies (e.g., Natural Resources Conservation Service, State Department of Agriculture, and Cooperative Extension Service), farm organizations, and private entities such as sporting and other outdoor groups. An effective **advisory group** is invaluable in forming realistic goals and benchmarks of success while having a key role in legitimizing and promoting the effort.

Working with Landowners

There is often a direct relationship between effective **interactions among biologists and landholders** during the planning process and the subsequent success of the program. Biologists must learn what farm operators want accomplished on their land because it is the management **goals of the landholder** (not those of the managing agency) that are likely to be applied and maintained over the years. Skills in communicating, marketing, and salesmanship are essential to success, but they must be supported with technical knowledge that demonstrates to farmers an understanding of wildlife management, agribusiness, and the complex world in which adequate cash flow and profitability are essential.

Of particular importance is recognition of the time and other resources required for the farm operator to complete the new tasks generated by the habitat plan. An ecologically sound habitat management plan will fail if the varied needs

of land users are not met. For example, the interests and options available to a **hobby farmer** with considerable time and other resources for habitat development would differ from those of a large-scale farm operator. The plan should include local contact information for the U.S. Department of Agriculture office, state wildlife agency, conservation organizations, and other groups that might be sources of cost-sharing monies or incentives, equipment, seed or plant materials, and labor.

Little habitat management will be achieved and little demand generated if the contact with a farm operator is represented only by a quick trip over his land and a hastily delivered “plan.” **Follow-up** is important because it gives the biologist opportunity to diagnose and correct unanticipated problems such as what to do about “all of the weeds” in the grass planting, and it provides opportunity to emphasize the need for long-term maintenance of vegetation, which is often a shortcoming in habitat plans. Follow-up also facilitates reevaluating and updating the plan as conditions change on the farm (e.g., government farm programs or finances). Further, maintaining a close liaison with program participants creates opportunities for the biologist to make additional contacts, allowing for expansion of the habitat program to other farms. If a professional plan is prepared with the landholder’s interests in mind, and follow-up assistance is provided as reinforcement and to correct unforeseen problems, wildlife biologists can be assured the demand for their assistance in the farm community will grow.

Being Opportunistic and Flexible

Habitat opportunities on farmland are strongly influenced by policy changes that are shaped by an increasingly global economy, public opinion, resources available to landholders and agencies, and changing priorities in resource conservation. Some of the most creative and effective habitat programs were crafted and have been kept alive by biologists who effectively anticipated these changes and articulated the benefits of aggressive action to society.

EVALUATING AND REFINING PROGRAMS

The success or failure of a program should be documented, cost effectiveness evaluated, and the appropriateness of program modifications considered. **Evaluation** can include (1) adherence by agencies to time tables, costs, and objectives, (2) success rates in establishing and maintaining desired vegetative configurations and structures, (3) participation by landholders, initially and over time (including assessments of opinions, attitudes, knowledge, and conservation behavior), and (4) responses by targeted species to management. The number of farmland habitat programs that have received rigorous evaluation with well-documented costs and benefits is small, and few published accounts are available.

Monitoring Vegetation

The extent to which monitoring of vegetation is warranted depends on how reliable the planting method is assumed to be. The success of vegetation established and maintained by landholders (when planting methods are proven and widely known) is likely to be more variable than if personnel from wildlife agencies had undertaken the task. **Monitoring vegetation** should minimally include the inspection of a randomly selected sample of treated sites; these should be evaluated with respect to initial and long-term success in achieving desired plant forms. Alternatively, landholders familiar with particular plant forms can provide feedback through questionnaires.

Monitoring Participation by Landholders

Participation by landholders can be evaluated in several ways. Opinion surveys can be taken before promotion of the program is initiated; follow-up surveys can document the effects of participation in the program on attitudes and knowledge. Special recognition of outstanding cooperators can enhance the visibility and importance of wildlife management programs to landholders. Ideally, a rural sociologist or an education specialist should participate in program development and evaluation.

Monitoring Responses by Wildlife

Evaluating responses by target species to habitat programs can be accomplished by direct or indirect means, depending in part on the extent to which species-habitat responses are known. Direct evaluation involves, at a minimum, the use of proven survey methods to establish trends in relative wildlife abundance. More involved evaluation of demographic responses may require activities such as nest and radio-telemetry studies. In some instances, abundance of wildlife is not necessarily an indicator of a demographically healthy population (Van Horne 1983, Vickery et al. 1992). Although increased visibility and access to wildlife are important components of farmland management programs, biologists must ensure habitat manipulations are creating self-sustaining and expanding “**source**” wildlife populations rather than “**sinks**” that drain animals from larger scale **metapopulations**.

Indirect methods of evaluating habitat programs are gaining wide use by wildlife agencies because they are easy to use and relatively inexpensive. The most widely used method of inferred evaluation is the habitat index in which changes in habitat quality are measured by computing change. Measuring and computing habitat indices are not, however, the same as measuring the responses of target species to management (Flather et al. 1992, Morrison 2001).

Game species are the most common target of management interventions. Hunter success rates and changes in perceptions of the quality of hunting experiences are highly appropriate measures of the success of a program. Indeed, the perception of the success of wildlife management programs by user groups is likely to be more important in many ways than actual responses by wildlife.

Evaluating Interactions Between Wildlife and Habitat

If responses by **target species** to habitat initiatives are a true measure of success, few farmland habitat programs have been evaluated, let alone proven successful over a sustained period. Following the concepts of validity in statistical design, faulty evaluations can be categorized as to type of error. For example, invalid procedures can lead the evaluator to conclude that a positive response by target species to habitat interventions occurred, when in fact the response was negative, negligible, or nonexistent. Other common errors are inappropriate evaluation period (typically too short), invalid measurement techniques for evaluating population responses, and management or evaluation over a limited spatial scale. In these instances, important underlying biological phenomena may go undetected, and some of the same factors that limit success of habitat interventions also lead to failure in evaluation.

SUMMARY

Forces that shape agricultural land use and frame the habitat needs and opportunities for wild vertebrates are now global. As the human population continues to increase, pressures to produce more food and fiber per unit of land are increasing on all continents. Concerns about how to address these challenges are now front-and-center in the news media, discussions by policy-makers, and opinion polls. The challenges are greater than ever, but so is the will of the public to make steady progress in achieving multiple natural-resource goals on farmland. The knowledge and performance of wildlife agencies and professionals will be important in integrating the habitat needs of wild vertebrates in these emerging programs. The spatial and temporal factors requisite for successful farmland habitat interventions are tied to a complex farming system with ecological and socioeconomic dimensions. Wildlife managers need to be aware of and influence this system, ranging from regional policies and programs, to the practices that are used on the ground, and to the perceptions of landholders.

Managing Urban Environments for Wildlife

ROBERT A. MCCLEERY,
CHRISTOPHER E. MOORMAN,
MARK C. WALLACE, AND
DAVID DRAKE

INTRODUCTION

GLOBALLY, >50% of the human population lives in **urban and sub-urban areas**, and >65% of the population is projected to live in cities by 2045 (United Nations 2008). **Urban areas account for only 2.4%** of Earth's surface (Millennium Ecosystem Assessment 2005), but because of the intensity and magnitude of this land use, it has a disproportionate influence on regional and global ecological systems and processes (Collins et al. 2000). Urban environments contain areas of dense human populations, buildings, impermeable surfaces, introduced vegetation, and high concentrations of food, water, energy, materials, sewage, and pollution (McDonnell and Pickett 1990, Pickett et al. 2001, Adams et al. 2006). From a landscape perspective, urban systems are a mosaic of residential, industrial, and commercial buildings, and infrastructure interspersed with green areas (Breuste et al. 2008). For wildlife, these important green areas often come in the form of a patchy network of lawn, parks, trails, golf courses, cemeteries, and a few areas of native vegetation.

Wildlife ecologists have become increasingly engaged in and around urban areas because of the potential impact of working in these environments. More than in any other setting, the world's human population interacts with wildlife in urban areas. The increased contacts of humans and wildlife in urban settings have implications for human health, quality of life, education, and esthetics; **biodiversity** in all environments **improves the health** of humans along with their perceived **quality of life** (Fuller et al. 2007, Sala et al. 2009). Urbanities experiencing nature in urban green-spaces have shown measurable **physical and psychological benefits**, and these benefits increased with increased species richness in the green-spaces (Fuller et al. 2007). The proximity of people and wildlife in urban locales also provides an educational opportunity to foster an understanding of sound ecological principles (Pickett et al. 2008a). These realities have encouraged wildlife professionals to better understand and manage urban ecosystems and educate the public about the wildlife living amongst them in their cities.

Wildlife professionals also have become active in urban areas because of the challenges posed by people and wildlife living in close proximity. **Interactions** between humans and wildlife in urban areas creates a need to find safe, humane, and socially acceptable means to reduce property and natural resource damage from **overabundant wildlife populations** (Fig. 31.1). Wildlife can host pathogens that can be detrimental to humans and other wildlife populations (Bradley and Altizer 2007). **Sprawl** from urban areas threatens native species and biodiversity, and has

Fig. 31.1. People and wildlife living in close proximity. In Monterey, California, there is a history of conflict between residents and black-tailed deer (*Odocoileus hemionus columbianus*) populations. Photo by M. Wallace.

fundamentally changed ecological processes in adjacent agricultural areas and wildlands (McKinney 2002, Pickett et al. 2008a).

In this chapter, we examine the features and processes that drive **ecological interactions** in the urban environment and make the urban environment inherently different from less developed areas. We explore how wildlife responds to **urbanization** and detail the influence of specific features of the urban landscape on wildlife. We describe study designs and methodological consideration that should be addressed before starting urban wildlife research. Also, we provide a discussion of the skills needed to be an effective urban wildlife professional and discuss management strategies that can be used to promote the health and persistence of wildlife in urban environments. We present management strategies that can be used for land-use planning, green developments, open space protection, backyard conservation, and design and construction of roads. We provide suggestions for limiting wildlife damage in urban areas, attracting wildlife around the home, and managing people in urban settings. Finally, we look ahead to the future opportunities and challenges in urban wildlife management.

Ecological Processes, Soils, and Vegetation

To understand why wildlife in urban areas are **fundamentally different** than their counterparts in adjacent rural, managed, and wild areas, it is important to understand the driving forces that have altered the dynamics, behavior, genetics, and physiology of urban wildlife. In this section, we briefly detail some of the large-scale ecological forces that shape urban ecosystems. Additionally, because of their indelible link to wildlife, we briefly touch on the unique nature of soils and vegetation in urban areas.

Energy

Most natural systems are solar-powered through the processes of photosynthesis; this is not the case for urban areas. The cores of urban areas are often covered with impervious surfaces that yield no net primary production; thus, the energy necessary to run cities must be imported. Most of the energy in urban environments comes from fossil fuels, allowing urban environments to transform about **70 times** more energy into heat per square meter than most natural systems (Collins et al. 2000). This release of heat and carbon from fossil fuel has been shown to increase local temperatures (Ichinose et al. 1999) and change global climate patterns (Bulkeley and Betsil 2003). An example of an abundant and imported energy source for wildlife in the urban environment is food. **Food resources** are often made available to wildlife in the form of **refuse or supplemental feeding**.

City peripheries differ considerably from their cores and can be **productive** because of the fertilizers and watering they receive. In fact, the managed lawns and parks have been shown to be more productive than adjacent wildlands (Imhoff et al. 2000), which might help mitigate the loss of primary production from areas of impervious surface in the core of the city (Shochat et al. 2006). Some common wildlife species that take advantage of the rapidly growing grasses, ornamentals, and ample invertebrate populations found on urban lawns (Falk 1976, McKinney 2002) include moles (*Talpidae*), groundhogs (*Marmota monax*), and armadillos (*Dasypus novemcinctus*).

Climate

Urban areas show **increased temperatures** compared to adjacent rural areas because of a greater amount of impervious surfaces and other heat-absorbing materials. This phenomenon is often referred to as the urban heat island. Moreover, the cores of cities are warmer than exterior areas, and temperature differences are most noticeable at night (Pickett et al. 2001). **Humidity is lower and precipitation is often greater** in the city during the day, especially in the downwind portion of the city (Kuttler 2008). It also is more likely for it to rain in cities on the weekend, probably due to the accumulation of particulates during the week (Collins et al. 2000). **Gaseous pollution** can be 5–25 times higher in urban areas, and wind speeds are commonly reduced by 10–20% (Sukopp and Starfinger 1999). Changes in climate of urban areas have been shown to alter the times of flowering, leaf emergence, and leaf drop (Sukopp 1998). Additionally, **moderated urban climates** have been shown to reduce migration, increase winter survival, and lengthen the breeding season of urban wildlife (Gliwicz et al. 1994, Jerzak 2001, Parris and Hazell 2005).

Disturbance

Urban areas have their own unique sets of **disturbances**. Urban areas can experience the large-scale natural disturbances

such as fire and floods that drive succession and create heterogeneity in less altered landscapes. However, these natural disturbances are often controlled or suppressed in urban areas (Collins et al. 2000). Urban areas do see an increase in disturbances in the form of anthropogenic activities such as construction, industry, landscaping, and recreation (Rebele 1994). The combination of mowing, trampling, and air pollution along with other **anthropogenic disturbances** all influence the structure, composition, and succession of plant communities and the wildlife associated with them (Guntenspergen and Levenson 1997).

Soils

Soils become increasingly **compacted, sealed, and impervious** with increasing urbanization (Pickett et al. 2001, Wesolek 2008). Damage caused to urban soils by compaction reduces the ability of oxygen, water, and minerals to penetrate the soil (Adams et al. 2006). Sealed and compacted soils not only destroy vegetation and alter wildlife habitats, but they increase the amount of runoff and the temperature in the urban environment (Wesolek 2008). Pollutants washed off impermeable surfaces collect in the topsoil and cracks in pavement (Wesolek 2008), helping to create soils with more heavy metals, salts, acidity, and inorganic nitrogen, along with a lower quality litter layer (Pickett et al. 2001). Additionally, despite more rainfall in urban areas, the **poor water retention** of urban soils often leads to drought condition for urban vegetation (Ash 1991).

Hydrology

The increase in **sealed and impervious surfaces** in urban spaces increases surface runoff while decreasing evaporation and groundwater recharge (Paul and Meyer 2008). Runoff from urban areas increases channel size of streams, water temperatures, and levels of nitrogen, phosphorus, heavy metals, and pesticides in urban streams (Paul and Meyer 2008). These changes generally lead to reduction in biodiversity, including declines in aquatic macroinvertebrates (Morse et al. 2003) and stream salamanders (Orser and Shure 1972, Willson and Dorcas 2003, Miller et al. 2007). Stream amphibian communities may be altered when as little as 8% of the watershed is developed (Riley et al. 2005).

Evolution

Humans and human technology are possibly the dominate evolutionary force in the world (Palumbi 2008). **Natural selection** has increasingly come under the direct or indirect influence of humans, through human actions such as hunting, road kill, species introduction, removal of predators, and climate change (Alberti et al. 2003). These **selective pressures** are pronounced in urban areas, where animals exist in novel environments with new selective forces. The urban environment has been shown to alter the genetics, physiology, morphology, and behavior of wildlife and might even-

tually lead to the speciation of urban populations (Gliwicz et al. 1994, Ditchkoff et al. 2006, Shochat et al. 2006, Slabekoorn and Ripmeester 2008).

Socioeconomic Considerations

Urbanization is a human process that is driven in part by social and economic processes. The scope, extent, and particular features of urbanization in any given locality are, thus, tied to **social, economic, and political realities**. This includes the features known to influence the presence and abundance of wildlife species. Studies have shown a clear relationship between measures of wealth, power, and status and building density, lawn size, tree size, garbage, soil compaction, and the richness of plant and wildlife communities (Grove and Burch 1997, Nilon and Huckstep 1998, Kinzig et al. 2005).

Vegetation

Urbanization has a profound influence on vegetative communities. In portions of the urban environment, vegetation has been removed and replaced with pavement and buildings. Still, there is ample vegetation to be found in cities and for simplification, we place urban vegetation into 3 broad categories: remnant communities, colonizing communities, and planted communities (Adams et al. 2006). **Remnant communities** are native vegetative communities surrounded by development. **Colonizing communities** are found on derelict lands and vacant lots. These communities are dominated by invasive, exotic, and early successional plants. **Planted communities**, which dominate the urban landscape, are highly managed communities of nonnative grasses and planted shrubs, trees, and ground cover that also are commonly not native to the region.

In general, the **structure** of urban vegetation becomes simplified as urbanization intensifies (Adams et al. 2006, McKinney 2008). It is common to find the shrub and understory layer of urban and suburban environments removed or modified, creating a savanna-like community of trees and grasses (Dorney et al. 1984). Suburban landscapes typically contain widely spaced plantings of few species, most of which are not native (Tallamy 2007). The **fragmented** nature of plantings in these landscapes causes animals to move frequently as they search for food and cover. Too much movement can expose wildlife to predators and traffic or cause them to use energy important for survival (Charnov 1976).

From the periphery of a city to its core, vegetative cover, species richness, and the number of native and rare species typically declines (Sukopp and Starfinger 1999, Pyšek et al. 2004). **Nonnative plants** often dominate the core areas of a city, and the larger a city is the greater its proportion of nonnative to native plant species (Sukopp and Starfinger 1999, Pyšek et al. 2004). These nonnative plants alter ecosystem function and can degrade wildlife habitat (Schmidt and Whelan 1999, Borgmann and Rodewald 2004, Burghardt

et al. 2008). Additionally, nonnative plants attractive to birds and other wildlife are prone to invasiveness because animals serve as great dispersers of their fruits and seeds. Autumn olive (*Elaeagnus umbellata*) and multiflora rose (*Rosa multiflora*), for example, are exotic plants that produce fruits favored by birds (Lafleur et al. 2007), and each grows and spreads quickly where the seeds are defecated. Further, bird nests located in multiflora rose and other exotic shrubs may experience higher rates of predation than nests in native shrubs, possibly due to lower nest height or larger shrub volume surrounding nests (Schmidt and Whelan 1999, Borgmann and Rodewald 2004).

Snags (i.e., standing dead trees) and downed woody debris are important features of forest ecosystems and provide critical habitat for a diversity of wildlife (Harmon et al. 1986). In the southeastern United States., for example, >55 mammal species, >20 bird species, and many reptile and amphibian species use downed wood for nesting, feeding, or protection from predators (Lanham and Guynn 1996, Loeb 1996, Whiles and Grubaugh 1996). However, built areas contain few snags (Blewett and Marzluff 2005) and, therefore, cavity-nesting bird densities are low in suburban areas (DeGraff and Wentworth 1986, Tilghman 1987, Blewett and Marzluff 2005, Fraterrigo and Wiens 2005). Similarly, **downed logs** and other **downed woody debris** occur in relatively low densities in built environments (Fig. 31.2). Downed debris is removed by homeowners; future downed wood recruitment is reduced as snags and dead portions of live trees are removed for public safety reasons.

Forests, remnant vegetation patches, parks, and nature preserves in and adjacent to urban areas are important for

Fig. 31.2. The abundance of snags and downed logs is low in built environments; therefore, efforts should be focused on conserving these critical habitat elements. Photo by C. Moorman.

wildlife conservation efforts, but face a number of threats to their quality and health. **Disturbances** from trampling, mowing, and recreational activities, along with fire suppression, have all been serious threats to maintaining native vegetation in urban landscapes (Guntenspergen and Levenson 1997). **Anthropogenic disturbances** (i.e., trampling and landscaping) in urban woodlots create open forests with reduced regeneration of overstory species (Pickett et al. 1997). Urban vegetation also has an increased risk of drought because of the elevated runoff from impervious surfaces and decreased nutrients in urban soils (Pyšek et al. 2004).

Wildlife Communities and Urbanization

Urbanization has been one of the primary reasons for the **extinction and local extirpation** of native vertebrate species (Czech et al. 2000, McKinney 2002). Moreover, most research suggests that diversity or richness of species, especially vertebrates, declines with rises in the degree in urbanization (Marzluff 2001, McKinney 2008). This is likely due to the loss and **degradation of habitats**, the loss of vegetation to impervious surface, and the simplification of vegetation as urbanization increases (McKinney 2008). While the creation and expansion of cities has removed many native wildlife species, **invasive nonnative species** have replaced them, filling the ecological vacuum. As urbanization increases, the proportion and density of nonnative birds and mammals increases (Mackin-Rogalska 1988, Marzluff 2001, McKinney 2002). This is helping to create a situation where the same few species can be found in the core of cities worldwide (McKinney 2006). Along with a pattern of decreasing diversity, there is an inverse relationship with the density and biomass of the remaining species. Animal densities are commonly higher in urban areas and biomass of birds has been shown to increase 1–3 times in urban areas when compared with less developed areas (Adams 1994, Marzluff 2001, Adams et al. 2005).

Still, some studies have indicated the diversity of species increases with moderate levels of urbanization. These findings are more common for plants and insects than for vertebrates and are believed to be a function of the heterogeneity of the landscape and humans helping to increase nonnative populations (McKinney 2008). **Species diversity** also may vary with the age of an urban area. Bird communities have shown greater diversity in older developments and parks (Fernandez-Juricic 2000, Chace and Walsh 2006). This relationship can possibly be explained by the increased complexity of vegetation that occurs with aging of these urban sites.

As the structure of animal communities change with urbanization, so do the types of species that can be found there. In general, wildlife can be grouped into 3 categories: (1) urban avoiders, (2) urban adapters, and (3) urban exploiters (McKinney 2002). As described by McKinney (2002), **ur-**

ban avoiders are species sensitive to human activities and not able to use the anthropogenic resources of urban environments. These species are often large, interior species, predators, or migratory in nature. **Urban adapters** are often edge or savanna species that are well adapted to the typical suburban, backyard, forest-park matrix. Adapters utilize many of the resources available around human development, including ornamental plants, crops, garbage, and supplemental food. **Urban exploiters, or synanthropes**, are a homogeneous group of species that are often not native to the region and highly adapted to urban environment. They are usually omnivorous and their populations are dependent on human resources with little reliance on local vegetative communities (Nilon and VanDruff 1987, McKinney 2002, Ortega-Álvarez and MacGregor-Forbs 2009).

Urban-adapted mammals found outside of the cities' impervious cores include burrowing species (skunks [*Mephitis* spp.], moles, rabbits [Leporidae]). Medium-sized omnivores (opossums [*Didelphis virginiana*], raccoons [*Procyon lotor*], and foxes [*Vulpes* spp.]) also are common in and around the core of cities (Pickett et al. 1997, McKinney 2002). Common **urban-adapted birds** (American robin [*Turdus migratorius*], crows [*Corvus* spp.], seedeaters [finches, Fringillidae], and aerial sweepers [swifts, Apodidae; nighthawks, Chordeilinae]) include both omnivores and ground feeders (McKinney 2002, Chace and Walsh 2006, Ortega-Álvarez and MacGregor-Forbs 2009). McKinney (2002, 2006) noted that **urban exploiters** common in the city core included house mice (*Mus musculus*), rats (*Rattus* spp.), pigeons (*Columba livia domestica*), and house sparrows (*Passer domesticus*). There also are a few examples of **native species** thriving in the city core. For example, the peregrine falcon (*Falco peregrinus*) thrives in inner cities and benefits from the similarity of buildings to cliff faces for nesting areas and from abundant food sources like pigeons and house sparrows.

Demographic and Behavioral Changes of Populations

Wildlife populations that have settled in urban areas often show distinct differences in their population **demography, behavior, and physiology** when compared to their counterparts in more natural areas. For example, urban populations commonly have higher densities and higher rates of fecundity and survival. Furthermore, individual animals found in urban populations are often larger and show reduced responses to humans and other predator stimuli. Recently, there has been a push to understand the mechanisms that are causing those changes (Schochat et al. 2006) and not to simply look at the patterns of change that wildlife show in response to urbanization. Table 31.1 provides examples of some dominate urban features that are believed to influence wildlife communities and populations. Many of the **relationships** between specific urban features that we present have not been tested as causal relationships. In some cases,

associations or correlations have been made, and in other cases, the relationships are simply hypothesis; nonetheless, we believe this table helps to illustrate how the specific features of the urban environment may influence wildlife populations and individuals.

Urban wildlife research as a subdiscipline has struggled to place appropriate boundaries and definitions on the use of the term urban. Too often researchers use the term "urban" and assume their audience knows the meaning (McDonnell and Pickett 1990, McIntyre et al. 2000, Marzluff et al. 2001). This problem has arisen because most of the places where wildlife ecologists work, including >75% of the ice-free portion of Earth's surface, have been modified by humans (Ellis and Ramankutty 2008) and there are not commonly used standard designations for all the types of human-altered landscapes. Additionally, the names and shorthand that have been given to **human-altered landscapes** (urban, golf course, urban park, suburban, exurban, rural, city core, city center, urban-wildlands interface, etc.) have not been consistent, nor have they specifically detailed how the landscape has been altered. The term urban clearly is at one end of the gradient of human land uses and indicates that researchers are interested in studying wildlife in altered environments. However, the extent and type of alteration is of vital importance to understanding wildlife's response to the different and numerous features of urban areas (see Table 31.1). As wildlife research in urban settings expands, there is a need to define the subdiscipline and for researchers to document and even quantify the extent of urbanization on their study sites.

The urban wildlife subdiscipline investigates wildlife in areas dominated or influenced by the built environment and/or human habitation. Within these areas, the **subdiscipline focuses** on the behaviors, dynamics, and physiology of, and interactions between, wildlife, as well as the interactions of wildlife with humans and the biotic and abiotic features of these areas. Urban wildlife research is not restricted to cities and their surrounding suburbs or to natural areas within them. Urban wildlife research also includes investigations of wildlife in and around concentrated human developments of varying sizes, and in areas and communities connected to cities through transportation, utilities, or the flow of materials (Pickett et al. 2001, Anonymous 2008). Due to their reduced scale, many towns and developments have not been classified as urban, but if these areas have the same features as urban areas they should be considered within the scope of urban wildlife research (see Table 31.1).

The study of urban wildlife also is an inherently **interdisciplinary** field. We cannot truly understand how patterns of human development influence wildlife without **integrating social sciences** into ecological research. Sociology, demography, psychology, urban planning, and political science are a few of the many disciplines that can help wildlife ecologists elucidate the processes and drivers of the urban

Table 31.1. Relationships and hypothesized associations between features of the urban environment, and wildlife populations, communities, and individuals

Urban feature	Associated wildlife response	Citations
Increased food supply (anthropogenic food, supplemental feeding, primary production from lawn and ornamentals)	Altered diet; reduced migration; increased population densities, fecundity, and winter survival; smaller ranges; longer breeding season; greater body mass	Andrzejewski et al. 1978; Gliwicz et al. 1994; Heusmann 1988; Beckmann and Berger 2003; Prange et al. 2003, 2004; Ditchkoff et al. 2006
Human presence	Reduced activity during daylight, reduced antipredator response, avoidance behaviors, habituation to humans	Beckmann and Berger 2003, Ditchkoff et al. 2006, McCleery 2009a
Reduction of predators	Reduced response to predators, lower predation pressure, increased longevity, higher survival, high population densities	McCleery 2009a, Gliwicz et al. 1994, Marzluff 2001
Moderated climate	Reduced migration, higher winter survival, longer breeding season, range expansion	Gliwicz et al. 1994, Jerzak 2001, Parris and Hazell 2005
Roads	Road mortality, road avoidance, barriers to movement, subdivided populations, associated noise can inhibit the ability of male songbirds to attract mates, fragmented habitats, altered stream and wetland hydrology, polluted water, facilitated plant invasions	Forman and Alexander 1998, Forman and Deblinger 2000
Windows	Bird strikes, bird mortality	Adams et al. 2006, Klem 1990, Hagar et al. 2008
Culverts	Movement corridors, roost sites	Tigas et al. 2002, Scales and Wilkins 2007, Ascensao and Mira 2007, Gosselink et al. 2007
Bridges	Nesting sites, roosting sites, hibernacula, migratory rest-stops	Adams et al. 2006, Mackin-Rogalska et al. 1988
Buildings	Shelter, nesting sites, roost sites, den sites, hibernacula, higher cat densities, barriers to migration and dispersal, bird strikes	Marzluff 2001, Pickett et al. 2001, Ree and McCarthy 2005, Adams et al. 2006, McCleery et al. 2007b
Reduced snags and downed wood	Loss of nesting sites, reduction in cavity nesters and tree roosters, increased nesting in buildings, increased predation pressure from lack of cover	Blewett and Marzluff 2005, Rottenborn 1999, Adams et al. 2006, McCleery et al. 2007b, Ree and McCarthy 2005
Domestics and feral cats	Extensive predation, restricted distribution of prey species, reduced densities of prey species, reduced diversity	Dickman and Doncaster 1989, Woods et al. 2003, Baker et al. 2005, Ree and McCarthy 2005
Patchy, fragmented landscape	Reduced juvenile dispersal, source-sink dynamics, loss of interior species, high wildlife densities in favorable habitats, increased exposure to predators, increased competition with exotics	Andrzejewski et al. 1978, Dickman and Doncaster 1987, Nilon and Pais 1997, Marzluff and Ewing 2008, Etter et al. 2002, Beckman and Berger 2003, Harveson et al. 2004, McCleery 2009c
Noise	Higher frequency bird calls, louder vocalization, restricted distribution, reduced reproductive success	Estes and Mannan 2003, Slabbekoorn and Peet 2003, Slabbekoorn and Ripmeester 2008
Pollution	Reduced reproductive success, reduced health and survival, interspecific competition	Ditchkoff et al. 2006, Bradley and Altizer 2007
Simplified vegetation	Decreased native species, an increase in invasive species, loss of species richness	Sukopp and Starfinger 1999, Guntenspergen and Levenson 1997, Savard et al. 2000, McKinney 2008

system. For more information on integrating social sciences into applied wildlife research see Chapter 23 (This Volume).

Classifying and Quantifying Study Sites

Due to the breadth of “urban research,” it is important not to simply describe any area developed by humans as urban, but to describe the extent of human development and alteration in and around each study site. Marzluff et al. (2001) spelled out definitions for classifying land uses (Table 31.2) that can be used to classify studies along an urban–rural gradient. A second and more precise approach would be to quantify the features of the urban environment that are hypothesized to influence wildlife on a particular study site. One common metric often used as a proxy of urbanization

has been the amount of **impervious surface** (Arnold and Gibbons 1996, McKinney 2002). Some of the features of the urban environment that also could be quantified to help explain the distribution, demography, or behaviors of wildlife are land cover type, age since conversion, road density, traffic patterns, and human population density (McIntyre et al. 2000).

Design of Studies Examining the Influence of Urbanization

Any number of **study designs** can be used to examine wildlife, but some designs are better suited to understanding wildlife ecology in an urban context. One of the simplest approaches to studying wildlife in urban areas has been to

Table 31.2. Classification for land uses in urban wildlife ecology studies

Classification	Percentage developed	Building/ha	Residential human density
Wildlands	0–2	0	<1/ha
Rural and exurban	5–20	<2.5	1–10/ha
Suburban	30–50	2.5–10	>10/ha
Urban	>50	>10	>10/ha

Adapted from Marzluff et al. (2001).

compare wildlife populations and/or communities in urban areas to less developed areas. This approach can help elucidate the basic difference between wildlife in urban and rural areas. However, this design is limited because it can underestimate the extent of development (Miller et al. 2001a), does little to explain what mechanisms are creating the difference, and does not help establish levels or thresholds of development where ecological changes will occur.

A design that helps to address the aforementioned problems with the urban versus rural design is the **gradient approach** proposed by McDonnell and Pickett (1990). The idea behind this approach is that influence and extent of urbanization changes in relation to distance from the center of the city. By studying wildlife at uniform distances from the city center, researchers should be able to see patterns in relation to urbanization. A problem with this approach is that looking solely at distance oversimplifies urban systems that do not always change predictably from the center of the city (Alberti et al. 2001). This is to say that cities don't always grow in even circles out from the city center. An alternate approach is to select sites that vary quantifiably by type or intensity of development. Similarly, one of the strongest study designs for understanding wildlife responses to urbanization is to hypothesize what features of the urbanization are influencing wildlife communities or populations of interest, quantify these features, and relate them to measured changes (diversity, reproduction, behavior, etc.). Additionally, Alberti et al. (2001) have argued that using **landscape and patch metrics** can provide useful measures of the urban environment to relate to ecological questions.

Regardless of what design is used to study the urban environment, it is important to **account for scale** when examining wildlife in urban environments. Take, for example, a study on the influence of urban vegetation on bird communities on 0.25-ha plots. Even if the vegetation on the plots was similar, we would certainly expect there to be detectable ecological difference between plots surrounded by houses with 0.25-ha lawns and plots next to a freeway surrounded by impervious surfaces. Animals select habitats on **multiple scales** (Johnson 1980); therefore, we suggest that researchers attempt to conduct research on multiple scales or to

couple fine-scale research (vegetative structure, food resources, nesting sites) with broad-scale landscape-level examinations of the patterns and intensity of development (see Miller et al. 2001a). By examining wildlife's response to urbanization on multiple scales, planners and ecologists will become better equipped to understand and mitigate at the scales at which urbanization has the greatest influence on communities and populations (Hostetler 1999).

The **timeframe** of most urban wildlife research has been 1–2 years (Marzluff et al. 2001). Despite the difficulties associated with conducting long-term research, it holds unique advantages in urban areas. Urbanization and cities are fluid systems and long-term research projects allow researchers to establish cause-and-effect relationships between the changes in the structure of a city and changes in wildlife communities. Additionally, **long-term population studies** of demographic and behavioral changes can help explain why we see the patterns of change in response to different levels of development (Marzluff et al. 2001). Long-term studies such as those currently underway in Phoenix, Arizona and Baltimore, Maryland as part of the Nation Science Foundation's **Long Term Ecological Research** (LTER) program also allow researchers to evaluate the potential for cumulative effect, time lags, and feedback mechanisms in urban systems (Pickett et al. 1997).

Research Logistics in the Urban Environment

Many of the **research techniques** used for researching wildlife in an urban environment are similar to those in other field environments; however, there are a number of issues to consider before conducting research in an urban study site. First, researchers should realize there are **multiple stakeholders** in urban environments, including individual landowners, local clubs, NGOs (Nongovernmental Organizations), and interest groups. Also, there are likely to be **diverse opinions** about, and considerable interest in, your research. Before starting, we suggest you meet with as many of these groups as possible to help gain their confidence. Therefore, budget a suitable amount of lead time ahead of your project's proposed start date. Some researchers have suggested distributing leaflets (VanDruff et al. 1996). We also recommend creating a website and using local radio, television, and newspaper to help **engage local residents**. We also have found engaging local groups can generate a great number of **volunteers** for your project. Be ready to have tasks where they might be able to help.

Access to urban study sites also should be considered before commencing field work. Depending on the nature of the study, researchers might have to gain permission for access to study sites from individual landowners (even going door to door), park managers, homeowner associations, and police. Tax maps or digital county property records can be useful for identifying landowners. Additionally, it is important to realize that jurisdiction for wildlife and property on

an urban site may fall under different or multiple entities such as individual landowners, and municipal, county, state, and federal governments.

Once field work has begun, it may be highly visible, and with this comes increased contact with the public. **Interacting with the public** and answering questions is part of urban research. Field workers should be courteous, patient, and prepared to answer questions. Special care should be taken with field research that includes the trapping and handling of animals (Peterson et al. 2003a). Every effort should be made to make trapping methodology acceptable to the public and to reduce the chance the public encounters a trapped animal. This means checking traps frequently or attaching remotely accessed triggers to notify researchers when a trap has been tripped (Larkin et al. 2003). We also recommend that **handling of animals** be conducted away from the public's eye. If it is possible, use a vehicle, tent, or building for concealment. The humane handling of animals might appear normal to a wildlife researcher, but might be misinterpreted as cruelty by others. To protect yourself and the study animals, make sure your animal handling protocol has been approved by your **Institutional Animal Care and Use Committee (IACUC)** before you start the study. Collars and marks on animals also generate interest in, and concern for, animals. Field workers and investigators should be prepared to answer questions about the safety and utility of animal collars and marks. Previously prepared written information available for quick dissemination can increase public awareness and community support.

Many urban wildlife researchers have encountered difficulties with **theft and vandalism** of their equipment. Traps can be hidden or labeled with information about the research. Alternatively, traps can be placed out in the evening and removed in the morning. When monitoring mammal distributions, use of infrared cameras without a flash might help reduce public attention to them, or scent stations can be used as a cheaper alternative.

There are **advantages to urban research**. Many animals are habituated to people, making them easy to observe without considerably altering their behaviors. This also can make it easier to get visual locations of marked or radio-collared animals. The network of roads in the urban environment also provides easy access to den sites and areas of high activity (VanDruff et al. 1996). Additionally, roads and landmarks make it easy to home in on or triangulate the locations of radiocollared animals. Another advantage of not being at a remote field site is the ease with which field crews can receive and fix equipment and the accessibility of the site to the principal investigator, who can provide support when necessary (VanDruff et al. 1996). Finally, urban research provides an excellent opportunity to promote wildlife ecology and provides opportunities for education and outreach (McCleery et al. 2005).

In some cases, researchers might be forced to alter their methodologies in the urban environment. For example, darting an animal that might access >100 properties before it becomes sedated is probably not a good idea. In these situations, researchers should consider portable drop nets or drive nets (Peterson et al. 2003a). Density estimation also can be complicated. Often the only access for researchers in the urban environment is limited to roads. This can **bias sampling** because roads are not an accurate representation of the rest of the study area. Fortunately, researchers are beginning to develop methods of adjusting samples from roads to make them more reliable (Marques 2007). An alternative is to use a helicopter to overcome the biases generated from road-based methodologies (Drake et al. 2005). Additionally, urban wildlife's varying **use and avoidance of the abiotic features** of the urban environment have forced researchers to consider buildings, pavement, fountains, and other features of the urban environment in their **habitat selection research** (McCleery et al. 2007b).

MANAGING IN THE URBAN ENVIRONMENT

Practitioners

Wildlife management in urban environments is often more complex than in remote or agricultural settings (Adams et al. 2006). Additional issues include agency image and credibility problems, conflicts between recommended solutions and values of diverse urban publics, and even public animosity toward regulatory agencies (Lowery and Siemer 1999). A few agencies have reached out to **nontraditional urban clientele** (Adams et al. 1997), but overall the wildlife profession has not left its traditional hunting and fishing comfort zone and has had difficulty communicating effectively with the general public (Decker et al. 1987). Agency responsibility for **wildlife conflicts** is a confusing maze of jurisdictions and poorly articulated policies (Berryman 1994). Agencies have often left resolution of **urban human-wildlife conflicts** to individuals or private wildlife-control operators (Hadidian et al. 1999), who may address the symptom, but often do not have adequate training or incentive to deal with the underlying issues (Barnes 1997). The result is that the American public has been frustrated and is unsure of whom to contact for help (Reiter et al. 1999).

Wildlife management is people management. This truism is even more important for the urban wildlife practitioner than the traditional one. It's relatively easy to solve the wildlife issue or at least to know HOW to solve the biological problem. The difficult part is getting people to connect with you enough to trust you and listen to what you say long enough to influence their way of thinking. The **number and diversity of landowners and residences** in urban areas can make this a challenging and time-consuming part of any management action. However, it cannot be over-

looked because the acceptance of a management activity by individual landowners and the community as a whole are vital to the success of any urban wildlife management program.

Practitioners can **promote their programs** through leaflets, signs, the internet, newspaper, radio, and television. It is equally important for urban wildlife managers to engage directly with individuals and groups. Engaging stakeholders door to door, at meetings, and even over the phone can be a highly effective means to spread information about the benefits of a management program. In efforts to change or alter behaviors, perceptions, and attitudes, this type of **direct contact with stakeholders** is believed to be more effective than passive means of communications (print, television, radio, etc. [McCleery et al. 2007a]). Still, nothing is more important than encouraging involvement or participation from the public. Individuals that have performed a behavior (e.g., put a bat box in their backyard) or participated in an activity (e.g., used nature trails at the city park) are more likely to have a favorable attitude toward it and to do it again if their experience was positive (McCleery 2009b). Practitioners should make every effort to include and recruit school children, volunteers, housing associations, and interest groups to physically help with and participate in management activities as a way to influence behaviors and perceptions. Not only does this **build community support and increase public awareness**, but it also reduces personnel and management costs.

To help initiate wildlife-friendly projects, practitioners should consider small symbolic projects in the urban area (VanDruff et al. 1996). People are more receptive to changing their behaviors and thinking if they can physically see the benefits of a project (McCleery et al. 2007a). Small and highly visible projects can serve as excellent opportunities for education and can help managers explain and demonstrate the benefits of wildlife management to the public.

Outreach, involvement, and interpretation are good initial steps to gain acceptance of management initiatives, but for program success, it might be necessary to gain a better understanding of what urban stakeholders value and why they value it. Depending on the scale of management action, this information can be gained from informal communication with individuals or collected through formal surveys of attitudes, experiences, and behaviors (see Chapter 24, This Volume). Armed with information about what communities and individuals value, practitioners can help to tailor management programs to specific communities (e.g., community-based wildlife management) and create programs that allow individuals to see value and benefits coming from their efforts, tax dollars, or donations. Another tactic to encourage involvement and to help individuals see the benefits of responsible management strategies is to provide **incentives** for the management activities you would like to en-

courage. This can be done in the form of cost sharing, cash grants, or tax breaks.

Urban wildlife practitioners should cultivate interests that can be readily shared with the urban public (e.g., birds, herps, native plants, xeric plantings). They also should broaden their knowledge base to be able to talk intelligently in **diverse arenas**. Success also takes persistence. Building connections over a period of years will pay off as the public you have “informed” begins to expand the influence of your voice to wider audiences. In addition to wildlife management, practitioners need an understanding of **landscape architecture and design**. Urban practitioners should also understand the **physics** behind stream flow and erosion, and the engineering requirements behind other environmental management problems, and cultivate a working knowledge of how to address them. Additionally, urban practitioners need a solid understanding of **economics** and an understanding that most decisions are driven by money spent and political will (J. Davis, Texas Parks and Wildlife Department, personnel communication). Practitioners will benefit from the ability to integrate the ecological needs of wildlife species into the concepts of landscape ecology that increasingly are used in urban planning and design. And, finally, patience, enthusiasm, and genuine desire to find ways to integrate information from different fields and communicate this information to people will help the practitioner find success in the urban environment.

Habitat Conservation and Management

Considerable opportunity exists to protect, restore, and manage wildlife habitats in urban and suburban environments, but efforts need to be matched to the density of humans and the extent of habitat needed by the wildlife (Table 31.3). In densely populated urban areas, land-use planning has lim-

Table 31.3. Opportunities for habitat protection and management in urbanizing landscapes, categorized by human density and by habitat extent required

Habitat extents	Exurban	Suburban and urban
Small	Protection through development ordinances, conservation subdivisions; collaborative backyard activity; appropriate park and open-space management	Protection through development ordinances, conservation subdivisions; collaborative backyard habitats; appropriate park and open-space management
Large	Protection through zoning and development ordinances, conservation subdivisions; collaborative backyard activity; appropriate park and open-space management	Limited options; corridors or stepping stones to help wildlife move through

ited potential for conservation of large habitats because most wildlife habitats already have been developed. In these areas, land-use planning for wildlife conservation activities can focus on integrating goals and objectives for **restoring degraded sites** (e.g., stream restoration), improving backyards, and protecting and managing existing open space or integrating open space into community planning documents. In addition, these initiatives can be undertaken by a variety of groups outside of the land-use planning process. In less dense, exurban areas, planning has more potential to link large, contiguous areas of open space, especially when integrated with the local-scale collaborative habitat management efforts in more densely populated areas.

These **habitat conservation efforts** should be directed by specific landowner or societal objectives and should be based on the target species of wildlife to be conserved, including consideration for the scale at which the species operates. Additionally, wildlife population responses to habitat management should be monitored continuously and adaptive adjustments to management practices should be used. Different wildlife species operate at different scales; therefore, the spatial extent of human activities will influence the effect on wildlife (Hostetler 1999). For example, homeowner efforts to appropriately landscape a yard might attract a northern cardinal (*Cardinalis cardinalis*) or a butterfly, but will have little effect on a coyote (*Canis latrans*) or a red-tailed hawk (*Buteo jamaicensis*) establishing a home range. To address ecological response at multiple scales, planning, design, implementation, and monitoring of wildlife response to urban land use should be **coordinated** collaboratively with urban planners and landscape architects (Hostetler 1999).

Land-Use Planning

Typically, planning departments place little emphasis on biodiversity conservation, except when mandated by water-quality guidelines or threatened and endangered species legislation (Miller et al. 2008). Planning departments with a staff specialist and funding allocated to biodiversity conservation are most likely to emphasize habitat protection, yet these conditions are uncommon (Miller et al. 2008). Few planning departments have these resources; therefore, Broberg (2003) suggested that ecologists **educate** local governments, participate in public hearings, **and volunteer** to serve on planning commissions or review boards. To integrate wildlife conservation into urban planning, it is important for wildlife biologists to work collaboratively with urban planners and developers during all phases of development (Hostetler and Drake 2009).

To appropriately conserve wildlife and their habitats, land-use planners must incorporate ecological principles into community planning and design. Planning departments can acquire **conservation data** (e.g., key habitat corridors, landscape context) and **natural resources inventories** (e.g., rare

species occurrences) from state natural-heritage databases or other government databases. State wildlife action plans identify priority species and habitats with high conservation needs and can be an aid to prioritizing conservation lands in urbanizing areas. A map of a jurisdiction's potential conservation lands can be developed using these data sources and with input from regional experts and other stakeholder groups (Carter 2009). Once created, maps of high-priority conservation areas can be used to guide regional open-space acquisition and local protection of natural areas during subdivision development.

Landscape Context

Factors that influence **wildlife demographic patterns** may differ between urban, suburban, and rural landscapes, so wildlife managers should consider landscape context in local and regional conservation planning (Burhans and Thompson 2006). Kennedy et al. (2003) suggested a minimum of 60% of the landscape should be conserved as suitable habitat to sustain long-term populations of area-sensitive species and rare species. Protecting a single, large habitat fragment may be superior to protecting several large fragments, especially for conserving vertebrate species (Soulé 1991a). For example, Donnelly and Marzluff (2004) suggested that large forest reserves (>42 ha) in landscapes with >40% urban land cover will support rich bird communities.

Connectivity

Small, isolated patches of habitat embedded in a built landscape are unlikely to support viable wildlife populations over the long term, so **corridors** often are suggested as a means to maintain patch connectivity (Forman and Godron 1986, Noss 1987). Riparian systems and road underpasses can be used to form the initial framework of a corridor network, and additional linkages can be made through coordinated protection of open space (e.g., see Greenways and Recreational Trails below). If the distance between remnant patches is short (for the species of emphasis) then a **stepping-stone approach** can be used to promote movement. In this case, the stepping stones are suitable patches of habitat positioned within the urban matrix so that an individual species is able to move across the landscape by moving easily from one patch to another (Kennedy et al. 2003). If the distance between remnant fragments is relatively far, **continuous corridors** likely are the more appropriate mechanism to maintain connectivity and increase inter-patch movements (Haddad 2000).

Zoning and Growth Boundaries

Zoning and development ordinances are 2 tools that local jurisdictions use for regulating new developments (Pejchar et al. 2007). County and city governments use zoning to segregate incompatible land uses and preserve the character of a community. Zoning ordinances often designate the **ac-**

ceptable land use (e.g., open space, residential, commercial), the allowable building density on a site, the allowable height and footprint of buildings, and the proportions of the types of space on a lot (e.g., landscaping and impervious surface). Within a subdivision ordinance (one type of development ordinance), specific guidelines and exceptions for subdivision development also are defined. Other types of development ordinances may include watershed, tree, and steep-slope protection. Some communities have integrated all development ordinances into one unified code called a “**Unified Development Ordinance**.”

Zoning and development ordinances direct future development patterns and have long-term effects on wildlife habitats. Ordinances that incorporate protection of natural resources are an important tool for habitat conservation in urbanizing regions. Activities associated with wildlife management on public lands, including hunting, timber harvest, and prescribed burning, can cause aesthetic and safety concerns for developments along property boundaries. Therefore, zoning can be used to **limit development densities** in areas that lie adjacent to working public lands (ideally, 1 dwelling unit/2 ha or 4 ha), thereby increasing the chance that wildlife management activities will be feasible in the future. These **low-density zoning districts** also might be used to protect the watersheds surrounding drinking-water supply reservoirs or to establish a rural buffer outside of urban areas. However, even dispersed homes can fragment habitat for area-sensitive wildlife such as bobcats (*Lynx rufus*) and forest-breeding songbirds (Theobald et al. 1997, Odell and Knight 2001). In **large-lot zoning districts**, homes should be located far away from sensitive habitats and open space on adjoining lots should be connected when possible.

Overlay District

An **overlay district** can be used to establish alternative land-development requirements for a specific environmentally sensitive area or an area where development might pose a risk to wildlife conservation (e.g., adjacent to working open space). The overlay is a mapped area that is usually superimposed over conventional zoning districts, but overlays can be stand-alone regulations. The regulations associated with the overlay district supersede those of the existing zoning district.

Urban Growth Boundaries

Government can protect natural resources using **urban growth boundaries** (UGB), which are zoning controls that separate designated development areas from rural lands (Carter 2009). Inside the UGB, development is encouraged, while outside the line, development is strongly discouraged.

Development Patterns

Protected open space either can be integrated into the built environment or consolidated into separate areas; these

2 approaches can yield spatial patterns of wildlife habitat that are distinctive. For example, city-center designs that concentrate development near the urban core may contain relatively little green-space as compared to municipalities with a more dispersed development pattern (Sandström et al. 2006), but the latter can promote **sprawling exurban development** that is detrimental to wildlife conservation. New urbanism is an urban design movement that supports compact, pedestrian-friendly, and mixed-use neighborhoods, and the strategies associated with New Urbanist design may reduce traffic congestion and limit urban sprawl relative to conventional approaches (Gordon and Vipond 2005).

Transit-Oriented Development

By promoting transit-oriented development, municipalities can cluster development around existing transit centers. This will avoid urban sprawl encroachment into wildlife habitat.

Conservation Incentives

Homes closer to open space may have increased property value; therefore, market forces may facilitate the adoption of green growth patterns by developers (Pejchar et al. 2007). If not, local or regional governments may choose to offer economic incentives to encourage changes in development patterns to better conserve natural resources (Pejchar et al. 2007). **Conservation incentives** include density bonuses, transferable development rights, and tax credits for donating conservation easements. **Density bonuses** may be used to allow developers to include more lots in a development than is allowed under the existing zoning regulations in exchange for setting aside larger contiguous blocks of habitat as open space. **Transferable development rights** allow development rights to be transferred out of ecologically important areas to receiving areas, usually with a density bonus or house size increase attached as an incentive. **Tax credits** for donating conservation easements can be used to protect rural areas on the urban fringe and to conserve agricultural lands near urban centers.

Considerations for Open-Space Management

Following protection of **open space** through outright purchase or a conservation easement, active management generally will be necessary in order to restore and maintain the appropriate habitat conditions for wildlife.

Invasive Plants

Volunteer groups (e.g., clubs, student organizations, and park friends groups) can be enlisted to help remove invasive plants. Plants either can be removed mechanically (e.g., pulled, cut) or sprayed with herbicides, and sometimes both practices may be necessary depending on the plant. However, removal programs likely will need to be perpetual to stay ahead of the rapid spread of nonnative plants in urban landscapes.

Recreational Effects

User-related effects on open-space resources include loss of soil and ground vegetation in recreational areas, soil erosion along trails, tree damage, and wildlife harassment (Cole and Landres 1996). Effects on wildlife can be either **indirect** (through habitat alteration) or **direct** (as excessive noise or disturbance from people and their pets). Visitor effects on open space can be contained by closing sensitive areas to users or by concentrating use along designated trails (Leung and Marion 1999). Pets that accompany users should be leashed to prevent disturbance or predation of wildlife, and pet waste should be collected to prevent contamination of adjacent water bodies. Developing a **Trails and Recreation Master Plan** is critical to directing recreation into the appropriate areas. This also provides a public forum by which to understand the recreation needs of the citizens.

Early Succession Habitats

Many wildlife species associated with **early succession or shrubland habitats** are uncommon in urban landscapes because their habitats are uncommon. Backyard hedges and other edge habitats abundant in urban landscapes do not provide quality habitat for many **early succession species** such as shrubland-breeding birds (Schlossberg and King 2008). Furthermore, backyard hedges and edge habitat may exacerbate issues with overabundant wildlife populations that inhabit these habitat types. Early succession habitats in urban areas are small and fragmented. In urbanizing areas, disturbance-dependent species that use early succession habitat suffer because of the unpopularity of timber harvest and prescribed burning. Increasingly restrictive air quality standards and the complexities of managing smoke make the use of prescribed fire a challenge, especially near areas of concentrated human dwellings. Many local governments also have land-use **regulations**, including zoning, tree protection, and landscaping regulations that can restrict the cutting of trees or disturbance of vegetative buffers. These ultimately limit the use of timber harvesting as a management tool when managing for wildlife. Managers can work with local planners to ensure that zoning ordinances and other land-use regulations do not restrict habitat management practices in urban settings.

Wildlife managers can work with parks staff and open-space planners to create and maintain early succession habitat. Where allowed, timber harvests and prescribed burning can be used to **reverse succession** and maintain habitat conditions for fire-dependent plants and animals. **Periodic** (every 1–2 yr) **disturbance** (e.g., mowing) of grassy areas or the margins of ball fields or other open areas will yield weedy or shrubby habitats used by early succession wildlife. Similarly, restored prairies or planted wildflower meadows create early succession habitat that may be aesthetically pleasing to local residents.

Green Developments Neighborhood Design

A variety of innovative design strategies have been proposed to create conservation developments or “**green neighborhoods**” (Milder 2007). One such concept is the cluster development or conservation subdivision (Arendt 1996, Odell et al. 2003). In **conservation subdivisions**, houses are grouped together using smaller lots, lower setback requirements (i.e., closer to road), and fewer and more narrow roads than in conventional subdivisions, so that a significant portion of the development property (>50% of the land area) remains in ecologically significant open space (Arendt 1996). Housing density across the property, including the open space, must be at least as high as what would have been allowed in neighborhoods of relatively low-density single-family housing; lower densities would promote more urban sprawl (Arendt 1996). Open space should target riparian areas and wetlands, steep slopes, threatened and endangered species’ habitat, historic sites, view sheds, and working agricultural lands and forests (Arendt 1996, Carter 2009). Ideally, conservation subdivisions are linked to regional land-use plans so that open space is connected, contiguous corridors are present on the landscape, and remnant open-space patches are large enough to provide habitat for area-sensitive wildlife (Arendt 2004, Carter 2009). However, the collaborative planning required to ensure that future development maintains open-space connectivity rarely occurs.

Dispersed homes in **conventional developments** fragment wildlife habitat and favor human-adapted wildlife species (Theobald et al. 1997, Odell and Knight 2001), so conservation subdivisions have been proposed as a strategy to simultaneously satisfy habitat needs for wildlife and provide human residences (Arendt 1996, Odell et al. 2003, Hostetler and Drake 2009). However, **cluster developments** may not provide habitat conditions any better than dispersed home neighborhoods if open-space areas are relatively small, if the set-aside open spaces are not the most important habitats on site or if large areas around homes are cleared of native vegetation and replaced with nonnative plantings (Nilon et al. 1995, Lenth et al. 2006). Hostetler and Drake (2009) reviewed the conservation subdivision concept and provided suggestions for modifications that would further improve wildlife habitat conditions. They suggested that the construction and postconstruction phases be given the same weight as the design phase (Hostetler and Drake 2009). More specifically, Hostetler and Drake (2009) suggested that

during construction:

- contractors protect residual trees and other native vegetation from fill dirt and heavy equipment; and
- contractors use well-maintained silt fences to prevent silt from entering water bodies.

during postconstruction:

- native plants are used for landscaping;
- pets are required to stay indoors or on a leash;
- water use does not draw down nearby wetlands;
- fertilizers and pesticides are used carefully and not allowed to enter local streams or wetlands; and
- open space is managed perpetually to sustain biodiversity (e.g., prescribed fire is used when appropriate, trail use is managed).

The long-term challenges of managing open space in conservation subdivisions can be met by setting up a permanent funding mechanism to cover management costs (Arendt 1996) and by implementing a neighborhood education program that teaches residents the best management practices for maintaining the biological integrity of conserved open space (Hostetler and Drake 2009). Alternatively, subdivision open space can be placed in a **conservation easement** with a local land trust and management responsibility shifted to the land trust or other partner organization (e.g., local chapter of the National Wildlife Federation).

Riparian Buffers

Forested **riparian buffers** placed between upland pollutant sources and the receiving water body can be used to mitigate the effects of impervious surfaces and pollution associated with urbanization. Buffers provide stream bank stability, maintain thermal and hydrologic regimes, and reduce pollution from sediment, nutrients, and pesticides.

Although buffers that are 30–50 m wide can effectively protect water quality, they do not adequately conserve habitats for some specialized wildlife species (Semlitsch and Bodie 2003). For example, semiaquatic reptiles and amphibian species move between wetlands and the adjacent uplands to forage, reproduce, and overwinter, and require core terrestrial habitat between 127 m and 290 m from the edge of the aquatic site (Semlitsch and Bodie 2003). In suburban areas in central North Carolina, riparian buffers 50 m wide contained no development-sensitive breeding bird species, and buffers ≥ 300 m wide were needed to conserve the entire breeding bird community (Mason et al. 2007). Rodewald and Bakermans (2006) suggested the **landscape matrix** also was an important predictor of the bird community in riparian forests, and recommended that low-density development buffers also should be established around wide riparian forests to maintain their integrity as wildlife habitats. Riparian buffers, no matter how wide, will not maintain stream salamander populations if pollutants enter from upstream, nonbuffered stretches or if buffers are breached by stormwater drains or other direct inputs (Miller et al. 2007). Therefore, catchment-wide, nonbreached buffers, especially along **first-order headwater streams**, are vital to maintaining sensitive aquatic species such as salamanders (Miller et al. 2007).

Greenways and Recreational Trails

Greenways are multipurpose, linear, protected, open spaces that link natural areas while providing recreation opportunities, alternative transportation, urban beautification, increased property value, floodplain protection, and habitat for some wildlife (Ahern 1995, Searns 1995, Bryant 2006). Wider forested greenways (>100 m) harbor more development-sensitive breeding birds and fewer mammalian nest predators in their interiors (Sinclair et al. 2005, Mason et al. 2007; Fig. 31.3). Migrating birds also favor wider forested greenways, especially those with multiple vegetation layers (Kohut et al. 2009). Human activities along **recreational paths** affect wildlife habitat in a variety of ways (van der Zande 1984, Miller and Hobbs 2000). In Colorado, specialist birds (e.g., western meadowlark [*Sturnella neglecta*] in grasslands, western wood-pewee [*Contopus sordidulus*] in forest) were less common and nest predation rates were higher near recreational trails (Miller et al. 1998; but see Miller and Hobbs 2000). Wide trails through forest corridors (when they break the forest canopy) essentially create 2 narrower corridors that are less suitable to forest-interior birds, so managers should avoid clearing trees and other vegetation adjacent to paths (Mason et al. 2007). Alternatively, **trails** can be consolidated along forest edges, as opposed to through the interior, or in open areas so that forested habitat is not fragmented (Miller et al. 1998). When considered in long-term regional planning efforts, wide greenways can be connected and used to provide wildlife corridors across large landscapes and large habitat blocks for interior species (Arendt 2004).

Impoundments and Artificial Wetlands

Construction of **stormwater control impoundments and sewage treatment lagoons** can create shallow-water wetlands used by wildlife. To benefit wildlife, these impoundments should be constructed with irregular shorelines and gently sloping banks (Adams et al. 1986). Irregular shorelines decrease sight lines and provide hiding places for waterfowl, and also reduce wave action and decrease bank erosion. In larger impoundments (>2 ha), **islands** can be constructed to provide breeding areas for waterfowl. Gently sloping banks of 10:1 provide a littoral shelf of shallow-water habitat along the wetland margin. To encourage aquatic plant growth and to improve feeding habitat for waterfowl, wading birds, and shorebirds, 25–50% of the water surface area should be ≤ 0.6 m deep (Adams et al. 1986). Seeding or planting generally is not necessary for vegetation establishment along wetland margins unless soils have been highly disturbed by urban activities. **Water-level regulation** through **periodic drawdown** promotes interspersed of a diverse vegetation community and the associated aquatic invertebrates. Public education programs and riparian buffers are critical to protect natural and artificial

Fig. 31.3. Greenways are multipurpose, linear, protected, open spaces that provide a means for alternative transportation and places for outdoor recreation. When designed appropriately (i.e., wide, well-connected areas of green-space), they also can conserve habitat for development-sensitive wildlife in the urban landscape. *Photo by G. Hess.*

water bodies from pollution. Urban stormwater, which can contain pollutants and superheated water, should not be diverted into existing wetlands because of the potential effects on aquatic wildlife.

Individual Home Lots Landscaping Practices

As much of the **predevelopment plant community** should be retained as is possible during land clearing and construction. However, vegetation can be restored on these areas via landscaping. To learn more about the growing conditions in a suburban landscape, soil samples should be collected from different areas on a property and then analyzed. The local **Cooperative Extension** office generally can provide detailed information on how to proceed with a soil sample analysis.

Despite the growing base of knowledge related to the potential problems of exotic plants, some exotic species continue to be used as plantings in urban landscapes. Additional **wildlife-friendly landscaping principles** are to

- include a diversity of native plants in the landscape, including species known as hosts for the Lepidoptera larvae that are important food sources for birds (Tallamy 2007);
- select plants that flower and bear fruit at different times of the year, thereby assuring fruits, seeds, and nectar will be available throughout most of the year;

- cluster similar types of vegetation to allow wildlife easy access to seasonally abundant food sources without excessive movement and increased exposure to predators;
- plant low-growing herbs and shrubs under taller shrubs and trees. This helps to provide the vertical complexity of the vegetation that is important to birds. Different birds nest and feed in the ground, shrub, midstory, and canopy layers of a landscape (MacArthur and MacArthur 1961); and
- minimize lawn coverage.

Managing Dead Wood

To ensure the availability of **snags** to birds and other wildlife in urbanizing areas, Blewett and Marzluff (2005) recommended conserving patches of forest with high densities of snags (>8 snags of ≥ 25 cm dbh/ha). Large-diameter, more decayed snags that pose no risk to human safety or property also should be protected when possible in built portions of suburban landscapes (i.e., in open space protected in conservation subdivisions), but educational efforts first will be required to convince planners, developers, and homeowners of the environmental value of dead wood (Blewett and Marzluff 2005).

Brush Piles

Brush piles, although not appropriate for every urban lot, can be constructed to provide cover for songbirds (e.g., win-

ter sparrows, towhees [*Pipilo* spp.], wrens [Troglodytidae], and brown thrashers [*Toxostoma rufum*]), rabbits, and other small mammals. **Brush piles** should be placed near food sources (e.g., bird feeders) or along travel corridors in the urban environment. They can be constructed from downed limbs, hedge clippings, or old Christmas trees. The woody debris should be loosely stacked 1.2–2.4 m tall and 3–6 m in diameter. As the wood decays and settles, new material should be stacked on the pile. Before construction, homeowners should check that brush piles are allowed in their neighborhood landscaping ordinance. Homeowners also should be aware that often unwanted animals like snakes, rabbits, and mice (Muridae) may be as likely to use brush piles as songbirds.

Nest Boxes

The retention of snags may not be compatible with some urban land uses; therefore, nest boxes (Fig. 31.4) may be used as **surrogates for natural cavities** to provide nesting sites for a variety of wildlife species, especially birds such as great crested flycatchers (*Myiarchus crinitus*), screech owls (*Megascops asio*), chickadees (*Poecile* spp.), wrens, titmice (*Baeolophus* spp.), and bluebirds (*Sialia* spp.).

Guidelines for putting out nest boxes include the following:

- Nest boxes should be built following recommended dimensions for box height, box width, entrance-hole diameter, and placement height.
- A well-designed nest box is made of sturdy lumber (e.g., pine [*Pinus* spp.], red-cedar [*Juniperus virginiana*], or cypress [Cupressaceae] wood), has a metal entrance guard to prevent expansion by woodpeckers (Picidae) or squirrels (Sciuridae), and does not have a perch. Perches

Fig. 31.4. Nest boxes can be used as surrogates for natural cavities in the built environment and should be designed and located as is appropriate for target wildlife species. Photo by C. Moorman.

increase the use of nest boxes by aggressive birds like house sparrows and European starlings (*Sturnus vulgaris*) and may limit use by native birds.

- Do not paint or stain the interior of the box. If you decide to paint or stain the exterior, use a nontoxic paint or stain. If painting, use a light-colored paint (e.g., white) to allow the box to reflect, rather than absorb, radiant heat.
- All boxes need ventilation and drainage.
- To prevent easy access by nest predators (e.g., snakes and squirrels), nest boxes may be placed on a wooden or metal post away from overhanging tree limbs. A predator guard, or baffle, can be placed below nest boxes to further limit nest predation.
- Boxes should be placed in a habitat and location appropriate for the target bird species. If a box goes unused for a year, it can be moved to another spot before the new nesting season begins.
- Nest boxes meant for woodpeckers should be filled with wood shavings or sawdust so the adults are able to complete the excavation process that is important for pair bonding.

Bird Feeders

Millions of Americans feed birds, and **bird feeding** is a critical means by which people remain connected to wildlife in urban settings. However, feeding can have positive and negative effects on bird populations (Temple 1988, Brittingham 1991). Potential **positive effects** include improved physiological condition, resulting in higher overwinter survival, especially during extreme weather, and higher reproduction. Potential **negative effects** include higher rates of disease transmission among individuals at feeders, higher rates of accidental collisions with windows near feeders, or increased predation. Feeders also may favor granivorous bird species at the expense of insectivorous species, cause birds to shift their geographic ranges (e.g., allow birds to survive harsher winters and shift ranges north), or alter migratory patterns (Brittingham 1991). To minimize disease risk, feeders should be cleaned regularly. Feeders should be incorporated into residential areas only as a complement to an appropriately designed landscape that includes a diversity of native plants and adequate cover. Placing feeders within close proximity to dense vegetation or brush piles provides feeding birds a quick access to escape cover.

Reducing Bird Collisions with Windows

Bird strikes with windows (Fig. 31.5) can be reduced by placing feeders close (within 1 m) to a window, angling windows downward 20–40° from vertical, minimizing the proportion of glass in new construction, reducing the reflectivity of the glass, and removing reflective vegetation from in front of windows (Klem et al. 2004, 2009). Additionally, planting trees and installing window awnings to block the

Fig. 31.5. Millions of birds die each year from collisions with windows; however, recent research has identified some window design options that may help reduce the number of collisions.
Photo by C. DePerno.

sun from hitting the window may eliminate some reflection. Window screen, flash tape, and bird netting can be used to break up the reflection on the outside of the window. Falcon or owl silhouettes attached to windows with suction cups are not effective deterrents.

Roads

The width of the ecological zone of **impact from roads** may exceed hundreds of meters, so protected open space should be separated from busy roads (Forman and Deblinger 2000). **Road crossings**, including underpasses or overpasses, may increase road permeability, facilitate wildlife dispersal, and reduce road mortality (Clevenger and Waltho 2000). The primary types of road **underpasses** are bridges and culverts. Underpass entrances should be framed with native vegetation, human use should be minimized, and the height and width should be based on target species even though larger dimensions tend to allow use by a wider range of species (Clevenger and Waltho 2000).

Overpasses typically are landscaped with soil and vegetation and offer continuity to adjacent habitats; hence, overpasses are expensive to construct. Overpasses are used by species, such as deer (*Odocoileus* spp.), elk (*Cervus canadensis*), and grizzly bears (*Ursus arctos*), which prefer not to use the small spaces offered by most underpass structures. Amphibian populations are especially susceptible to roads in urban landscapes (Findlay and Houlihan 1997), and amphibian tunnels are a means to mitigate these effects. Among the amphibian individuals that used experimental tunnels in France, all species showed a preference for tunnels lined with soil

over bare concrete pipe (Lesbarreres et al. 2004). **Placement** of road crossings is critical and should be based on known dispersal corridors or the location of preferred habitats of target species (Clevenger and Waltho 2000). **Fences** often are connected to crossings and run for several hundred yards along road margins in both directions. Fences prevent crossings where they are erected and direct animals into crossing structures. Fences should be sufficiently high to limit crossing by target species, and they should be buried to prevent animals from digging underneath.

Attracting Wildlife

Backyards have tremendous potential for wildlife if they are landscaped or modified. Altering backyards to attract wildlife also can increase property values while decreasing energy costs with careful selection and placement of trees (Diekelmann and Schuster 1982). Additionally, backyard wildlife habitats can provide children a place to explore and develop a lifelong interest in wildlife and conservation (Louv 2005).

Attracting wildlife to backyards involves the same principles used in traditional wildlife management. The process should start with mapping and inventorying the property, identifying where water, cover, and foods are already available. Special note should be taken of trees or shrubs that provide fruits or seeds during at least some part of the year, nectar-producing flowers, old snags, and stumps. Additionally owners may want to have soils tested, consult experts and texts about local plants or wildlife, or find out what native plants are readily available in their areas. Owners should then decide what animals could prosper in their yards and determine what will need to be added or removed to support them (Martin et al. 1961). We advise **growing an array of foods** instead of providing food supplements with a feeder. Landowners also should introduce plants (Table 31.4) that provide food or shelter for target species. Plants should be arranged so food and shelter are readily accessible and in close proximity. If cover is not available it can be grown or built (Henderson 2009) for target species. It is important to note that plantings, feeders, houses, and other resources added to a backyard will require continued maintenance to make them effective for the desired species.

Birds

Because of their mobility and the adaptability of many species to human-dominated sites, birds are perhaps the easiest animals to attract to urban habitats. **Water** is particularly lacking for wildlife in urban areas and, because it is scarce, shallow frog ponds, water gardens, or bird baths can be used to attract birds and other wildlife. **Bird feeders** (see previous section) can provide a quick and reliable food source for seed-eating birds and mammals. **Bird houses** are a quick way to replace cavities that are commonly missing in the urban environment. However, birds are very selective, and

Table 31.4. Generalized list of recommended plants that are useful landscaping additions for wildlife in residential areas. Check with local sources for native plants best suited for each region of the country. This table provides examples that might not be native or suited to all regions of North America.

Kinds of plants	Wildlife needs fulfilled	Example species
Conifers	Escape cover, winter shelter, and summer nesting sites. Some also provide sap, buds, and seeds.	Pines, spruces, firs, arborvitae, junipers, cedars, and yews
Summer-fruiting plants that produce fruits or berries from May through Aug.	Provide foods for small mammals, brown thrashers, catbirds (<i>Dumetella carolinensis</i>), robins, thrushes (<i>Turdidae</i>), waxwings (<i>Bombicilla</i> spp.), woodpeckers, orioles (<i>Icterus</i> spp.), cardinals, towhees, and grosbeaks (<i>Coccothraustes</i> spp.).	Cherry and plum (<i>Prunus</i> spp.), raspberry (<i>Rubus</i> spp.), serviceberry (<i>Amelanchier</i> spp.), blueberry (<i>Vaccinium</i> spp.), grape (<i>Vitis</i> spp.), mulberry (<i>Morus</i> spp.), and elderberry (<i>Sambucus</i> spp.)
Autumn-fruiting plants that produce fruits or berries from Aug through Dec	Important for increasing migratory birds' fat reserves prior to migration and as foods for nonmigratory species that need to enter the winter in good condition.	Dogwoods (<i>Cornus</i> spp.), mountain ash (<i>Fraxinus texensis</i>), winter-berries (<i>Ilex verticillata</i>), cotoneasters (<i>Cotoneaster</i> spp.), and buffalo-berries (<i>Shepherdia</i> spp.)
Plants with fruits that remain attached to the plants through winter.	Many fruits are not palatable until they have frozen and thawed numerous times; also, fruits provide long-lasting foods for animals through the toughest periods of winter.	Glossy black chokecherry (<i>Photinia melonocarpa</i>), red splendor crabapple (<i>Malus</i> spp.), snowberry (<i>Symphoricarpos</i> spp.), sumacs (<i>Rhus</i> spp.), American highbush cranberry (<i>Viburnum</i> spp.), and Virginia creeper (<i>Parthenocissus</i> spp.)
Nectar-producing plants	Provide nectar that attracts hummingbirds (<i>Trochilidae</i>), orioles, bees, and butterflies.	Flowers with tubular red corollas attract hummingbirds. Other fruiting trees, shrubs, vines, and flowers can also provide nectar and sugars.
Grasses and legumes	Provide cover for small mammals and ground nesting birds—especially if the area is not mowed until 15 Jul or later. Some grasses and legumes also provide seeds.	Native prairie grasses: grammas (<i>Bouteloua</i> spp.), switchgrass (<i>Panicum</i> spp.), and bluestems (<i>Schizachyrium</i> spp. and <i>Andropogon</i> spp.), are becoming increasingly popular for landscaping purposes.
Maat- or nut-producing plants	Nuts and acorns are eaten by a variety of wildlife. These plants can also provide good nesting habitat.	Oaks (<i>Quercus</i> spp.), hickories (<i>Carya</i> spp.), buckeyes (<i>Aesculus</i> spp.), chestnuts (<i>Castanea</i> spp.), butternuts (<i>Juglans</i> spp.), walnuts (<i>J. major</i>), and hazels (<i>Corylus</i> spp.)

each species has different requirements for nest cavity size, shape, and location (Henderson 2009). Although we've primarily mentioned artificial provision of habitat to attract birds (and other wildlife), **landscaping** to provide natural sources of habitat is highly recommended.

Homes also create hazards for birds. **Feline predation** is a major threat to backyard birds and small mammals (Dickman and Doncaster 1989, Woods et al. 2003, Baker et al. 2005, Ree and McCarthy 2005). Cats are a serious threat to fledglings, birds roosting at night, and birds while they're on the nest, at the feeder, or using a bird bath. Cats should be kept indoors for their health and safety as well as to eliminate cat-caused predation. Owners who are not willing to keep their cats indoors should be discouraged from attracting birds to their yards.

Mammals

Small brush piles, intended for amphibians and reptiles, also provide shelter for rabbits and mice. Chipmunks (*Tamias* spp.) and woodchucks (*Marmota monax*) will dig their own burrows. Trees may provide shelter for squirrels, raccoons, and opossums. Food set out for birds may attract many of these animals. Squirrels, chipmunks, and mice will readily eat birdseed. Raccoons will feed on suet and on the trash, as well as on any dog or cat food you inadvertently leave out.

Woodchucks and rabbits will eat a variety of vegetation, including garden vegetables and flowering plants. **Precautions** should be taken to avoid unwanted encounters with animals that are attracted to backyards; for example, garbage cans should be placed in a secure shed or garage or metal cans that scavengers cannot chew through should be used (see Wildlife Damage Management in Suburban and Urban Areas [this chapter, below] for more suggestions).

Bats

People don't want bats in their houses, and urban arborists seldom allow old decadent trees to persist; therefore, bats lack shelter in urban areas. **Bat houses** are an excellent way to provide shelter for bats. Proper roost temperature is probably the most important factor for a successful bat house. Interior temperatures should be warm and as stable as possible (ideally, 27–38° C in summer) for maternity roosts. Bat house **construction** should be tight, roosting partitions should be rough, and roosting crevices should be 1.9–2.5 cm wide (Tuttle et al. 2004). Plans for constructing bat houses are readily available on the internet or at your local library or wild bird store. Keys to occupancy involve temperature (exposure), location, and maintenance. Houses should come with instructions (appropriate to the region) on painting houses and locating them to receive adequate solar heating.

Failure to consider these points accounts for >80% of bat house rejection (White 2004).

Reptiles and Amphibians

Most toads, frogs, lizards, turtles, or snakes found in backyards are harmless and all are beneficial—feeding on destructive insects or rodents. Backyard habitat for these animals can be easily created. Several **rocks** can be piled in a sunny, south-facing spot for basking. **Cover** can be provided by planting shade-tolerant, native groundcovers under trees and leaving leaf litter under trees and shrubs. Stumps, rotting logs, and stones should be left where possible for hiding spots, or cover can be constructed with wooden rails or fence slats to provide lizards with perches on which to bask and catch insects. Adding a **small pond** for frogs and toads to live and breed in (don't add chlorine or fish because neither one is good for amphibians) also will provide water for other wild-life species.

Butterflies

Adult **butterflies** feed in the sun and in areas protected from the wind and can be attracted to red, yellow, orange, pink, and purple flowers (Fig. 31.6). Butterflies and Moths of North America is an excellent online resource (<http://www.butterfliesandmoths.org/>) for determining what butterflies or moths occur in particular regions and what host plants can be grown to attract them. Plantings should be planned so that when one plant stops blooming, another begins. **Planting caterpillar-host plants** also will increase the chance of attracting unusual and uncommon butterflies. Insecticides should not be used in or near **butterfly gardens** and shallow pools of water with a sand or small pebble bottom can be used to provide a source of **drinking water** for butterflies.

There are many sources of information on the internet for people interested in ways to enhance their residential property for wildlife (Table 31.5). We caution against relying on information from **commercial vendors** who are selling their products; such sources often may not have the best interests of wildlife or homeowners in mind. For example, birds are species-specific about the **placement and size** (of entrance hole, nest box interior, and depth of box) of the nest boxes they will use (Henderson 2009). Farmhouse, windmill, and gingerbread bird houses, made to appeal to people, usually just contribute to the problem of invasive and generalist cavity nesters like the house sparrow and starling. Table 31.5 presents several useful government sites, many of which serve as the source material for the better extension publications about backyard wildlife.

Backyard Wildlife Habitat Programs

The **National Wildlife Federation** (NWF) certification program is designed to help individuals develop and apply a wildlife habitat plan for a home site or small acreage. On request, NWF will send you an application package and instructions for its **Backyard Wildlife Habitat Program**. If your application and plan meet the criteria, you will receive a certificate, and if you wish, a sign to show your commitment to wildlife conservation.

Backyard Wildlife Habitat Program

Wildlife Damage Management in Suburban and Urban Areas

Wildlife can cause significant economic, health-related, and natural resource damage (Conover 2002). The focus of this section is on **wildlife damage management** from the perspective of property damage (economic) because it is the most common motivating factor urban residents have for managing wildlife damage. For a broader context regarding wildlife damage management, see Chapter 34 (This Volume).

Urban residents spend an estimated **US\$8 billion annually** to manage wildlife damage in and around residential and commercial buildings (Conover 1997). Some of the species that have caused the **greatest economic damage** to metropolitan households include mice and rats, squirrels, raccoons, moles, European starlings, and pigeons. Other species commonly involved in negative human–wildlife interactions in urban environments (Conover 1997, 2002) include white-tailed deer, beaver (*Castor canadensis*), woodchuck, Canada geese (*Branta canadensis*; Fig. 31.7), wild turkey (*Meleagris gallopavo*), and American crow (*Corvus brachyrhynchos*). Regardless of how common a species is, there is no wildlife species that someone doesn't perceive as a problem at some time.

Wildlife managers have struggled to control population growth for many of the abovementioned species (see *Wild-*

life Society Bulletin, Vol. 25, 1997; DeStefano and DeGraaf 2003). These species tend to be **edge-oriented and habitat generalists**. As such, they have benefited from the creation of abundant edge habitat as urban environments are fragmented and developed to meet human needs (Marzluff et al. 2001, DeStefano and DeGraaf 2003). **Additional factors** that make many wildlife species inhabiting urban areas difficult to manage is their ability to adapt to human-dominated landscapes and achieve their reproductive potential, and the lack of sufficient natural (e.g., predation) or cost-effective, human-implemented, population control (Conover 2002, DeStefano and DeGraaf 2003).

Many people incorrectly equate wildlife damage management with urban wildlife management. In suburban and, to a lesser degree, urban areas, wildlife habitat is juxtaposed within residential and commercial development. The human and wildlife populations in suburban and urban areas are contained within a matrix of bounded space, creating increased opportunities for human–wildlife interactions relative to human–wildlife interactions in rural environments. Furthermore, urban residents, especially younger generations, spend more time indoors than out, and may not feel comfortable encountering wildlife (Louv 2005). Thus, with the exception of backyard bird feeding, many of the interactions suburban and urban residents have with wildlife are often **perceived to be negative**. For example, common encounters such as a deer darting in front of, but not colliding with, a vehicle, or a skunk meandering across a front lawn, can be perceived negatively. More problematic wildlife interactions, like a raccoon nesting in a chimney or bats roosting in the attic, only reinforce many people's idea that wildlife damage management and urban wildlife management are synonymous. Keep in mind, however, that what one person perceives as a problem, another may consider a benefit.

Fig. 31.7. Groups of Canada geese in residential areas are often viewed as pests because of the mess their droppings make and the damage they can cause to residential lawns, golf courses, and ornamental plants. *Photo by M. Wallace.*

PRINCIPLES OF WILDLIFE DAMAGE MANAGEMENT

The general principles of wildlife damage management can be used to improve success, reduce frustration, and save time and money when resolving a wildlife interaction that could result in damage or a health-related issue. The **first step** is to correctly identify the species causing the problem. Sometimes there may be more than one species. Signs, such as tracks, feathers or fur, scat, or the damage itself (i.e., browsed vegetation or a hole in the side of a house) can be used to determine which species are causing the problem. Once correctly identified, the **knowledge** of the animal's life history, ecology and behavior can be used to resolve the problem. For example, if you want to trap an animal, you must understand where the animal is likely to travel and what it eats, for correct and successful trap placement and baiting. Field guides can be used to learn about the animal's life history, ecology, and behavior.

Choices for **controlling nuisance animals** and populations include doing nothing and letting the problem resolve itself, or implementing nonlethal or lethal management practices singularly or in combination. Taking no action may be appropriate if the problem is not causing intolerable damage or health concerns and is relatively short-lived. An

example may be an American robin or northern cardinal frequently fluttering against a picture window of a house in an attempt to ward off a perceived, albeit reflected, competitor. Once mating season ends and he no longer needs to defend his territory, the fluttering will stop.

Nonlethal management practices (Table 31.6) are intended to reduce or eliminate wildlife damage using management practices that do not kill. Nonlethal management practices include **frightening techniques** like noise-making harassment (e.g., clappers), visual harassment (e.g., eye-scare balloons or predator decoys), or techniques that combine both noise and visual harassment (e.g., dogs), **exclusion methods** like fencing and chimney caps, taste and odor repellents, capture and translocation, habitat modification to deter damage-causing wildlife or to attract predators that prey on damage-causing wildlife, or changing human behaviors that attract damage-causing wildlife (also known as cultural modification). **Lethal practices** (Table 31.7) are intended to humanely kill individual animals to reduce populations of damage-causing wildlife. Lethal management practices include body-gripping traps, trap-and-euthanize, shooting, fumigants, and toxicants.

Each lethal and nonlethal management technique has its own set of **advantages and disadvantages**. One **advantage of lethal management** practices is that they can decrease

the number of animals in a population that is causing damage, thereby reducing the amount of damage. In some cases, one or a few animals are causing the problem, and lethal management can eliminate the damage once the individual(s) causing the damage are killed. A **disadvantage of lethal management** is that it is neither universally accepted nor applicable, and certain practices like shooting may not be legal or safe in urban areas. One **advantage of nonlethal techniques** is that they are generally more accepted by the public than are lethal techniques because they do not kill animals and can be used in areas with high human density more readily, and often more safely, than lethal techniques. A **disadvantage to nonlethal management techniques** is that they are often not effective and typically make the animals causing the problem move to another location. Although nonlethal techniques may reduce or eliminate the problem at the first location, the animals causing the problem may move and cause the same problem at a different location.

Reproductive control techniques are a unique set of wildlife management practices that have been employed in an attempt to regulate overabundant populations of wildlife (DeNicola et al. 1997). Conover (2002) provided an overview of fertility control. In brief, these techniques are used to control reproduction in urban wildlife populations where lethal methods like shooting are not practical, safe, legal, or accepted. Reproductive control practices include **sterilization, immunocontraception, and contraigestation agents**. Some reproductive control methods can only be used for re-

search purposes, and all are expensive relative to traditional population-control methods (e.g., hunting). Although these methods have demonstrated efficacy in controlling reproduction in individuals, delivery and specificity are still challenges, and they have not proven cost effective on a population or landscape scale.

An **integrated approach** to wildlife damage management is necessary in most cases, especially when using nonlethal management techniques like harassment and repellents. Most wildlife species will habituate to a foreign object in their area, and more so the longer that object is present. The **more diverse and varied** the management techniques used, the less chance for habituation to occur and the more successful the wildlife-damage management program (Fig. 31.8). Another factor that will increase the success of a wildlife-damage management program and combat habituation is randomness. The more random the application of the wildlife management techniques, the more successful one will be in reducing or eliminating damage because the wildlife will be less sure about when it is safe to be in the area. **Randomness** may include implementing different management practices, applying management techniques at different times or locations, or all of the above.

Not all wildlife damage management practices are equally effective or applicable in all areas; often, it is necessary to develop a wildlife-damage management program specific to the problem that is occurring. **Proactively** combating a problem before it occurs if it is predictable (i.e., seasonal), or as

Fig. 31.8. Nuisance wildlife, like these once-endangered brown pelicans (*Pelecanus occidentalis*), can easily habituate to people. Elimination of hand-outs, and the random implementation of diverse harassment techniques, can help combat habituation.

soon as the problem is noticed, will resolve a damage problem more quickly than letting the problem persist prior to resolving it. And finally, it is important to be knowledgeable about all local, state, and sometimes federal **laws** that regulate the wildlife being managed, especially when using lethal management techniques. State and federal permits may be available to kill game species that cause damage outside of established harvest seasons, and (with the issuance of appropriate permits) even select nongame species may be killed when they cause damage. However, even if state and federal laws are observed, local laws such as those dictating no discharge of weapons, or zoning ordinances relative to fencing, may prohibit the implementation of certain management practices within municipal boundaries. In addition to legal considerations, **ethical considerations** may be necessary. For example, trapping and translocating problem animals may not be humane, especially for animals that are territorial (see Chapter 36, This Volume).

Future Directions

Scientific research in urban areas has increased in the past decades, due in part to the establishment of 2 **Urban Long-Term Ecological Research Sites** (Urban LTERS; Marzluff et al. 2008). Nonetheless, organisms that have not been domesticated for human use, but have adapted to living within human-dominated landscapes, have been far less studied than their ex-urban counterparts (Hadidian and Smith 2001). It is imperative that we seize the opportunity to further our understanding of how urbanization will continue to alter the composition of wildlife communities as well as the demographics, behaviors, and physiology of wildlife populations.

Urbanization may be better understood from an ecological perspective than it is from a socioeconomic one (Hadid-

ian and Smith 2001). Work in the Urban LTERS has recognized that urban areas not only offer many advantages as laboratories for understanding ecological theory, but also requires integrating that understanding with social theory. Such work is increasing our understanding of humans' effects on nature and nature's on humans. Recent research has shown that many of our assumptions and the tools we have used have misled us about the homogeneity and simplicity of the social and biophysical processes in urban areas (Pickett et al. 2008a, b). There will continue to be **growing opportunities for urban ecological research** to learn more about this neglected system. The interaction of biological sciences and social sciences can help us to understand the dynamics of the only habitat that is increasing on our planet. Shochat et al. (2006) and Pickett et al. (2008a) provide new hypotheses and paradigms for the next generation of scientists interested in these new research objectives in cities.

Most importantly, as urbanites live and work farther away and more isolated from nature (Louv 2005), it is imperative that those currently involved in urban wildlife research and management lead the way to increasing urban residents' awareness and appreciation of nature. Both native and exotic species can help counter the experience deficit for nature in cities (Louv 2005, Miller 2005). We can start by helping the public understand the wildlife living with them in urbanizing habitats; for example, by explaining why there are so many individuals of only a few species are frequently found in human-dominated habitats, and why those that cannot coexist in human-dominated habitats are not found, or are found in lower numbers. We need to show what can be done to increase the biological diversity and decrease the problems associated with living with wildlife in the urban and suburban habitats in which most people live. **Urban wildlife practitioners** will be in greater demand as municipalities and citizen groups look for biologists trained in the ecological, political, design, planning, and people skills necessary to enhance the livability and reduce the footprint (Rees 1996) of their homes and lives. This is critical to maintain the next generation's support for traditional, as well as urban, wildlife management programs.

To achieve this, we must provide diverse educational experiences for the wildlife students of the future. It is incumbent upon wildlife programs at colleges and universities to change the way they train future wildlife managers. A **standardized curriculum** should be developed that could be adopted by wildlife programs. Urban wildlife ecology and management still includes, but is so much more than, animal damage control in the city. Today's **urban biologist** needs to take a leadership role in changing the rat-and-pigeon-control stigmata with which "urban biologists" have been saddled. We must move away from the perception that wildlife does not live in the city and overcome the fact that many of us chose to enter natural resources management to "get away from people." We may have to convince our-

selves, as well as the public, that a more diverse wildlife and the most important ecological questions (Pickett et al. 2008a) exist with us in our cities, not just outside the city. Effective urban wildlife managers will need a more diverse and integrated skill set than the traditional wildlife manager needed. Modern generations of students, interested in different objectives than growing more quail or bigger deer, will find the challenges and opportunities of making a real impact on how we design our future and work to integrate nature

back into the American lifestyle to be a most exciting part of the new urban ecology and management. Exciting, dynamic new careers are growing in the intersection of the social sciences (human dimensions and others) and traditional wildlife ecology and management. The **future** of urban wildlife ecology and management depends upon the new cohort of biologists, and it will be what they make of it. Their actions, as the next generation of urban wildlifers, will help define what urban wildlife management becomes.

LEONARD A. BRENNAN

Assessing and Managing Wildland Recreational Disturbance

INTRODUCTION

GUTZWILLER AND COLE (2005) provided a landmark chapter in The Wildlife Society's "techniques manual" by providing a synthesis that combines elements of human dimensions and recreational use of wildlands research and management. Our intent in this chapter is to provide an overview of assessing and managing wildland recreational disturbance. We believe that by providing the reader with this overview and these literature citations, we provide students, wildlife biologists, and managers an understanding and ability to apply these methods to field situations. For readers with a desire for more detail on this topic, literature citations provide more detailed coverage of the topics discussed in this chapter.

Wildland recreation refers to nonwork outdoor activities that are conducted in natural environments (Gutzwiller and Cole 2005). Wildland recreation depends on one or more natural resources (e.g., forests, water, and wildlife) that occur in a wild or undeveloped environment. In wildland recreation, a primary focus and source of motivation for activities is the natural setting itself or components thereof.

Although not all wildlands are **wildernesses**, wildland recreation occurs in places where natural conditions are the management goal. Recreation occurs in undeveloped lands that are close to urban areas, but lands used for wildland recreation are typically isolated from dense human populations. Roads, when present, are often of lower quality, and trails may not exist (Gutzwiller and Cole 2005). Most wildland recreation occurs on **public lands**, such as federal and state parks, refuges, forests, and grasslands, but some occurs on private lands.

Wildlife-dependent activities are pursued with the goal of encountering wildlife for some purpose (e.g., harvest, observe, and photograph). Other recreational activities are not contingent on wildlife. Wildlife may add enjoyment, present risk and challenge, or may be a nuisance, but participation does not depend primarily on wildlife occurrence because wildlife encounters are incidental. Activities (e.g., big-game and upland-game hunting) involving harvest are referred to as consumptive, and recreational activities that do not involve harvest are referred to as nonconsumptive. The latter term can be misleading, however, because some of those activities can decrease wildlife reproduction and survival, causing these activities to be consumptive in their effects (Gutzwiller and Cole 2005). This chapter emphasizes nonharvest activities.

Outdoor recreation demand has grown since the late 1940s, when the post-World War II economy expanded and general affluence increased (Flather and Cordell

1995, Cordell and Super 2000). During the last 5 decades, the number of participants and days of participation have increased for **consumptive** pursuits and **nonconsumptive activities** (e.g., camping, backpacking, hiking, off-road vehicle driving, horseback riding, swimming in natural waters, boating, waterskiing, downhill and cross-country skiing, and snowmobiling). Recently, some of the most dramatic increases in participation have occurred for **wildlife watching**. In addition, **newer activities**, such as mountain biking, mountain climbing, rock climbing, spelunking, orienteering, rafting and tubing, and jet skiing have become increasingly popular (Gutzwiller and Cole 2005).

Most **non-wildlife-dependent recreational activities** and participation (no. of trips) in many of these activities will increase in the future (Gutzwiller and Cole 2005; Fig. 32.1). Participation in fishing and in wildlife-dependent activities that do not involve harvest is expected to increase 63–142% during 1985–2040 (Gutzwiller and Cole 2005). During this period, big-game hunting participation is predicted to remain stable and small-game hunting participation is projected to decrease. Future **disturbance from consumptive activities** may stabilize or decline; **nonconsumptive activity disturbance**, which is frequently detrimental to wildlife (Boyle and Samson 1985), is expected to rise. Thus, wildland managers should expect recreational disturbance of wildlife to continue to increase in intensity and geographic scope as the public demand for experiences in natural environments increases.

Disturbance from direct contact with recreationists has been implicated as a factor responsible for declines in wildlife reproduction, survival, and vigor; higher depredation rates; increased vigilance at the expense of brooding of young and foraging; displacement from habitats that are needed for important life requirements; and alteration of food habits (Boyle and Samson 1985, Burger 1995, Knight and Gutzwiller 1995, Joslin and Youmans 1999). **Indirect effects** are defined as those that arise through habitat degradation by recreationists, which can be just as problematic as direct effects (Cole and Landres 1995, Joslin and Youmans 1999). Effects of human disturbance in wildlands can vary among individuals, populations, and species (Knight and Temple 1995a) and with time of year (Hamr 1988, Götmark 1992), prior experience with humans (Knight and Fitzner 1985, Marzluff 1988), noise levels (Bowles 1995), speed of recreationist movement (Richens and Lavigne 1978, Burger 1981), location of recreationists (Herbert and Herbert 1965, Hicks and Elder 1979, MacArthur et al. 1982), and type of recreation (Burger 1995, Knight and Cole 1995a). **Cumulative and synergistic effects** of these influences are possible (Bell and Aus-

Fig. 32.1. Projected participation indices (growth in wildland recreation trips, 1987 = 100) for land- (A), water- (B), and snow-based (C) activities in the United States, 2000–2040. Data from Flather and Cordell (1995); figures from Gutzwiller and Cole (2005).

tin 1985, Gutzwiller 1995). Accordingly, assessment and management of recreational disturbance typically does not entail simply applying approaches used previously; instead, efforts must be tailored to a particular disturbance situation (Gutzwiller and Cole 2005).

Land-management agencies operate under **multiple mandates**, including providing recreational opportunities; therefore, minimizing recreational disturbance to wildlife must usually be balanced with other goals. The public derives substantial benefits from viewing wildlife, so management actions that limit such activities may not be appropriate. In some situations, recreational activities have minimal negative effects on wildlife (Knight and Gutzwiller 1995). Many groups of wildland recreationists are among the strongest advocates for wildlife or the environment, and it is important that wildlife professionals not alienate these groups by acting on preconceived notions about the effects of their recreation. Thus, during **assessment and management efforts**, it is crucial that wildlife scientists remain objective about potential influences and that wildlife managers carefully consider both the **costs and benefits** of providing recreational opportunities. Gutzwiller and Cole (2005) recommend that techniques be used to develop and implement a policy that seeks a **balance** between wildlife protection and the provision of opportunities for recreation.

The need to assess and manage recreational disturbance to wildlife populations is pressing because it is occurring on public and private wildlands, which are the most natural areas that support wildlife. This chapter reviews **methods** for assessing the nature and magnitude of recreational disturbance and for avoiding or reducing that disturbance to wildlife. Specifically, we (1) describe how existing information can be used to evaluate the potential for harmful effects, (2) indicate how to conduct field studies to obtain new information, (3) present a framework for disturbance management based on objectives, monitoring, and effects of previous management actions, (4) provide options for managing recreationists, including approaches for informing visitors and regulating aspects of their activities, and (5) explain how to reduce recreational disturbance through wildland planning and management, with emphasis on facilities and infrastructure placement, and regulation of their use.

ASSESSING EFFECTS OF RECREATIONAL DISTURBANCE ON WILDLIFE

Recreational disturbance of wildlife occurs on all wildlands; therefore, the severity of effects of recreational disturbances on wildlife should be assessed routinely. The nature of assessments will vary with management goals, available information, perceived threats, and available funding. All areas should **assess impact potential**, most should conduct routine monitoring, and some should initiate field studies. As uncertainty about how some recreational activity affects wild-

life and the importance of wildlife conservation grows, managers face 2 choices—either conduct field studies or err on the side of unnecessary restriction when managing these activities. Field studies can be costly in the short term. However, long-term costs can be greater if wildlife is severely disturbed or recreationists are needlessly restricted (Gutzwiller and Cole 2005).

EVALUATION OF IMPACT POTENTIAL

An **evaluation** of impact potential uses existing information (data, expert knowledge, and logical thinking) to identify wildlife species that may require unusual management emphasis. These may be species with special status (e.g., threatened and endangered species), game species, or species that are major attractions for recreationists. In addition, they may be species that are vulnerable to substantial recreational disturbance in particular places and at certain times. Definitions of what constitutes high vulnerability and substantial disturbance are not absolute; they will vary from place to place. An assessment of the relative vulnerability of different species, places, and times is a means of prioritizing monitoring efforts and management techniques. If there is sufficient uncertainty about effects, field studies are warranted.

The initial step in any evaluation of impact potential is to compile an **inventory of species** either known or likely to occur in the area. Next, gather existing literature and expert opinion about likely effects on these species. Joslin and Youmans (1999) provide an excellent example of the wealth of insight that can be gained by compiling existing information about recreational effects on Rocky Mountain wildlife in Montana.

Species with special status should be identified first. The most obvious are species listed under the **Endangered Species Act**, those proposed for listing, or those identified as sensitive by the U.S. Forest Service, U.S. Bureau of Land Management, or state agencies. These species will probably be the focus of most monitoring, field studies, and most of the recreation management program.

The species most vulnerable to recreational disturbance are those for which a large portion of the population is exposed to recreational activities and individual animals are adversely affected by recreational disturbance. In **large wildlands**, the majority of species will probably not be affected by recreation because their populations are widespread, seasonal ranges or territories are small, and recreational disturbance is often localized around the recreation site. Many invertebrates, amphibians, reptiles, birds, and small mammals may fall into this category. If there is little potential for widespread impact, then little effort needs to be expended on monitoring recreation effects on these species unless the situation changes (e.g., increasing habitat fragmentation or development of adjacent lands). This does not mean that there is no impact on these species. Nor does it mean that educa-

tional programs should not be developed to reduce effects as much as possible (Gutzwiller and Cole 2005).

Of the **species with small seasonal ranges or territories**, the most vulnerable are those that are highly selective in the habitats they occupy. Suitable habitat for such selective species can be mapped, either on the basis of direct observation or from predictive models, and the information can be overlaid on maps of recreational use to identify areas of potential conflict or to suggest where trails and facilities should not be constructed. Recreationists are often attracted to riparian strips (Blakesley and Reese 1988), where species of concern often occupy these same riparian zones. Some species (i.e., invertebrates, reptiles, and amphibians) are concentrated and, therefore, more vulnerable at certain times of the year. **Management of the timing** of recreational activity can effectively limit impact on these species (Gutzwiller and Cole 2005).

It is difficult to generalize about effects on species that are numerous and have large seasonal ranges or territories. These species may have a large proportion of individuals in the population come into conflict with recreationists even when use is localized. These individuals have the capacity to learn from encounters with recreationists. The severity of impact to such species is influenced by the nature of the **learned response**, along with the spatial pattern of recreational use and critical habitat. Populations in which most individuals learn strong avoidance behavior may be substantially affected if recreational use is widely dispersed and/or occurs within much of the preferred habitat for feeding, breeding, or birthing. Populations in which most individuals exhibit **strong attraction responses** also can be affected significantly if the outcomes of encounters are often lethal, as is the case with black bears (*Ursus americanus*; Singer and Bratton 1980).

MONITORING

Recreational use and wildlife populations of concern should be monitored. It is important to monitor recreational activity because most techniques for mitigating wildlife impact involve managing visitor use (Gutzwiller and Cole 2005). The **amount and type of recreational use**, including how use is distributed in space and time, should be monitored. Techniques for monitoring visitor use are varied and highly developed. For example, numerous devices are commercially available for measuring vehicular traffic and flow through facilities. Monitoring dispersed travel, particularly foot travel in remote wildlands, is more challenging. Watson et al. (2000) provide a handbook on alternative techniques for estimating magnitude, type, and location of recreational use in wildlands.

Techniques for **monitoring wildlife populations** also are diverse and well developed. Monitoring the effects of recreation on wildlife can be problematic because it is seldom possible to separate the effects of recreation from other in-

fluences on wildlife populations. It is often necessary to conduct field studies to establish cause-and-effect relationships between recreation and wildlife and then to monitor recreation activities carefully. If dramatic changes in management are undertaken, then monitoring of wildlife populations can provide crucial information about the effectiveness of these actions.

CONDUCTING FIELD STUDIES

When potential exists for significant recreational disturbance to wildlife, and when available information does not provide an adequate scientific basis for evaluating the actual effects of this disturbance, **field studies** should be conducted. These studies should attempt to evaluate factors that influence the nature and magnitude of impact and whether the activity is detrimental. This work is needed to verify suspected recreational effects so that decisions about how to manage these activities are consistent with their real impact. If careful studies confirm that an activity with significant disturbance potential actually has **negligible effects**, then restrictive management would not be necessary; indeed, regulation of recreation in this case would be indefensible and detrimental to relationships between recreationists and wildland managers. If field studies indicate that a recreational activity is **substantially detrimental** to wildlife, then decisions must be made about how to manage the activity so that wildlife effects are not significant. Because of the context-specific nature of recreational effects on wildlife, it is not wise to apply blindly a management technique that has been used previously for a similar problem. **Differences** between one's local situation and the situation in which the management technique was applied previously (e.g., the species, frequency of recreation, habitat conditions, historical context of human disturbance) may reduce or eliminate the method's effectiveness. Thus, in many cases, field studies may be needed not only to reveal actual effects, but also to **evaluate the success** of a management approach.

Field Study Type and Design

Experimental and nonexperimental (observational or correlative) studies can provide information about recreational disturbance and how to manage it. Each of these 2 study types has **advantages and disadvantages**, and which type of study to conduct will be determined by the specific type of recreational disturbance, available resources (i.e., funding, personnel, time), and the need to determine cause-and-effect relationships. Simple **pilot studies** can be used to identify the factors on which more costly, **in-depth research** should focus, but such initial studies may not be rigorous enough to formulate management policy. Research must be scientifically **valid** if intended to direct management because inaccurate information may lead to mismanagement of wildlife or recreational activity, and user groups may challenge

management actions in court. Regardless of study type, the usual principles of **sampling, replication, statistical power, study design, and data analysis** must be applied. We do not discuss these principles because they are described in detail elsewhere (e.g., Green 1979; Hurlbert 1984; Cohen 1988; Hairston 1989; Hair et al. 1998; Zar 1999; and Chapters 1 and 2, Volume 1).

Experimental Studies

Lack of understanding about **cause-and-effect relationships** is an impediment to managing recreational disturbance. The most credible, defensible, and efficient way to surmount this problem is to conduct properly designed experiments. Assessment of recreational disturbance lends itself quite well to experiments (Gutzwiller 1991). The reason is that human activity is the primary factor of interest, and such activity can often be experimentally manipulated (Yarmoloy et al. 1988, Skagen et al. 1991, Knight and Cole 1995a). In a recreational disturbance experiment, one **manipulates the activity** of concern to test a hypothesis about the effect of that activity on wildlife. **Controls** (no disturbance occurs) in space and time, along with treatments, allow cause-and-effect relationships to be established. Examples of **experimental units** in recreational studies include sites (Gutzwiller et al. 1997), nests (Knight and Fitzner 1985), individual animals (Stalmaster and Newman 1978), and family groups (Keller 1991).

Nonexperimental Studies

When **constraints** on logistics, funding, timing, or other resources preclude experimental assessment, nonexperimental studies can often be used to identify associations between recreational disturbance and wildlife responses. **Nonexperimental studies** may be more realistic to implement because they can be quicker, easier, and less expensive to conduct (Gutzwiller 1991). These characteristics may be especially advantageous when influence of a recreational activity must be discerned quickly, as might be the case when species of special concern are involved. Wildlife scientists can use nonexperimental studies to help identify the most relevant factors and hypotheses to address in subsequent experiments.

Gutzwiller and Cole (2005) describe the various experimental and nonexperimental approaches for investigating the effect of recreation activity on wildlife. **Experimental approaches** include (1) mimicking recreational disturbance through use of investigators who conduct the recreational activity, and (2) an adaptive approach where activities of actual recreationists are manipulated in time, space, or both through management actions.

Complex Effects

Gutzwiller and Cole (2005) discuss **interaction, cumulative, ripple, threshold, and lag effects**. These may often reflect

reality better than simple **main effects**. Wildlife scientists have not typically assessed complex effects of recreational disturbance on wildlife.

Deciding Which Response and Disturbance Variables to Measure

Management objectives, the potential for **direct and indirect (habitat) effects**, and the importance of addressing **wildlife fitness** (reproduction, survivorship, longevity) should be used to decide which **response and disturbance variables** to measure. To be maximally useful, response and disturbance variables must directly reflect the spatial **scale, time-frame, and level of biological organization** (e.g., population, community, ecosystem) that a management objective addresses (Gutzwiller and Cole 2005). Gutzwiller and Cole (2005) discuss response and disturbance variables in relation to recreational activity research.

MANAGING RECREATIONAL DISTURBANCE OF WILDLIFE

In terms of time, personnel, funding, disturbance to wildlife, and inconvenience to recreationists, it usually is less costly to preclude a recreational problem than it is to correct one. Although not all situations lend themselves to **preemptive strategies**, we recommend that managers apply **proactive** (rather than reactive) approaches to manage recreational effects whenever feasible.

Framework for Management

Managing recreational disturbance of wildlife is both art and science. It involves value judgments and scientific information. Contemporary management frameworks attempt to bring values and science together (while making the distinctions clear) in processes that lead to effective management solutions to problems that are explicitly defined and based on societal values. The **Limits of Acceptable Change** process is the original and best known of these processes (Stankey et al. 1985). Another closely related process is **Visitor Impact Management** (Vaske et al. 1995). These processes are equally useful as informal ways to structure decision-making.

Each process involves (1) identifying problems—situations where monitoring data (scientific information) show that management objectives (value judgments) are not being met, (2) implementing management solutions to problems based on insight into causal factors, and (3) obtaining feedback from periodic monitoring to assess both the effectiveness of management solutions and whether new problems have developed (Gutzwiller and Cole 2005; Fig. 32.2). Although these steps are conceptually simple, their **implementation** is often hindered by managers not making their value judgments as transparent and explicit as they are in

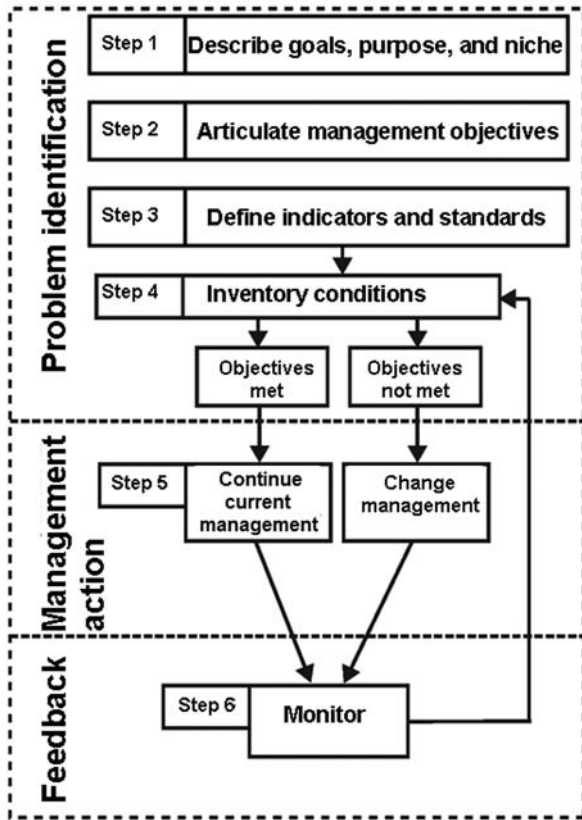

Fig. 32.2. A framework for managing recreational impacts on wildlife. From Gutzwiller and Cole (2005).

this process. Implementation often is stymied by the challenge of making monitoring an integral part of management. Management in the absence of science or based on personal biases of mid-level managers is no longer acceptable to a pluralistic and democratic society (Gutzwiller and Cole 2005).

The **initial step** in these frameworks involves **collecting information**, assessing values, and then codifying value judgments in quantifiable management objectives. The **second step** is to develop narrative descriptions of management objectives or what are frequently referred to as **desired future conditions**. The **third step**, **defining indicators and standards**, amounts to stating objectives in quantifiable terms. The **fourth step** involves **inventorying conditions**, with most attention given to monitoring selected indicators. The **fifth step** is to develop or fine-tune **management programs** to reflect where problems do and do not occur. The **final step**, often neglected in the process, is **monitoring**. Gutzwiller and Cole (2005) discuss each step in more detail.

Management Strategies

There are many potentially effective approaches for managing recreational disturbance of wildlife. Working through a

management framework should **narrow the array of alternatives** by (1) specifying problems in terms of what, where, and when, and (2) suggesting the relative social acceptability of different approaches. However, it is important to consider all possible management avenues, and it is often most effective to combine approaches and attack a problem from several different perspectives.

The **magnitude of wildlife disturbance** is a function of the magnitude of recreational disturbance and the vulnerability of wildlife to that disturbance. This suggests 3 **basic strategies for management**: (1) manipulate visitor characteristics to reduce recreational disturbance; (2) manipulate wildlife to reduce vulnerability to disturbance; and (3) manipulate habitat either to reduce wildlife vulnerability or to compensate for recreational disturbance. Each of these 3 primary strategies consists of several substrategies (Gutzwiller and Cole 2005; Table 32.1).

Manipulation of Visitor Characteristics

The amount of recreational use on a given area is one obvious factor that influences the magnitude of disturbance. One strategy is to **reduce or limit amount of use**. There are many ways to limit use, ranging from requiring entry permits to more subtle approaches such as limiting parking spaces, making access more difficult, and even manipulating the type of information provided to visitors. Somewhat counterintuitively, reducing amount of use by itself is often not an effective management approach. As use levels increase, additional use has less and less additional effect (Ferguson and Keith 1982). Limiting use may be most worthwhile in

Table 32.1. Strategies for managing recreational effects on wildlife

Manage people	
	Reduce amount of recreational use.
	Reduce per capita impact of use.
	Manipulate type of use.
	Manipulate visitor behavior.
	Concentrate recreational use.
	Manipulate location of use.
	Manipulate timing of use.
Manage wildlife	
	Reduce vulnerability to disturbance.
	Increase habituation to recreational use.
	Decrease attraction to humans.
	Increase avoidance behavior.
Manage wildlife habitat	
	Reduce vulnerability to disturbance.
	Attract wildlife to locations far from users.
	Screen wildlife from recreationists.
	Compensate for disturbance.
	Create new habitat.
	Improve habitat quality.

From Gutzwiller and Cole (2005).

places where use levels are currently low and regulations are effective in keeping disturbance levels below thresholds (Hammitt and Cole 1998).

Other strategies try to **reduce the per capita impact** of recreationists (see Table 32.1). The type of recreational activity can have a large effect on disturbance. Although there are exceptions, motorized uses will generally cause more disturbance than will nonmotorized uses, groups with livestock and/or dogs will cause more impact than will groups without animals, and overnight users will cause more disturbance than will day users (Knight and Cole 1995b, Hammitt and Cole 1998).

The **behavior** of recreationists may have an even greater influence on the magnitude of disturbance than type of activity. Disturbance depends on decisions about whether or not to approach wildlife and, if they are approached, how close to get to them. Research shows that fast-moving snowmobiles cause more disturbances to white-tailed deer (*Odocoileus virginianus*) than slow-moving snowmobiles, but that the greatest disturbance occurs when the snowmobile stops (Richens and Lavigne 1978). **Noisy behavior** can be particularly problematic (Bowles 1995). Some of the worst cases of disturbance are the result of **malicious acts**; but, well-intentioned, uninformed people likely cause most impact.

In most situations, impact on wildlife should be less when recreational use is concentrated as opposed to being widely dispersed. **Concentration** of recreational use and related activities also increases the predictability of human activity. Many animals **habituate** to (and, therefore, are not highly disturbed by) human activities that are predictable and nonthreatening (Knight and Cole 1995a). Miller et al. (2001b) found, for example, that the alert distance, flush distance, and distance moved by deer and birds increased when hikers were off-trail compared to when hikers were on-trail. They attributed these results to trail-use habituation by wildlife and to the unpredictability of off-trail activity.

The **location** where recreation occurs also influences the magnitude of disturbance. When recreational activities occur, near or even within the view of nest sites, nests can be abandoned or depredated (Miller et al. 1998). Miller and Hobbs (2000) found birds that were able to nest close to trails actually suffered less nest depredation. Activities close to preferred feeding sites can result in reduced feeding, increased energy expenditure, and even displacement of birds to less productive habitat (Stalmaster and Kaiser 1998).

Finally, **timing** of recreational use has a pronounced effect on the likelihood of serious impact because animals are most susceptible to disturbance at critical times of the year, especially during the nesting season and the postnatal period. There is substantial evidence that disturbance while feeding can be cause for concern (Hobbs 1989, Skagen et al. 1991). Some species are particularly vulnerable at certain times because they are highly concentrated. Examples include mi-

grating birds concentrated on stopover sites, and amphibians migrating during the breeding season.

Manipulation of Wildlife

There may be potential to manipulate wildlife so they are not severely affected by ongoing recreational disturbance. The most obvious examples are **aversive conditioning** of animals that are attracted to humans, and attempting to habituate animals to recreational activities. In Glacier National Park, managers have used cracker shells, rubber bullets, and specially trained Karelian dogs to teach bears to stay away from human food (Joslin and Youmans 1999). It is not clear how successful such attempts have been. Bears also have been the subjects of successful attempts to habituate animals to human activities. In Alaska, McNeil River Falls is where people come to watch brown bears (*U. arctos*) fish in salmon streams. The bears' feeding habits are not disrupted by this activity because viewer number, location, timing, and behavior remain constant, and the bears habituate to the viewers (Aumiller and Matt 1994). Whittaker and Knight (1998) observe that there can be unintended consequences of such efforts. For example, habituated bears may become easier targets for hunters and poachers.

Manipulation of Habitat

Habitat modification can serve both to reduce disturbance and to compensate for recreational disturbance. Hockin et al. (1992) provide examples of manipulations that **reduce disturbance** (e.g., creating attractive nesting sites away from areas of recreational activity or visually screening recreationists from nesting sites). They also discuss examples of **compensation** (e.g., creating habitat to replace habitat altered by recreational use and improving feeding areas to which recreation displaces wildlife).

Synergistic Effects

It is important to consider the effects of **multiple management strategies** working in combination (Gutzwiller and Cole 2005). **Limiting amount of use** is seldom an effective management strategy. However, it can be a highly effective supplement to actions that concentrate and control location of use. The **most effective management programs** apply a variety of management techniques, particularly visitor education, activity restrictions and zoning, and thoughtful design of roads, trails, and facilities.

Visitor Education

Education is one of the keys to reducing recreational effects on wildlife (Gutzwiller and Cole 2005). By **changing human behavior** (Klein 1993), education can be an effective means of reducing per capita impact. Through education, management can become more proactive and preventive in nature. Education is not a panacea; instead, it is a foundation on

which to build a comprehensive management program. Development of an effective **low-impact educational program** requires considerable thought. It requires attention to the content of educational messages and to the communication media that will be used to disseminate messages.

Message Content

Knowledge about appropriate low-impact techniques has developed slowly during the past few decades with accumulation of personal experience and recreation ecology research. Progress in developing consistent educational messages for wildland users has been profound. Over the past 2 decades, numerous books have been written about low-impact use of wildlands (Hampton and Cole 1995), and a national **Leave No Trace** low-impact education program was developed (Swain 1996). Leave No Trace is a partnership between federal land-managing agencies, nonprofit educational organizations, and the recreation industry, with a mission to develop a nationally recognized minimum-impact education system to educate federal land managers and the general public through training, publications, videos, and web sites (<http://www.LNT.org>). Consistency in low-impact education has emerged, even among the different land-managing agencies. This consistency is most apparent in the **7 low-impact principles** that are the crux of the program (Gutzwiller and Cole 2005; Table 32.2).

Although “**Respect Wildlife**” is one of the Leave No Trace principles, recommended behaviors for “respecting wildlife” are poorly developed. **Recommendations include:** (1) travel quietly and give animals the space they need to feel secure; (2) avoid approaching animals too closely, feeding them, or touching them; (3) learn about locations and times of the year when disturbance of animals is particularly problematic; and (4) leave pets at home or keep them under control (Gutzwiller and Cole 2005). Individual managers must craft recommendations that are specific to the situation that exists in the place they manage. The Leave No Trace program recognizes that education needs to be tailored to individual places and user groups. Ultimately, visitors must use their own judgment and ethics with respect to how they behave in these circumstances.

Table 32.2. Leave-no-trace principles, proposed for visitors using public recreation sites

Plan ahead and prepare.
Travel and camp on durable surfaces.
Dispose of waste properly.
Leave what you find.
Minimize campfire effects.
Respect wildlife.
Be considerate of other visitors.

From Gutzwiller and Cole (2005).

Effective Communication

There are many different ways to try to persuade recreation visitors to adopt **low-impact practices**. Some of the most common educational media include brochures, personnel at agency offices, maps and signs, personnel in the field, and displays at visitor centers or in parking areas. Research by social psychologists, who have been studying persuasive communication for years (Eagly and Chaiken 1993), suggests that low-impact education is a difficult task. Principles of low-impact education that have been compiled from experience and research are varied (Roggenbuck 1992, Gutzwiller and Cole 2005; Table 32.3).

Activity Restrictions and Zoning

A common means of limiting disturbance is to **restrict or prohibit activities** that are particularly disturbing to wildlife populations and/or their habitats. Motorized use is perhaps the most common activity that is restricted, both because motorized use can be particularly destructive and because motor vehicles can reach and disturb wildlife in remote places. **Complete restriction** of motorized vehicles is typically the policy that is enforced in areas designated as

Table 32.3. Principles for effective communication when addressing the public

<ul style="list-style-type: none"> Educational programs should be guided by specific objectives. It is important to identify specific problems and users that are the primary cause of the problems. Focus the message. Address a few critical problems and desired behaviors instead of overwhelming the visitor with information. Clearly state the problem, type of behavior that aggravates the problem, and how a change in behavior will improve the situation. Identify the audience. Different messages should be targeted to specific users and problems and delivered using different media in different places. For example, hunters should receive a different message than nonhunters and should be contacted in different places and manners (e.g., in hunter-safety classes). Certain behaviors and user groups will be more amenable to change than will others. Use a combination of techniques. A combination of techniques allows messages to be repeated and makes it more likely that most visitors will be contacted. Personal contact supplemented with written materials can be particularly effective. Present messages in a professional manner. Productions need not be slick, but they should not be perceived as amateurish. If they are, credibility will suffer. Text and dialogue should be accurate and easy to understand. High-quality equipment and materials should be used for graphics and productions. Personnel who contact the public should be cheerful, polite, outgoing, have a positive attitude, and be trained in communication skills and low-impact techniques.

“wilderness” in National Forests. In some situations, however, motorized use is less disturbing to wildlife than is slow-moving, less predictable pedestrian use (MacArthur et al. 1982).

Zoning is a means of restricting activities while not prohibiting them entirely. Certain activities are allowed in some zones, but not in others. In the context of managing wildlife, the general idea is to provide refuge for wildlife from repetitive disturbance. Depending on the situation, zones that provide refuge might be particularly critical locations for birthing, watering, roosting, or feeding, or they might simply provide some portion of the area to which disturbed animals can escape.

Zones might provide **absolute protection** from disturbance by prohibiting all recreational use. Alternatively, zones may only provide **protection from severe types of disturbance**. In these zones, recreational use would be allowed, but it might be restricted in quantity or in terms of the activities and behaviors that are allowed. In some zones, the only option for access might be to join a guided group of limited size. In other zones, recreationists might be required to travel on designated roads or trails.

Timing can be critical to the overall effect of recreational disturbance; therefore, **temporal restrictions** can be an important part of a management scheme. Use could be prohibited in critical locations (nesting sites) during crucial periods (nesting season). Knight and Temple (1995b) observed that, although most temporal restrictions involve seasonal closures for weeks or months, daily cycles of vulnerability also exist, with wildlife feeding primarily at night or, alternatively, primarily during the morning hours. In these cases, restrictions would be frequent, but short lived.

Wildlife-Sensitive Design of Roads, Trails, and Facilities

Wildlife disturbance is affected largely by where and when people and wildlife come in contact; thus, the **design of traffic networks and facilities** is important. Planning and design, to keep wildlife disturbance to acceptable levels, must be done at multiple spatial scales. Particularly in smaller areas, linkages between the management area and **surrounding lands** must be considered. For example, it is important to consider the possibility of displacing wildlife from public to private lands, where increases in conflicts between humans and wildlife may occur. Effects of noise and development, as well as the likelihood that nonindigenous species might invade from adjacent lands, should be considered. Regardless of the size of the management area, it is important to develop a broad-scale perspective of the distribution of species, their habitat, and their corridors of movement. Roads, facilities, and the flow of traffic should be designed to minimize vehicle collisions with wildlife, disruption of travel corridors, fragmentation of habitat, and impact to regionally rare species and habitats (Gutzwiller and Cole 2005).

The **location of access points or trailheads**, beyond which motorized use is not allowed, can influence the spatial distribution of visitor use. **Use distributions** also can be influenced by the placement of facilities such as viewpoints, which attract use away from sensitive areas. Viewpoints can be located and designed to minimize impact (Gutzwiller and Cole 2005).

Campgrounds should be located and designed to minimize disturbance. Campgrounds are often placed in riparian zones because humans are attracted to water. However, the importance of riparian zones to wildlife means that location and design of riparian campgrounds are critical. Blakesley and Reese (1988) found that species that nest on the ground or in shrubs and small trees were underrepresented at campsites. To support a diversity of bird species in campgrounds, active intervention may be necessary to maintain a diverse vertical structure and appropriate spatial pattern of vegetation. Maintenance of shrub and tree patches between individual campsites and between the campgrounds and streams is critically important for such species.

One of the keys to controlling wildlife disturbance is the design of an appropriate trail system. Design at broad scales can leave portions of the area without trails, providing refuges for wildlife. **Trails** should avoid sensitive locations, such as ungulate wintering areas, key foraging areas, areas used for birthing and the immediate postnatal period for mammals, and breeding areas for birds. At finer scales, trail design should seek to avoid fragmenting habitat and to provide adequate buffering between hikers and wildlife. It is often possible to use natural features (topography and vegetation) as visual and acoustic buffers (Gutzwiller and Cole 2005).

Information about flush and flight distances can be helpful in deciding on desirable widths of **buffer zones** around refuges for wildlife. For example, in deciding where to locate their wildlife viewing facility in relation to nesting wading birds, Colorado Parks and Outdoor Recreation relied on the research of Erwin (1989) and others, which indicated that colonies of nesting wading birds did not respond to human intrusions at distances >150 m (Larson 1995). Unfortunately, there can be considerable variation in **flushing responses** within the same species as well as over time (Knight and Temple 1995b). Fernández-Juricic et al. (2001) propose using **alert distance** (the distance between an animal and an approaching human at which the animal begins to exhibit alert behaviors to the human) as a conservative estimate of approach distance.

In addition to considering direct effects on wildlife, trail system design should consider **indirect effects** (i.e., effects of recreation on vegetation, soil, and water) on the living space and food source for wildlife. Vegetation and soil vary spatially and temporally in their vulnerability to disturbance (Hammit and Cole 1998). Trails and facilities should be

placed in more resistant environments. Careful trail design can reduce the need for spatial and temporal restrictions on use (Gutzwiller and Cole 2005).

SUMMARY

Recreational disturbance can detrimentally affect wildlife reproduction, survival, distributions, and behavior, and such activities can affect their habitat. Recreational activities are expected to increase in the coming decades, indicating that mitigating the effects of these activities will continue to be a challenge for wildlife managers. Wildland recreation occurs on most lands that are valuable for supporting wildlife, so the need to assess and manage recreational disturbances is

pressing. To conserve wildlife and maintain support for wildlife from wildland recreationists, Gutzwiller and Cole (2005) advocate management actions that protect wildlife *and* permit recreational activity. We, too, concur with this philosophy. Such approaches must be based on evaluations of existing data and, because recreational effects are often context-dependent, new field studies. Field studies, assessing recreational disturbances on wildlife, should be (1) directly relevant to management objectives, and (2) responsive to management. A variety of techniques are available to manage recreational effects. Most involve managing the behavior, activities, or distribution of recreationists; managing habitat; or designing facilities and transportation infrastructure that are minimally disruptive to wildlife.

Harvest Management

INTRODUCTION

INTEREST IN MANAGING wildlife harvests has been widespread throughout history. Elements of harvest management can be dated to the **eighth century** when Charlemagne instituted a detailed set of **game laws** (Caughley 1985). Current deliberations leading to **hunting regulations** may be little different than those of the hunting subcommittee of the Mongol Supreme Command in **13th-century China** (Caughley 1985). However, concepts of **hunting licenses and bag limits** are reasonably new, having been introduced only in the second half of the **19th century** (Leopold 1933, Caughley 1985). In 1864, New York became the first state to require a license for hunting, and in 1878, the Iowa legislature enacted one of the first bag limits, restricting prairie-chicken (*Tympanuchus* spp.) hunters to 25 birds/day (Leopold 1933).

Harvest management in North America dates to colonial times, when colonies established **closed seasons** for white-tailed deer (*Odocoileus virginianus*; Schmidt 1980). The Texas legislature closed Galveston Island to hunting of northern bobwhite (*Colinus virginianus*) in 1861, although in 1883, 130 Texas counties declared themselves exempt from all game laws (Cooke 2007). By the early 20th century, thoughts about harvest management and sport hunting were influenced by the **doctrine of wise use** advanced by Theodore Roosevelt and Gifford Pinchot in 1910 (Strickland et al. 1994, Herman 2001). Early management efforts were largely directed at recovering populations and preventing overharvest (Schmidt 1980). As populations of game species (particularly deer) recovered, concerns developed about the impact of wildlife on their habitats and emphasis changed toward **population control** (Schmidt 1980, Strickland et al. 1994). Prior to establishment of professional state fish and wildlife agencies in the 1930s, harvest management decisions were largely based on anecdotal data and decisions were often politically motivated (Wing 1951, Trefethen 1964). Increased mobility of the American public and a doubling of licensed sport hunters from 3 million to 6 million between 1910 and 1920 led to increasing concerns over the welfare of wildlife populations (Trefethen 1975, Autenrieth 1981). Both hunters and nonhunters demanded a greater accountability on the part of the states for managing wildlife resources (Hornaday 1916, Trefethen 1975).

Following publication of the *American Game Policy* (Leopold 1930), *The Bobwhite Quail* (Stoddard 1931), and *Game Management* (Leopold 1933), the profession of wildlife management in North America developed rapidly. Together, these 3 publications stressed the importance of a **biological approach** to managing wildlife. Moreover,

the *American Game Policy* called for training of wildlife professionals, to “find facts” or conduct research. Enactment of the **Federal Aid to Wildlife Restoration Act** (Pittman–Robertson program) in 1937 provided states with a stable funding source to fund the needed research and monitoring projects to further support harvest management programs (Murray 1938, Williamson 1987). As a result, information on the population dynamics of a variety of wildlife species was obtained rather quickly and this new knowledge was applied to harvest management.

Sport hunting of game species is an extremely popular and economically important activity. In 2006, >17 million hunters in the United States spent >236 million days hunting on >172 million trips, and spent >US\$15 billion in hunting-related expenditures (U.S. Fish and Wildlife Service and U.S. Census Bureau 2007; Box 33.1). Sport hunting can result in substantial harvests. For example, an estimated 16.1 million ducks and 4.2 million geese were harvested in the United States and Canada during the 2001–2002 recreational hunting seasons (Martin and Padding 2002), with unknown additional numbers of waterfowl harvested by subsistence hunters. In some cases, recreational harvest can represent up to 25% of the postbreeding population size (Anderson 1975).

For many biologists and managers working for state and provincial wildlife agencies, harvest management is where the “rubber meets the road” with regard to their constituents. Developing harvest strategies and regulations is the culmination of extensive data gathering (see Chapter 1, Volume 1) and analysis (see Chapter 2, Volume 1), incorporation of habitat conditions and wildlife behavior, and the melding of stakeholder and political input into the most widely circulated documents produced by most agencies: their hunting-regulations publications. At smaller scales (e.g., private ranches, hunting leases, Native American reservations), managers may follow a similar process.

This chapter discusses species commonly hunted in North America. Although harvest of furbearers also is important and involves some of the same concepts discussed here, furbearer management is beyond the scope of this chapter. Our **purpose** is to discuss the rationale and biology under-

lying harvest management in North America and provide examples of successful harvest-management programs. We focus primarily on techniques used to address biological goals for harvest management. Nevertheless, we also understand hunter participation and satisfaction are important considerations in formulating hunting regulations, and managers typically are interested in maximizing hunting opportunity to meet these objectives (Smith and Roberts 1976, Babcock and Sparrowe 1989, Johnson and Case 2000). Some principles providing a foundation for harvest management strategies have been criticized (McCullough 1979, Romesburg 1981). In fact, Guthery (2000) stated the results of field research in the past 2 decades did not support the early thinking on harvest management. Thus, we also provide a synopsis of the important literature related to harvest management and attempt to identify and briefly discuss these principles. We recognize there is no “one-size-fits-all” approach and focus on differences in harvest management among groups of species.

RATIONALE FOR HARVEST

North American Model

Two relatively early court decisions influenced development of harvest management in the United States. In 1896, a Connecticut court (**Greer vs. Connecticut**) ruled that states have the right to control the manner in which wildlife is taken (Smith and Coggin 1984). In 1910, a Missouri Court decision (**State vs. Heger**) found that wildlife species within the boundaries of a state are the sole property of that state and not subject to private ownership on the land they inhabit (Autenrieth 1981). These decisions, combined with passage of the **Weeks–McLean Act** (1913) and **Migratory Bird Treaty Act** (1918), placing migratory birds under federal custody (Williamson 1987), largely provided a legal foundation for harvest management in the United States. **Canada’s system** is similar to the United States. In Canada, wildlife is considered government property, but the Canadian government’s roles are not as clearly defined as they are in the United States (Smith and Coggin 1984). Generally,

Box 33.1. HUNTING ACTIVITY IN THE UNITED STATES DURING 2006

	Upland game	Migratory birds	Big game
Hunters	4,797,000	2,293,000	10,682,000
Trips	40,856,000	16,390,000	115,255,000
Days of hunting	52,395,000	19,770,000	164,061,000
Expenditures (US\$)	2,365,778,000	1,349,148,000	11,754,122,000

U.S. Fish and Wildlife Service and U.S. Census Bureau (2007).

in North America, states and provinces are responsible for harvest regulations pertaining to “resident” wildlife, while federal authorities set regulations for migratory game birds. Unlike in Europe, these regulations apply regardless of ownership of the land the animals occupy.

A general underpinning of a harvest management system is that a **biological surplus** exists, which can be harvested with little impact on subsequent breeding populations (Denney 1978, McCullough 1979). A major objective of most harvest management programs is to apportion harvest opportunity equitably among hunters. The **3 approaches** to harvest management include (1) harvesting at a low rate to ensure population increase, (2) harvesting to maintain a population, and (3) harvesting to reduce a population (Smith and Coggin 1984). The actual amount and type of harvest is affected by population objectives set by the responsible agency (Denney 1978). The appropriate harvest level may vary among and within species depending on the status of the population (e.g., stable versus increasing) and whether or not the environment fluctuates annually (Caughley and Sinclair 1994).

Harvest management includes **3 basic components**: (1) inventory of populations, (2) identification of population and harvest goals, and (3) development of regulations allowing goals to be met (Strickland et al. 1994). These components are usually part of harvest management programs for some species (e.g., deer, elk [*Cervus canadensis*]), but one or more are often lacking for other species (e.g., spruce grouse [*Falcipennis canadensis*], gray partridge [*Perdix perdix*]). Most harvesting of wildlife for recreational purposes has been largely managed by trial and error, but this strategy often works well because of the conservative approach taken by management agencies (Caughley and Sinclair 1994, Hardin et al. 2005).

In recent decades, there has been a greater emphasis on informed management decisions, based on knowledge about the effects of harvest on game populations (Sutherland 2001, Sinclair and Metzger 2009). There are **4 basic requirements** for successful, informed management of game harvests (Nichols and Johnson 1989, Nichols et al. 1995). **First**, managers must develop and agree upon explicit goals and objectives for harvest management. **Second**, managers must be able to implement actions designed to achieve harvest management objectives. **Third**, managers must have some idea of the likely effects of alternative management actions. **Fourth**, systems must be in place to measure the outcome of actions in relation to management objectives (e.g., population size and harvest). Additionally, Beissinger (2001) argued that **6 areas** of biological knowledge are necessary for setting harvest levels at large spatial scales. These areas include (1) population size and range, (2) habitat requirements and movements, (3) resilience to human disturbance and habitat change, (4) estimates of demographic rates, (5) key

factors regulating populations, and (6) effects of environmental regulation. This observation reinforces Kokko et al.’s (2001) statement that slight differences in life histories can manifest themselves as major effects on the outcome of harvesting.

Principles—Past and Present

Many wildlife management principles and concepts currently applied to harvest management were first developed and then reinforced by research conducted from the 1930s through the 1960s (Wing 1951, Allen 1962, Dasmann 1964, Giles 1978). The writings of Aldo Leopold, Paul Errington, and Durwood Allen, among others, and principles they introduced, still influence harvest management decisions (Strickland et al. 1994, Guthery 2000). We define the most common of these principles below and provide a brief assessment of their usefulness as reflected in recent literature.

Additive Mortality

The premise of **additive mortality** is that each animal killed by hunters is an additional death that adds to the natural mortality, resulting in total mortality being greater than if hunting did not occur (Anderson and Burnham 1976). Mackie et al. (1998) reported that hunting was additive to overwinter mortality for white-tailed deer and mule deer (*Odocoileus hemionus*). Bergerud (1988) suggested this applied to many grouse species and Connelly et al. (2000a, 2003) provided additional evidence this was the case for greater sage-grouse (*Centrocercus urophasianus*), a species generally having low overwinter mortality.

Compensatory Mortality

Compensatory mortality occurs when animals have relatively stable annual mortality, regardless of which decimating factors may be acting on the population; that is, removal of hunting will result in increased mortality from predation or disease (Dasmann 1964). Hunting has long been thought to be a compensatory form of mortality for virtually all species of upland game. However, relatively recent work (Roseberry 1979, Smith and Willebrand 1999, Connelly et al. 2000b, and others) suggests hunting mortality is often not compensatory. Ellison (1991) concluded there is little evidence for density-dependent breeding in tetraonids and hunting may result in an age structure that lowers a population’s productivity. Compensatory survival has been characterized as dogma within the field of wildlife management (Romesburg 1981, Warner 1992a) and Guthery (2000) argued that additive and compensatory harvest mortality are intertwined for northern bobwhite.

Diminishing Returns

This principle is often referred to as a **the law of diminishing returns** (Wing 1951, Strickland et al. 1994), a concept

indicating that, past a certain point, hunting is largely unrewarded (i.e., few successful hunters), resulting in relatively few hunters in the field, and suggesting hunting is largely self-regulating (Allen 1962, Guthery 2000). In conjunction with the concept of compensatory mortality, the idea of diminishing returns was used to support the argument that small game seasons could be quite long without any risk of harming the population. Cole (1995) provided some evidence to support this concept, but Roseberry (1979) concluded that seasonal declines in hunter success were considerably less than expected considering the progressive loss of birds throughout the hunting season. This concept has generally been applied to upland game hunting and has not been widely accepted among waterfowl and big game managers. This concept also fails to recognize observations that late-season hunters may be more experienced and effective hunters (i.e., the “diehards”). The idea of diminishing returns appears to have little value for present-day harvest management programs.

Doomed Surplus

Doomed surplus has been considered the number of animals produced that exceed the capacity of the habitat to support and keep secure from predation (Errington 1956, Roseberry 1979, Bailey 1984). Roseberry (1979) argued that, for northern bobwhite, there is a considerable “carryover” effect from year to year. Thus, birds not harvested in the autumn may contribute to the next breeding population and are not necessarily part of a doomed surplus. Moreover, Guthery (2000) argued that the research that initially proposed this concept (Errington and Hamerstrom 1935) was poorly designed by today’s standards and that the work has little value. A number of wildlife species actually have high overwinter survival (Keppie 1979, Wood et al. 1989, Mackie et al. 1998, Schroeder et al. 1999) and this concept would seem to have limited usefulness.

Harvestable Surplus

Leopold (1933) formulated the concept of **harvestable surplus** to indicate most animals produce more young than necessary to maintain the population; this extra number can be removed by hunting without affecting the population. McCullough (1979:233) challenged this concept by arguing that it fails to include “the dynamic and compensatory nature of population responses.”

Inversity

An **inverse relationship** has been proposed to exist between productivity and abundance; when a species is particularly numerous in an area, that population is assumed to have relatively low productivity (Wing 1951, Errington 1956). Roseberry (1979) suggested that, for bobwhites, the rate of increase is linear or slightly curvilinear, but the amount of recruitment necessary to maintain stability increases expo-

entially. He concluded that the system’s ability to compensate for hunting losses progressively deteriorates as harvest increases.

Opening Day Phenomenon

This concept suggests most mortality for a given species occurs on the opening day (or opening weekend) of the season because that is when most hunters are afield (Giles 1978, Guthery 2000). Although this seems intuitively correct, there appear to be few published quantitative data available that document hunting pressure and harvest throughout the season. Rusch et al. (1984) reported that >40% of the harvest of ruffed grouse (*Bonasa umbellus*) occurred in the last 3 months of a season that extended from October to January.

Threshold of Security

Threshold of security is the population size above which some animals are not secure from predation; a carrying-capacity concept indicating habitat ultimately decides population size (Errington 1956, Bailey 1984). Romesburg (1981) indicated that this concept passed into the wildlife profession’s lore without being critically evaluated or tested. Myrberger (1989) referred to this idea as a **winter bottleneck hypothesis**, and provided evidence to refute this concept for willow ptarmigan (*Lagopus lagopus*). The “doomed surplus” and “threshold of security” concepts are related and are subject to the same criticism.

Uncertainty in Harvest Management

Increased knowledge of wildlife populations suggests many of the concepts discussed above have limited application for today’s manager. Thus, rather than blindly adhering to principles developed 30–70 years ago under vastly different environmental conditions, today’s manager should first ask if any of the concepts currently apply, and second, under what conditions. Wildlife professionals should follow Roseberry’s (1981:1056) advice: “as professionals, we are obligated to provide more credible justification for hunting than clichés such as ‘they would have all died anyway.’”

Assuming explicit management objectives can be agreed upon, managers charged with developing harvest regulations are faced with several **sources of uncertainty** (Box 33.2). Each of these sources poses challenges, but they also interact to complicate efforts to understand the effects of hunting regulations on game populations and to use this knowledge to make informed harvest management decisions. For example, limits on the ability to precisely monitor harvest and population sizes hamper efforts to understand the structural relationships between these measures. Similarly, lack of control over actual harvest rates resulting from a given set of regulations, due in part to uncontrolled environmental conditions, is further complicated by limitations on the ability to precisely observe harvest rates (Williams et al. 1996).

Box 33.2. SOURCES OF UNCERTAINTY ABOUT THE RELATIONSHIP BETWEEN HUNTING REGULATIONS AND THE STATUS OF GAME POPULATIONS

Partial Observability

Although extensive, costly monitoring systems have been developed to track some game populations and their harvests, results of these efforts are imprecise and/or subject to bias (Williams et al. 1996). This inability to perfectly observe the managed system hampers the ability of managers to make informed decisions (e.g., increased protection or increased harvest; Nichols et al. 1995, Williams et al. 1996). New or expanded monitoring efforts may provide improved information and at finer spatial resolutions, but this benefit must be weighed against the costs of such programs (Johnson and Case 2000).

Partial Management Control

Harvest managers attempt to influence harvests through changes in hunting regulations, but harvest levels cannot be precisely controlled through regulations (Nieman et al. 1987, Trost et al. 1987, Johnson et al. 1997). Biologically meaningful changes in harvest or harvest rates may only occur between relatively different, discrete sets of regulations (Nichols and Johnson 1989, Johnson et al. 1997, Nichols 2000).

Structural Uncertainty

This type of uncertainty refers to our limited understanding of the influence of harvest rate on subsequent population size (Nichols 1991, Williams et al. 1996, Johnson et al. 1997). Uncertainty about the structure of population dynamics is the source of many of the debates over how to manage harvests (Johnson et al. 1993, Nichols et al. 1995). The 2 central components of structural uncertainty involve hunting as additive or compensatory mortality (Burnham and Anderson 1984, Burnham et al. 1984, Nichols et al. 1984), and density dependence of the reproductive process (Nichols 1991, Hilborn et al. 1995). These hypotheses have important implications for harvest management because if harvest mortality is largely compensatory and reproductive rate is strongly density dependent, populations can sustain higher harvest levels than if hunting mortality is largely additive to other forms of mortality and reproductive rate is largely density independent (Nichols et al. 1995, Williams et al. 1996). Thus, structural uncertainty may lead managers to make decisions that are too liberal for sustaining populations or overly restrictive of hunting opportunity (Williams et al. 1996).

Environmental Variation

Habitats supporting many game populations in North America are subject to large, uncontrolled spatial and temporal variation and these changing conditions can have significant effects on the status of populations (e.g., Pospahala et al. 1974). Managers cannot precisely (or accurately) predict future conditions when setting current regulations. Nevertheless, efforts have been made to examine the relationships between habitat status and population size, which can in turn assist managers in assessing the expected harvest under different environmental conditions (Johnson et al. 1997).

From Nichols et al. (1995), Williams et al. (1996), and Johnson et al. (1997).

MANAGEMENT OF UPLAND GAME HARVESTS

Development of Harvest Strategies

Early Years (1900–1944)

In response to public demand and a general lack of biological knowledge, harvest management during the early part of the 20th century was largely characterized by a reduction in **bag limits and season length** for many species of upland game. By today's standards, established seasons in the early

20th century tended to vary considerably among years, often with liberal bag limits (Tables 33.1, 33.2). Leopold (1933) indicated that the season for ruffed grouse in the north-central states declined from about 50 days in 1900 to about 10 days in 1930, while daily bag limits changed from 25/day to 7/day over the same period. Similarly, in Idaho, the greater sage-grouse season decreased from 137 days with a bag limit of 18 grouse/day in 1903 to being completely closed by 1939 (see Table 33.1). During this same period, laws also were enacted to regulate firearms, hunting from boats and vehi-

cles, and provide refuges (Leopold 1933). Game bird hunting was generally restricted to the use of shotguns no larger than 10 or 12 gauge. **Shooting hours** were implemented and some states eliminated hunting on Sunday. Use of nets and traps was outlawed (Leopold 1933, Strickland et al. 1994).

Changing Strategies (1945–1980)

The general approach to harvest management of upland game was developed during the 1930s and 1940s. During this period, the concepts of threshold of security, doomed surplus, and compensatory mortality were introduced and subsequently formalized in several early wildlife management textbooks (Wing 1951, Allen 1962, Dasmann 1964). Taken together, these concepts suggested that small game populations produce a large number of young each year, most of which are available for harvest because they would not survive the winter or add to the next season's breeding population. These ideas further suggested hunting was a compensatory form of mortality and implied that a large portion of a small game population could be harvested each autumn because, if not taken by hunters, they would likely die prior to the next breeding season from some other cause. **Harvest strategies** tended to stabilize and became somewhat more liberal in the 1960s and 1970s compared to the 1940s and 1950s (see Table 33.1).

Early researchers (Errington and Hamerstrom 1935; Leopold et al. 1943; Errington 1945, 1956; Bump et al. 1947; Allen 1962) provided evidence to support their ideas from studies of muskrat (*Ondatra zibethicus*), northern bobwhite, ring-necked pheasant (*Phasianus colchicus*), ruffed grouse, and cottontail rabbit (*Sylvilagus* spp.). There was a strong tendency to believe reproductive characteristics and effects of exploitation were the same for all species of upland game (Allen 1962, Strickland et al. 1994). Allen (1962:43) summarized this situation well when he wrote, “Our populations of small animals operate under a one-year plan of decimation and replacement; and Nature habitually maintains a wide margin of overproduction. She kills off a huge surplus of animals whether we take our harvest or not.” Unfortunately, these early studies provided virtually no empirical evidence to assess the effects of exploitation. Population characteristics were often documented for relatively discrete areas rather than compared over large portions of the species’ range. Moreover, the habitats, landscapes, and general conditions under which these populations existed are markedly different now than in the 1930s, 1940s, and 1950s. For northern bobwhite, many agencies and individuals still rely on management guidelines (Stoddard 1931, Rosene 1969) developed during eras when land-use practices were drastically different than today (Kuvlesky et al. 1993).

By the 1970s, new techniques and long-term studies provided wildlife managers with a wealth of new information on many species of upland game. Modeling began to be used to assess the effects of exploitation on wildlife (Box 33.3). Upland game populations were being routinely monitored, and at least some of these data were considered in harvest management decisions (Braun 1979, Roseberry 1979, Braun and Beck 1985, Hoffman 1985, Brennan et al. 2008). Despite this increase in knowledge, the general approach to harvest management had not changed from the 1950s or 1960s. As an example, in reporting on sage-grouse management in Montana, Wallestad (1975:27) provided the statements quoted from Allen (1962) above and then wrote, “Gamebird seasons in Montana are largely based on the philosophy that most birds will not survive the winter, hence replacing natural mortality with hunting mortality.”

BOX 33.3. EARLY MODELING EFFORT TO ASSESS IMPACTS OF HUNTING

Roseberry (1979) used field and simulated data to assess the effects of hunting on northern bobwhite and concluded harvests >55% of the autumn population would depress the following spring’s population.

Current Knowledge (1981–2009): A New Paradigm

Although early efforts suggested that response to exploitation was similar for most, if not all, upland game species, Peek (1986:279) argued “each population responds to **exploitation** according to its characteristics; to the nature, timing, and duration of the exploitation; and to the effect on other organisms that it interacts with.” Peek further indicated it might be inappropriate to apply inferences from data collected on one population to another population of the same species, especially if the 2 populations had different demographic characteristics, or were affected by different environmental factors. Similarly, Caughley and Sinclair (1994) observed that a safe **sustained yield** could only be estimated with knowledge of the population’s growth pattern, measured by the relationship between the population and its resources.

Both Peek (1986) and Caughley and Sinclair (1994) were reflecting new information suggesting earlier views of harvest management were not always correct. In referring to upland game in general and wildlife managers in particular, Brennan (1994:411) leveled relatively harsh criticism of upland game management when he observed “I have a nagging suspicion that wildlife and natural resource professionals have been missing the mark with respect to operating as responsible stewards for these unique vertebrate resources.” Gutiérrez (1994) reinforced this idea by also concluding that research and management have not met the challenge of upland game management.

During the 1980s and 1990s, evidence began to accumulate suggesting that, under some circumstances, harvesting may have an **additive effect** on mortality for a number of species (Gregg 1990, Robinette and Doerr 1993, Dixon et al. 1996). Bergerud (1985, 1988) summarized the effect of exploitation on a variety of game bird species (Box 33.4). Robertson and Rosenberg (1988) also addressed the issue of compensatory and additive mortality and concluded that in natural populations hunting mortality usually falls between the 2 extremes of being totally additive or totally compensatory. Strickland et al. (1994:463) indicated that through the early 1990s, trends in harvest management were generally toward liberal seasons based on the idea that “hunting has so little effect on upland game populations.” That approach seems to be changing (see Table 33.1) with a greater recognition that effects of hunting may vary depending on population and habitat characteristics (Guthery 2000, Sutherland 2001). As examples, Idaho changed the sharp-tailed grouse (*Tympanuchus phasianellus*) season to begin later in the autumn to relieve hunting pressure on birds during the autumn lekking period, and also to reduce hunting pressure on isolated and possibly declining greater sage-grouse populations (the seasons were held concurrently). Additionally, Idaho (see Table 33.1) and Wyoming reduced harvest on sage-grouse, and Wyoming changed the opening date for greater sage-grouse from 1 September to mid-September, and re-

Box 33.4. ADDITIVE MORTALITY AND GROUSE

Bergerud (1988) concluded hunting was additive to overwinter mortality for sooty grouse, white-tailed ptarmigan, ruffed grouse, and greater prairie-chickens.

ported that these changes resulted in lower harvest (Heath et al. 1997). In 1995, hunter participation and sage-grouse harvest rates were significantly reduced in Wyoming, and other more conservative harvest strategies have been implemented since then (Christiansen 2008). Recent information supports the views of Robertson and Rosenberg (1988), and suggests hunting mortality should be viewed as occurring along a continuum and not as categorical (i.e., either compensatory or additive). Clearly, if a population was very small (one male and one female as an extreme example) then all hunting would become additive, because if one animal is shot there is no way hunting can be compensatory.

Agencies are beginning to integrate information acquired from the last 30 years of research into their upland game management strategies. There seems to be a growing recognition that a successful harvest management program must integrate knowledge of a species' reproductive characteristics and quality of habitat that a population occupies. This change appears to be accompanied by an increasing awareness that it is no longer acceptable to base management decisions on dogmatic beliefs and findings from early wildlife studies. More information is needed on the effects of exploitation on a variety of upland species over relatively large areas. The importance of this information for establishing biologically sound harvest-management programs will continue to increase as habitats are continually lost to expanding human populations and populations of some species continue to dwindle.

Inventory

A general approach to harvest management would base harvest on abundance of the species (Sutherland 2001) but this is rarely done for upland game. Instead, as Caughley and Sinclair (1994) suggested, most harvest strategies seem to have been developed through trial and error.

Some states conduct routine **population surveys** just prior to the hunting season. For example, the Iowa Department of Natural Resources used roadside surveys to assess upland game populations. Pheasants, quail, partridge, cottontail rabbits, and jackrabbits (*Lepus* spp.) were counted along survey routes during August each year. Trautman (1982) described an inventory program for pheasants in South Dakota that included crowing counts, brood surveys, winter surveys, aerial counts, and storm mortality surveys. Traut-

man (1982) suggested that these data were used in formulating recommendations for hunting seasons, but did not explain how this was done. Similarly, Schulz (1990) reported that North Dakota conducts a variety of gray partridge surveys to aid in establishing hunting regulations, but did not indicate how these data might be used. Other states have similar programs; the main purpose of these inventories appears to be public information rather than assessing populations to guide decisions on hunting seasons. Kurzejeski and Vangilder (1992) summarized wild turkey (*Meleagris gallopavo*) hunting seasons and regulations. They reported that seasons tend to be either conservative or liberal, but gave no indication that population inventory data were used to establish season frameworks. Strickland et al. (1994) also summarized factors considered in turkey hunting seasons and concluded that many of the factors were **political rather than biological**. One of the few instances of using inventory data to guide harvest management of small game species occurs with greater sage-grouse in Oregon. In Oregon, the Oregon Department of Fish and Wildlife uses data from lek counts and production surveys to help adjust hunting seasons, so harvest takes $\leq 5\%$ of the estimated autumn population.

Seasons for most small game species vary among states. However, they are kept relatively constant from year to year (Table 33.3). Strickland et al. (1994:463) reported that many states have de-emphasized collection of population data for upland game species "because the lack of harvest impact indicates little need for the data." In contrast, many others have argued that biologists should track population trends and demographics to help examine the outcome of management activities (Linden 1981, Stauffer 1993, Sutherland 2001, Sedinger and Rotella 2005).

Harvest Surveys

A recent survey (Connelly et al. 2004) of states with sage-grouse seasons indicated that, at a minimum, all states estimated harvest, number of hunters, and number of days hunting, usually with telephone or mail **questionnaires** (J. W. Connelly, unpublished data). Similar estimates for hunted species are available from most, if not all, states because states have emphasized collection of harvest data (Strickland et al. 1994). However, many estimates of harvest have wide confidence intervals, making comparisons among areas or years difficult. Moreover, the lack of population data makes it virtually impossible to assess the proportion of the population taken by hunters. Clearly, where concerns have been identified, greater effort must be made by professional biologists to better document harvest and the relationship of harvest to the overall population. Over 30 years ago, Roseberry (1979) and Linden (1981) suggested that reliable estimates of harvest rates and knowledge of population characteristics are necessary requirements for sound management, but information was generally lacking for up-

Table 33.3. Variation in season lengths and bag and possession limits for small game species among states (USA)

land game populations. Although progress has been made, the same observation could be made today.

Developing Regulations

Development of regulations varies among wildlife agencies, but initial steps normally include soliciting comments from agency personnel and the public, often through meetings or open houses. Regions or other administrative units then formulate recommendations and pass these on to the chief administrator for the agency's wildlife program. At some point, these recommendations are discussed with the agency director, who may ask for modifications. Ultimately, recommendations are passed on to the **Wildlife Commission** for approval and possible changes. Seasons are sometimes set 2–3 years in advance; in other cases, they may be set just a few weeks before opening day.

Hurst and Rosene (1985) reported that quail harvest regulations developed from numerous factors including tradition, biopolitics, sportsmen's perceptions, and research. A similar assessment was made for wild turkeys (Kurzejeski and Vangilder 1992, Strickland et al. 1994). We suggest the same holds true for harvest regulations for most species of upland game. Thus, seasons vary within and among states even though the species hunted is the same. The Policy Analysis Center for Western Public Lands reviewed seasons for sage-grouse in the western United States (Wambolt et al. 2002). They reported opening dates ranging from 1 September to 13 October, with season lengths of 2–62 days. Bag and possession limits also varied considerably. We examined season lengths, and daily bag and possession limits provided by state wildlife agency Internet sites ($n = 35$) for 4 commonly hunted species: cottontail rabbit, tree squirrels (*Sci-*

urus spp.), ring-necked pheasant, and bobwhite (see Table 33.3). Regulations varied regionally and among states, but tended to be more conservative in the heavily populated northeastern United States. Overall, season lengths for cottontails varied from 63 days to 365 days and daily bag limits varied from 2 rabbits to 12 rabbits. For squirrels, season lengths similarly varied from 78 days to 365 days and bag limits ranged from 4 to none (i.e., no regulation of daily take). Several states had no bag or possession limits for either rabbits or squirrels. Regulations for game birds were equally varied, but tended to be more conservative than those for rabbits or squirrels. Pheasant seasons ranged from 10 days to 99 days, while daily bag limits ranged from 1 bird to 4 birds. However, one southeastern state reported having no bag or possession limits for pheasants. Season lengths for bobwhite were perhaps the most varied, ranging from 15 days to 151 days, while daily bag limits varied from 2 quail to 15 quail (see Table 33.3).

Burger et al. (1994) argued for broad-scale experiments to better understand the effects of exploitation on quail. Thus far, field research to assess the effects of harvest and guide season setting seems relatively rare. Both Weeden (1972) and Braun et al. (1993) suggested that later hunting seasons were appropriate for reducing effects of harvest on ptarmigan (*Lagopus* spp.) populations. There also is some evidence that later opening dates are more appropriate for sharp-tailed grouse and sage-grouse (Gregg 1990, Heath et al. 1997). There is apparently much uncertainty associated with the effects of exploitation on game birds (see Box 33.2), but population declines, usually related to habitat deterioration or loss, have been documented for many species. Ellison's (1991) strategy, that of basing seasons on the assumption that hunt-

ing is additive to adult mortality but at least partially compensatory for juvenile mortality, may be the most appropriate one in many cases. Moreover, Sutherland (2001) observed that a simple system of monitoring populations and adjusting regulations according to long-term population change is often the best method of harvest management.

Population Responses to Hunting

Until the late 1970s, most studies of the effects of exploitation on upland game species suggested there were few **adverse effects** of hunting. Within the last 25 years, numerous investigations have documented adverse effects of hunting on a variety of upland game species. In some cases, early researchers may simply have drawn erroneous conclusions, especially when dealing with species having relatively low reproductive rates and long lives (e.g., sage-grouse). In other cases, recent findings may reflect the results of changing environments occupied by upland game. Climate and landscape-scale habitat changes have recently been linked to long-term declines of black grouse (*Lyrurus tetrix*) in Europe (Loneux and Ruwet 1996, Loneux 2000). It is likely similar changes in North America have affected the distribution and populations of many upland game species. The earlier studies concluding that hunting had no effect on a species may have been correct at that time, just as more recent results correctly reflect current conditions.

Strickland et al. (1994:459) reported, "Hunting of upland game, as practiced since the 1950s, has not been shown to have a measurable adverse effect upon upland game populations." The authors did not define the term "measurable adverse effect," but over the last 25 years, numerous papers have been published challenging this general assertion. As an example, the Policy Analysis Center for Western Public Lands concluded that, in some instances, hunting might slow population recovery of sage-grouse or stabilize populations at "lower-than-desirable levels" (Wambolt et al. 2002:20). The Center further concluded that states should not assume hunting is a totally compensatory form of mortality, nor should they base hunting seasons on the concept that seasons and bag limits can be liberal because of high annual turnover in the population (Allen 1962, Wallestad 1975).

We define **adverse effect** as an action resulting in reduction in the size of subsequent breeding populations or a reduction in average survival of a population or a specific age or gender group within a population. Population characteristics such as recruitment and survival may affect the response of a population to exploitation (Peek 1986), and these characteristics vary among species and perhaps even populations within species. Kokko (2001:148) warned that ignoring information on mating systems, age structures, density dependence, and seasonal behaviors will "easily cause hunting to be harmful to an unnecessary extent." Thus, we address effects of harvest by species and groups of species and include a brief description of population characteristics for

each species discussed to allow a better understanding of opportunities and potential constraints on harvest management. We also try to avoid gross generalization while seeking common patterns that may help establish biologically meaningful harvest practices among groups of species.

Pheasants, Quail, and Partridge

These species (Box 33.5) are characterized by relatively short lives and high reproductive rates (Rosene 1969, Farris et al. 1977, Trautman 1982, Carroll 1993, Schemnitz 1994, Hernández and Peterson 2007). In North America, these species are often associated with agricultural lands or, at least for part of their life, depend on landscapes dominated by early successional stages. The chukar (*Alectoris chukar*) is one of the few exceptions, but it depends on habitats dominated by cheatgrass (*Bromus tectorum*), an exotic annual.

George et al. (1980) and Trautman (1982) reported that hunting season length and season closures had no impact on **pheasant** populations in the upper midwestern United States. Edwards (1988) indicated hunting seasons should open early in the autumn because of high nonhunting mortality in the autumn and early winter, and 40–60-day, cocks-only, seasons were reasonable. However, Whiteside and Guthery (1983) reported that a longer hunting season (30 versus 16 days) was associated with decreased survival of pheasants in northwest Texas. They also noted (1983:252) those seasons longer than 30 days "could result in excessively distorted sex ratios and low productivity." Further, illegal and accidental harvest of hens is often $\geq 15\%$ of the autumn population of hens; thus, legal hunting of hens is rarely warranted (Edwards 1988).

Many studies of **quail** and hunting suggested harvest had little or no adverse effect on populations, and biologists often argued that harvest would substitute for natural population reductions (Parmalee 1953, Kabat and Thompson 1963, Vance and Ellis 1972, Campbell et al. 1973, Robinette and Doerr 1993). Cole (1995) evaluated effects of hunting on northern bobwhite and concluded that hunting had no ef-

Box 33.5. PHEASANT AND PARTRIDGE PRODUCTIVITY AND SURVIVAL CHARACTERISTICS

The ring-necked pheasant has an average clutch of 10–12 eggs and will readily reneest. This species also has relatively low annual survival and high overwinter mortality. Gray partridge and chukar lay 5–25 eggs/clutch, readily reneest, and have relatively short life spans and high annual mortality (Yeatter 1934, Christensen 1970, Carroll et al. 1990, Church and Porter 1990, Carroll 1993).

fect on spring breeding populations or recruitment. Rosene (1969) indicated that it was “safe” to remove about 45% of a bobwhite population by hunting without adversely affecting the breeding stock.

Stoddard (1931:226) was the first to report that, in some cases, hunting may result in population declines when he wrote “the balance between the reproduction of the birds and their natural mortality may be so nearly even that to shoot any considerable number for sport will quickly deplete the supply.” Almost 50 years later, Roseberry (1979) reported that compensation for hunting losses is incomplete from autumn to spring, resulting in depression of breeding populations for northern bobwhite. Roseberry (1979) further argued that liberalized regulations for bobwhite are inconsistent with the realities of a shrinking resource and contended that hunting seasons should be structured to provide reasonable recreational opportunities while not seriously depleting stocks. Robinette and Doerr (1993) and Dixon et al. (1996) reported that survival of bobwhites in hunted coveys was significantly lower than in nonhunted coveys. Moreover, with respect to northern bobwhite, Hernández and Peterson (2007:54) wrote, “Without doubt, harvest is typically to some degree additive . . . to other forms of bobwhite mortality.” Haines et al. (2009) reported that **crippling loss** of northern bobwhite in their study was 50% of the retrieved harvest and noted that crippling loss information could substantially change an assessment of harvest impact to this species. Given evidence supporting both contentions that hunting has little impact on the population and that hunting may adversely impact populations, the recommendations that research be conducted to identify **threshold densities** and hunting pressures that may result in additive mortality, and that state resource agencies be creative in their approaches to season length and bag limits (Kuvlesky et al. 1993), seem reasonable.

Although **gray partridge** are common in many states, they are often shot opportunistically by hunters pursuing other species (e.g., ring-necked pheasants, chukar, sharp-tailed grouse; Vander Zouwen 1990). Weigand (1980) indicated that about 3% of the gray partridge population was harvested in his Montana study area and suggested that doubling the bag limit (i.e., from 6 birds/day to 12 birds/day) was biologically acceptable. Similarly, Carroll (1990) suggested that hunting was not a problem for most populations in North America because of low hunting pressure and interest. Christensen (1958) reached the same conclusions for **chukar** in Nevada. However, Bro et al. (2003) recommended that a prudent approach to managing gray partridge populations in France was to consider hunting mortality as additive.

Grouse and Ptarmigan

Species in this general group can be classified as **forest grouse** (blue [includes dusky grouse, *Dendragapus obscurus*, and sooty

grouse, *D. fuliginosus*], spruce, ruffed grouse), **prairie grouse** (greater [*Tympanuchus cupido*] and lesser prairie-chicken [*T. pallidicinctus*] and sharp-tailed grouse, greater and Gunnison sage-grouse [*C. minimus*]), and **ptarmigan** (white-tailed [*Lagopus leucura*], willow, rock [*L. muta*]). Compared to pheasants, quail, and partridge, many grouse and ptarmigan species (Box 33.6) tend to be longer lived with lower reproductive rates (Johnsgard 1973, Arnold 1988, Zwickel 1992, Braun et al. 1993, Connelly et al. 1993, Schroeder et al. 1999). Many of these species depend on habitats dominated by late seral or climax vegetation and some have large annual ranges (Zwickel et al. 1968, Connelly et al. 1988, Schroeder and Robb 1993, Connelly et al. 2000a, Leonard et al. 2000).

BOX 33.6. GROUSE AND PTARMIGAN PRODUCTIVITY AND SURVIVAL CHARACTERISTICS

Clutch sizes range from 1 egg to 12 eggs, 3 eggs to 24 eggs, and 4 eggs to 9 eggs for blue, ruffed, and spruce grouse, respectively, and annual survival may exceed 70% for adult blue grouse and 50% for adult spruce grouse (Edminster 1947, Johnsgard 1973, Ellison 1974, Robinson 1980, Zwickel 1992).

Lesser and greater prairie-chickens lay 5–17 eggs/clutch and readily reneest (Hamerstrom and Hamerstrom 1949; Johnsgard 1973; Taylor and Guthery 1980a, b; Svedarsky 1988; Schroeder and Robb 1993). Greater prairie-chickens may have relatively high survival during summer, autumn, and winter (McKee 1995). The average clutch size for sharp-tailed grouse is about 12 eggs and they also readily reneest (Hillman and Jackson 1973, Connelly et al. 1999).

In contrast, sage-grouse have low annual turnover, several studies have indicated that not all females nest each year (Schroeder et al. 1999, Leonard et al. 2000), average clutch size ranges from 6 eggs to 9 eggs, and reneesting is uncommon in many populations (Schroeder et al. 1999). Generally, prairie-chickens and sharp-tailed grouse have greater reproductive rates and lower annual survival rates than sage-grouse.

All ptarmigan species seem to have population characteristics similar to sage-grouse (i.e., relatively low reproductive rates and annual turnover; Choate 1963, Giesen et al. 1980, Martin et al. 1989, Braun et al. 1993), but reproductive characteristics may vary substantially among years and populations (Myrberget 1988, Martin et al. 1989).

FOREST GROUSE

Mussehl (1960) concluded that hunting had only a minor influence on yearly population turnover of **blue grouse**. Similarly, Hoffman (1985) indicated that spring densities of blue grouse were not affected by the preceding autumn's harvest. Zwickel (1982) argued that adult female blue grouse in British Columbia, Canada were more vulnerable to hunting than males, resulting in an age structure shifted toward yearlings, thus reducing productivity of the population. However, Zwickel (1982) indicated that under the existing hunting pressure, reduction in productivity appeared to have no effect on subsequent breeding densities. Zwickel (1992) also suggested that autumn migration into rugged areas reduced hunting effects.

Early studies of the effects of hunting on **ruffed grouse** suggested exploitation had little adverse impact on grouse populations (Edminster 1947, Dorney and Kabat 1960). Dorney and Kabat (1960) concluded, from an 8-year study, that there was no detectable relationship between hunting and subsequent ruffed grouse populations. Palmer and Bennett (1963) compared ruffed grouse populations on hunted and nonhunted areas in Michigan, and concluded that hunting had no effect on population size and a much longer hunting season was justifiable. Fischer and Keith (1974) also indicated that autumn hunting had no measurable effect on spring population levels of ruffed grouse in Alberta, Canada. Clark (1996, 2000) examined survival of ruffed grouse in hunted and nonhunted areas in Michigan and suggested that hunting may decrease juvenile survival, but reported there was little evidence suggesting hunting was additive to natural mortality.

Other research has provided evidence that hunting may have adverse effects on some ruffed grouse populations. Kubisiak (1984) compared ruffed grouse populations on hunted and nonhunted areas in Wisconsin and found that exploitation may be a major factor depressing populations in areas subject to relatively heavy harvest. Similarly, Small et al. (1991) suggested that hunting mortality of ruffed grouse was at least partially, if not completely, additive to natural mortality. They further concluded ruffed grouse numbers would be substantially reduced in fragmented habitats with high hunting mortality. Clark (2000) suggested that reducing harvest during population lows might benefit ruffed grouse populations. Finally, Bergerud (1988) summarized data from 3 study areas in Minnesota and reported that populations occupying heavily hunted areas were being depressed by excessive harvest.

Spruce grouse have high overwinter survival (Keppie 1979), but there appears to be little information on the effects of harvest on this species. Ellison (1974) reported that about 13% of grouse banded within 3.2 km of roads were killed by hunters on the Kenai Peninsula, Alaska. Bergerud (1988) reexamined Ellison's data and concluded that hunting increased natural mortality by 14% (i.e., hunting was additive to the natural mortality rate).

PRAIRIE GROUSE

Differences in population characteristics (see Box 33.6) and annual home ranges complicate attempts to assess effects of harvest on **prairie grouse**. Sharp-tailed grouse tend to have small annual home ranges (Hillman and Jackson 1973, Connelly et al. 1999). In contrast, greater sage-grouse, and lesser and greater prairie-chickens, have relatively large annual ranges (Hamerstrom and Hamerstrom 1949; Johnsgard 1973; Taylor and Guthery 1980a, b; Svedarsky 1988; Schroeder and Robb 1993; Schroeder et al. 1999; Leonard et al. 2000). Moreover, juveniles of both lesser and greater prairie-chickens make extensive movements in autumn (Robel et al. 1970, Taylor and Guthery 1980a, Schroeder and Robb 1993).

Early information on the effects of hunting on prairie grouse follows the same pattern as other game bird species, indicating that hunting does not negatively affect populations. Although there is little published information on the effects of hunting on prairie-chickens (Schroeder and Robb 1993), Hamerstrom et al. (1957) suggested that hunting did not pose any problems for greater prairie-chicken populations in Wisconsin during periods of population highs. Hart et al. (1950), Ammann (1963), and Hillman and Jackson (1973) provided evidence that hunting had little effect on sharp-tailed grouse populations. Numerous studies also suggested that hunting had little impact on sage-grouse populations (June 1963, Crawford 1982, Braun and Beck 1985, Braun 1987). Wallestad (1975) reported that, despite fluctuating population trends, Montana maintained liberal sage-grouse seasons because of high annual turnover, **law of diminishing returns**, and **opening day phenomena**.

Despite the fact that these species differ in life-history traits, and some information to the contrary, much of the available data suggest hunting may adversely affect many populations of prairie grouse, regardless of species. Hamerstrom and Hamerstrom (1973) reported that hunted cohorts of **greater prairie-chickens** in Wisconsin had higher average mortality rates than nonhunted cohorts. They concluded hunting increased **normal mortality** by 25%. Copelin (1963) suggested that hunting seasons for **lesser prairie-chickens** in Oklahoma only open during years when populations were increasing, but provided little information on the effects of harvest on this species. For **sharp-tailed grouse** in Wisconsin, Grange (1949) considered a 24% harvest of the autumn population to be excessive and Gregg (1990) reported that harvest rates ranging from 15% to 56% of the autumn population were associated with stable to declining breeding populations. Similarly, Mossop (1994) reported that harvest rates in parts of the Yukon Territory, Canada ranged from 4% to 39% and, in some years, harvest may negatively affect populations. **Sage-grouse** may be more susceptible to overharvest than other upland game bird species (Schroeder et al. 1999) because they have population characteristics more typical of k-selected species (relatively low reproductive rates, long lives, low annual turnover).

Autenrieth (1981) and Crawford and Lutz (1985) suggested that hunting might have some negative effects on sage-grouse populations. Johnson and Braun (1999) analyzed lek count and hunter-harvest data and concluded that, up to some **threshold level**, hunting mortality was compensatory, but at or beyond that level, exploitation of sage-grouse may be additive. Connelly et al. (2000a, 2003) concluded that hunting can slow the rate of increase for sage-grouse populations, and harvest losses are likely additive to winter mortality and may result in lower breeding populations. Sedinger and Rotella (2005) critiqued the work by Connelly et al. (2003) as being inconclusive. However, Reese et al. (2005) noted Sedinger and Rotella (2005) misinterpreted several aspects of the study. Sedinger and Rotella (2005) did not argue for compensatory or additive mortality from harvest of greater sage-grouse, but stressed the need for more research to further refine understanding of the relationships of density dependence, life-history stages, and population size and growth to harvest of sage-grouse. Subsequently, additional work in California (Gibson et al. 2011) supported the conclusions of Connelly et al. (2000a, 2003) and further argued that additive, rather than compensatory, hunting mortality should be the default assumption for harvest management of sage-grouse.

Sika (2006) reported no deaths from hunters over 2 hunting seasons in a study of 93 radiomarked female sage-grouse in central Montana. However, apparently 30% of the study area was closed to hunting and it was not clear how this may have affected vulnerability of radiomarked birds to harvest. Wik (2002) indicated that sage-grouse use of lands closed to hunting may have confounded harvest estimates. Van Kooten et al. (2007) suggested that hunting mortality for a greater sage-grouse population in Nevada was likely **compensatory** to other causes of mortality. Unfortunately, their conclusion was based on analysis of an incomplete data set of lek counts coupled with observational data. Moreover, it is not clear whether the observational data were obtained from casual observations made by field biologists, systematic counts, aerial surveys, or a combination of these approaches. The timing of observations was not provided nor did the authors indicate what was counted (e.g., broods, all birds, adult males). These problems were confounded by the authors' lack of direct knowledge of sage-grouse biology and inappropriate use of supporting data.

PTARMIGAN

Bergerud and Huxter (1969) reported that harvest rates removing up to 70% of populations apparently had no effect on trends in breeding populations of willow ptarmigan in Newfoundland, Canada. Although Weeden (1972) suggested that spring hunting of **rock ptarmigan** may affect breeding populations, he generally concluded that harvest of 40% of the autumn population had no effect on subsequent breeding populations. Similarly, McGowan (1975) reported that

hunting had no effect on rock ptarmigan breeding populations. Bergerud (1970, 1972) indicated that late-hatched **willow ptarmigan** young are more vulnerable to hunting than early hatched birds and vulnerability of ptarmigan populations to hunting varied among years.

Braun (1969) was one of the first to suggest that autumn hunting could reduce subsequent breeding populations of **white-tailed ptarmigan**. Bergerud (1988) reviewed data from hunted and nonhunted populations of white-tailed ptarmigan from Colorado and concluded that birds in hunted populations had mortality rates approximately double those of nonhunted populations. Additionally, Mossop (1994) provided information suggesting that, in some years, hunting in the Yukon Territory may remove enough willow ptarmigan to negate any population increases and Steen and Erikstad (1996) produced similar results by modeling a willow ptarmigan population. Other research has provided evidence indicating that hunting can remove relatively large portions of the autumn population of willow ptarmigan (Smith and Willebrand 1999, Willebrand and Hörnell 2001). Finally, Smith and Willebrand (1999:722) concluded "hunting mortality was mostly, if not totally additive to natural mortality" of willow ptarmigan in Sweden.

Wild Turkey

Hunting for **wild turkey** differs from other game birds because male turkeys are traditionally hunted during spring when females are protected. Some areas support both **spring** (male only) and **autumn** (either gender) **seasons**. Markley (1967) indicated that harvest rates vary widely among areas and years, but suggested that in good southeastern United States habitat, 40–60% of turkey populations could be harvested without harming the population. He further concluded that hunting is not a serious limiting factor to population increases where suitable habitat exists. Weaver and Mosby (1979) examined the influence of hunting regulations on turkey populations and concluded that a population can continue to decline even with restrictive autumn harvest regulations (bearded-turkey [males, few females] only), but a productive population can withstand at least a 20% annual harvest.

Lobdell et al. (1972) indicated that **spring hunting** of male turkeys was biologically innocuous if reproduction (Box 33.7) was adequate to ensure a self-sustaining population. However, Kurzejeski and Vangilder (1992) suggested that the effects of spring season length and bag limits on turkey populations were not well understood.

Some research has demonstrated that **autumn harvest** exceeding 10% of the population can result in a population decline (Vangilder and Kurzejeski 1995, Hubbard et al. 1999), but minimal autumn harvest with restricted numbers of hunters seems to have little impact (Hubbard et al. 1999). Pack et al. (1999) compared survival of radiomarked turkeys in areas closed and open to autumn hunting. They reported

Box 33.7. WILD TURKEY PRODUCTIVITY AND SURVIVAL CHARACTERISTICS

Wild turkeys have low to moderate annual survival rates (15–75%) and high reproductive potential (Peterson and Richardson 1975, Vangilder 1992). Thus, they tend to be more like pheasants, quail, and partridge than grouse and ptarmigan.

that mean annual survival rates were higher in closed areas than in open areas and attributed these differences to legal hunting. Kurzejeski and Vangilder (1992) reported that autumn seasons have a greater potential than spring seasons to affect populations, especially in years of poor production. Generally, a 15% autumn harvest level can result in population declines (Kurzejeski and Vangilder 1992).

Rabbits and Squirrels

Regardless of variation in reproductive rates, given the relatively high reproduction of these small game species, they should have a high likelihood of compensatory responses to hunting mortality (Peek 1986). Most of the published literature for both squirrels and rabbits indicates this is the case (Wight 1959, Mosby 1969, Mosby et al. 1977). Nevertheless, some instances of inappropriate harvest levels have been documented for both **gray** (*Sciurus carolinensis*) and **fox squirrels** (*S. niger*; Peek 1986). Nixon et al. (1974) concluded that an adult fox squirrel population was reduced by hunting to a level that could not produce enough young to bring preseason densities up to population levels attained in previous years. These authors also indicated that small woodlots on public hunting areas may be difficult to manage for fox squirrels without restraining hunting opportunity. Management of these woodlots should be based on sustained yield rather than hunter success, because hunter demand exceeds the supply of squirrels (Nixon et al. 1974). Nixon et al. (1975) further concluded that harvest and population densities affect subsequent survival of adult female gray squirrels. Additionally, Rose (1977) provided evidence that cottontail rabbits had higher mortality rates resulting from hunting, but also argued that greater hunting mortality was compensated for by increased production, increased survival, or immigration.

Future Directions

Stocking

Stocking game birds is seen as a legitimate and often necessary function of harvest management. In part, the release of pen-reared **pheasants**, **northern bobwhite**, or other species is likely reinforced among the hunting public because

stocking is a common activity of fisheries management. There are 2 different harvest management programs involving game bird stocking, although the differences may not be apparent to some sportsmen. The first is the release of birds before the gun, usually just before or during the hunting season (Sokos et al. 2008). Maple and Silvy (1988) found that the recovery of pen-reared **northern bobwhites** released during the 5 months preceding the hunting season was 7.5%, whereas 38.6% of birds released during the first 3 months of the hunting season were recovered compared to 55.4% of those released during the last 2 months. Release of birds just prior to the hunt decreased the cost per bird recovered by almost 3-fold compared to birds released 14 days before the hunt. Krauss et al. (1987) reported that survival of wild male **pheasants** was considerably higher than pheasants from state or commercial hatcheries. Strickland et al. (1994) summarized information on harvests of pen-reared birds and indicated that survival rates were generally low. Stocking pen-reared birds also tends to concentrate hunters in relatively small areas and may create lead shot “hot spots” (Strickland et al. 1994). These authors concluded that stocking was not an appropriate harvest management practice. Similarly, Sokos et al. (2008) questioned the ethics of **put and take** hunting, but recognized that this approach may be justified in areas with high human populations, degraded habitats, and poor access to public lands for hunting.

The second stocking program involves attempts to establish or **augment** existing game bird **populations** and, thus, expand hunting opportunity (Putala and Hissa 1998, Musil and Connelly 2009). Although stocking activities now principally involve ring-necked pheasants, chukar, and quail, early efforts involved a variety of species, including Reeves pheasants (*Syrnaticus reevesii*), francolins (*Francolinus* spp.), Chilean tinamou (*Nothoprocta perdicaria*), red-legged partridge (*Alectoris rufa*), and others (Korschgen and Chambers 1970, Banks 1981). Initial successes in the late 19th and early 20th centuries with ring-necked pheasants, chukar, and gray partridge encouraged agencies to attempt to establish other non-native game bird species. With few exceptions, most releases of other species were unsuccessful (Banks 1981). Additionally, many of the more recent efforts to augment existing populations failed because of relatively low survival and reproduction (Korschgen and Chambers 1970, Krauss et al. 1987, Prince et al. 1988, Leif 1994, Niewoonder et al. 1998, Parish and Sotherton 2007). Prince et al. (1988) suggested that a program to release Sichuan pheasants (*P. c. strauchi*) might enhance existing pheasant populations. However, Niewoonder et al. (1998) reported that survival and reproduction of female Sichuan pheasants was low, and concluded that survival of released pheasants in their study could not sustain a wild population. Musil and Connelly (2009) demonstrated that survival of wild female ring-necked pheasants was significantly greater than pen-reared females. Moreover, comparing **translocated wild and pen-reared**

pheasants, costs were US\$170/pen-reared egg hatched in the wild and US\$62/wild egg hatched (Musil and Connelly 2009). Low survival, poor productivity, and higher costs of pen-reared compared to wild birds provide compelling evidence that stocking pen-reared birds is an inappropriate management tool for increasing game bird numbers (Parish and Sotherton 2007, Sokos et al. 2008, Musil and Connelly 2009).

Shooting Preserves

Suburban sprawl and limited amounts of publicly owned areas with adequate game bird habitat, coupled with declining game bird populations, have increased the popularity of shooting preserves. These **preserves** raise and stock their own birds (usually pheasants, but they sometimes include quail, chukar, and gray partridge). Depending on the organization, guides and dogs may be provided. Generally, preserves operate either as a club open to members only, or as a business charging by the bird and day. In both cases, meals, lodging and other activities, including fishing and sporting clays also may be offered. Hunting seasons on preserves are usually much longer than those set by state agencies for wild birds, and preserve operators set daily bag limits.

Hunting preserves offer additional hunting opportunity, as well as a chance for individuals to train dogs prior to a general season. They often provide habitat used by wild game birds and other wildlife. Hunting preserves (although rather expensive) appear to fill a need for more hunting areas at which hunters have a better than average chance at being successful (Ratti and Workman 1976).

A somewhat different approach to the traditional hunting preserve occurs in some states, and is used by clubs that own little or no land. Instead, they lease hunting rights on privately owned land and stock these areas with domestically reared game birds, usually pheasants. These clubs regulate hunting pressure and monitor take by their members through a reservation and mandatory reporting system. They also are responsible for posting the property and establishing safety zones around buildings and livestock. In at least one case in Connecticut, private lands are "leased" by simply offering free membership in the club to landowners.

MANAGEMENT OF MIGRATORY GAME-BIRD HARVESTS

Development of Harvest Strategies

Approaches to harvest management of **migratory game birds** in North America have been shaped primarily by the recognition these highly mobile animals routinely cross local, state, provincial, and international borders over the course of their life cycles. Consequently, effective monitoring of populations and harvests, and development of appropriate hunting regulations, depends upon cooperation across multiple levels of government. In contrast to management

of most other wildlife in North America, **primary regulatory responsibility** and authority for migratory game birds lies with federal governments.

Until reliable population and harvest surveys were developed, migratory bird hunting **regulations** in the United States were set subjectively, and often were consistent across the country. As information from monitoring programs was incorporated into the regulatory process, regional or flyway-specific differences in bird distribution and harvest pressure were recognized, and regulations became more spatially complex (Nichols et al. 1995). In addition, a general approach emerged in which relatively restrictive regulations were imposed when populations appeared to be declining or at low levels. Regulations for many lightly harvested species often have remained relatively stable over long periods, whereas **waterfowl** regulations have been subject to much annual variation and widespread use of special regulations (Boyd 1983, Ladd et al. 1989).

Over time, **population models** were developed for use in setting **duck** hunting regulations, incorporating information from large-scale operational monitoring programs (Crissey 1957, Geis et al. 1969, Brown et al. 1976). Early models assumed hunting mortality acted in a completely additive, density-independent manner to increase overall mortality (Nichols 2000). Anderson and Burnham (1976) produced new analyses of the relationships between harvest and survival of mallards (*Anas platyrhynchos*) that supported compensatory or density-dependent hunting mortality, and formally introduced the concept of structural uncertainty into the management process (Nichols 2000). Subsequent analyses have provided mixed evidence concerning the effects of hunting mortality on annual survival in ducks (Nichols et al. 1984, Smith and Reynolds 1992), whereas hunting mortality appears to be primarily additive for **geese** (Rexstad 1992, Hestbeck 1994) and **cranes** (Tacha et al. 1994). Efforts to obtain estimates of demographic parameters and develop population models for use in harvest management strategies have continued to be a key focus for waterfowl and other migratory game birds (e.g., Otis 2002, Hauser et al. 2007).

The recognition of alternative hypotheses about the effects of hunting on population dynamics led to a greater focus on addressing partial management control and structural uncertainty in harvest management of migratory game birds. However, because regulations, harvests, and population sizes have traditionally varied together over time and space, the ability to understand the relationship between hunting and populations is limited (Nichols 2000). In addition, increasing complexity of regulations at smaller spatial scales, particularly for waterfowl, confounded attempts to understand relationships between regulations and harvests (Nichols 1991, Nichols et al. 1995). Proposals for formal experiments with hunting regulations to directly address uncertainties about the effects of harvest on populations (Nichols et al. 1984, Anderson et al. 1987, Nichols and John-

son 1989) were largely resisted by managers seeking to maintain traditional hunting opportunities and regulatory approaches. In a notable effort, the United States and Canada stabilized duck hunting regulations during 1979–1985, in an attempt to examine the relationships between hunting regulations and harvests (Brace et al. 1987, Sparrowe and Patterson 1987). Results of monitoring information for mallards during stabilized regulations indicated that while regulations were held steady, harvest varied mainly in response to mallard population size and hunter numbers, but harvest rates remained relatively constant over the period (Trost 1987, Trost et al. 1987). However, key questions about the potential effects of harvest on duck populations remained unanswered (Blohm 2006).

After the period of stabilized regulations, federal authorities in the United States adopted an approach of **risk-averse conservatism** toward setting hunting regulations, in which relatively restrictive regulations would be adopted for populations at low levels (U.S. Fish and Wildlife Service 1988). In addition, a policy of controlled use of special regulations (see Annual Regulations Process, below) was adopted (U.S. Fish and Wildlife Service 1988), based on the idea that the scale of harvest management should be consistent with the availability of monitoring information and the ability to evaluate the impact of regulations on harvests and populations (Babcock and Sparrowe 1989, Nichols and Johnson 1989). This idea emphasized that **partial observability** and **partial management control** (see Box 33.2) impose limits on the scale at which informed management can be used. This perspective led to the conclusion that improved harvest opportunities, associated with fine-scale regulations, may not justify the increased costs of monitoring and evaluation (Nichols and Johnson 1989, Johnson and Case 2000).

Inventory

Federal mandates to consider the status of migratory game birds when setting hunting regulations motivated the development of extensive **monitoring programs** in North America, particularly for waterfowl (Martin et al. 1979, Hawkins et al. 1984, Blohm 2006). These monitoring programs support the annual regulatory process and consist of annual collection of data on abundance, production, distribution, harvest levels, and other population parameters, as well as habitat conditions (Martin et al. 1979, Reynolds 1987, Smith et al. 1989b).

A variety of operational surveys is conducted annually to obtain estimates or indices of the size of migratory bird populations. **Coo-counts** for mourning (*Zenaidura macroura*) and white-winged doves (*Z. asiatica*) provide indices of population trends for these species (Dolton 1993, George et al. 1994). **Singing-ground surveys** are conducted to provide estimates of relative abundance of American woodcock (*Scolopax minor*) throughout much of its primary North American breeding range (Sauer and Bortner 1991). Hunted popu-

lations of sandhill cranes (*Grus canadensis*) are monitored through **annual counts** on spring (Midcontinent population) and autumn (Rocky Mountain population) staging areas, or on breeding and wintering areas (Pacific Coast population; Tacha et al. 1994, Sharp et al. 2002). No specific population surveys are conducted for some other migratory game birds, particularly lightly harvested or secretive species such as Wilson's snipe (*Gallinago delicata*) and rails (Rallidae). For these species, the **North American Breeding Bird Survey** (Robbins et al. 1986) provides indices to the distribution and relative abundance of breeding populations.

Population monitoring programs for waterfowl have a longer history and are more extensive than surveys developed for most other migratory game birds in North America (Smith et al. 1989b). Since 1955, the U.S. Fish and Wildlife Service and the Canadian Wildlife Service have conducted **annual aerial transect surveys**, coupled with ground counts in some areas to correct for visibility bias, during May to estimate numbers of **ducks** in >3.6 million km² of breeding habitat in the north-central United States, western and northern Canada, and Alaska (Reynolds 1987, Smith 1995a). In recent decades, survey coverage has been expanded to include eastern Canada and the northeastern United States, and efforts are being made to establish reliable population surveys in western North America (Blohm 2006). Traditionally, a portion of these transects were surveyed annually to obtain counts of total duck broods (an index of duck production), but this survey was discontinued in 2004. Breeding Canada geese (*Branta canadensis*) also are recorded in the continental duck survey area, and additional operational surveys have been established to track breeding populations of geese that occupy other areas (Trost et al. 1990).

Winter (Jan) surveys of waterfowl have been conducted since the 1930s (Martin et al. 1979). Prior to implementation of breeding ground surveys, the winter survey was intended to provide information on the relative abundance and population trends, as well as the winter distribution, of waterfowl species; **cranes and American coots** (*Fulica americana*) also are counted during winter surveys. This survey is still the primary population index for duck species that occur outside of the May survey area, and provides population indices used to manage many goose populations in North America. Federal and state personnel in the lower 48 states conduct the survey cooperatively, and methods vary from state to state (Smith et al. 1989b). Portions of Mexico are periodically included in winter aerial surveys conducted by the U.S. Fish and Wildlife Service (Saunders and Saunders 1981).

Although variation in habitat conditions is considered an important influence on the status of many migratory game bird populations, few large-scale, operational surveys are conducted to assess the status of habitats. One exception is the annual monitoring of **wetland numbers** and conditions in northern prairie regions to assess habitat for breeding

ducks (Smith et al. 1989b). During the aerial waterfowl surveys conducted in May and July, observers record the number of ponds containing water along each transect in southern Canada and the north-central United States. In addition, the Canadian Wildlife Service monitors wetland habitat conditions on a sample of survey transects each year in southern Canada (Turner et al. 1987).

Harvest Surveys

In the United States, annual waterfowl harvest estimates are obtained using surveys consisting of 2 components. The **Hunter Questionnaire Survey**, in operation since 1952, traditionally sampled names and addresses of hunters who purchased federal waterfowl stamps from randomly selected post offices (Martin and Carney 1977, Martin et al. 1979). The Hunter Questionnaire Survey is used to obtain information on hunter activity and number of ducks and geese harvested each year. The **Parts Collection Survey** involves mailing special envelopes to a sample of hunters who are asked to mail in wings of ducks and tail feathers of geese they shoot during the hunting season. These parts are identified to species, gender, and age by federal, state, and private biologists during annual **wing bees** conducted after each hunting season, to identify the composition of the annual waterfowl harvest in the United States. Parts collection surveys also are conducted for American woodcock, mourning doves, and band-tailed pigeons (*Patagioenas fasciata*) to provide indices to annual recruitment.

The traditional sampling frame used for conducting waterfowl harvest surveys did not include hunters who did not purchase a waterfowl stamp, but hunted migratory game birds other than waterfowl (Tautin et al. 1989). The International Association of Fish and Wildlife Agencies and the U.S. Fish and Wildlife Service began working to address this problem in 1989. In 1991, a new **Harvest Information Program (HIP)** was initiated to provide a reliable, nationwide sampling frame of all migratory bird hunters to conduct annual harvest surveys for each migratory game bird species (Elden et al. 2002). Under HIP, each state is required to collect the name, address, and date of birth of each person hunting migratory game birds in that state, ask each hunter a series of screening questions about their hunting success the previous year (for the purpose of improving the precision of estimates from subsequent harvest surveys; Moore et al. 2002), and provide this information to the U.S. Fish and Wildlife Service each year. HIP became fully operational in 49 states (HI is exempted) in 1998, and the traditional sampling procedure used in the federal waterfowl survey was replaced with the HIP sampling frame beginning with the 2002–2003 hunting season. Using the 49 sampling frames and hunter responses to screening questions, the U.S. Fish and Wildlife Service conducts separate annual harvest surveys for (1) waterfowl, (2) mourning doves, white-winged doves, and band-tailed pigeons, (3) American coots,

gallinules, rails, and Wilson's snipe, (4) American woodcock, and (5) sandhill cranes.

In **Canada**, harvest surveys have been conducted since 1967, using purchasers of Migratory Game Bird Hunting permits as the sampling frame (Cooch et al. 1978). As in the United States, the survey has 2 components. The **National Harvest Survey** involves a mail questionnaire sent to a sample of permit purchasers, who provide data on their hunting activity and harvest of species or groups of migratory game birds. In the **Species Composition Survey**, a sample of permit purchasers supply wings (ducks and woodcock) and tail feathers (geese) from birds they harvest for use in identifying the species, gender, and age composition of the annual harvest.

Some estimates from operational surveys are adjusted for crippling loss (birds downed, but not retrieved by hunters) to obtain estimates of total harvest (Martin and Carney 1977, Martin et al. 1979). No operational surveys have been developed to estimate magnitude or composition of **subsistence harvest** in Alaska or Canada, where short-term studies indicate this take can represent a significant portion of total annual mortality for some bird populations (Raveling 1984, Finney 1990). In addition, **illegal harvest** by recreational hunters is not accounted for in harvest estimates, but is usually assumed to be insignificant (U.S. Fish and Wildlife Service 1988; but see Gray and Kaminski 1994).

The Role of Banding

Mark–recovery methods (Brownie et al. 1985, Williams et al. 2001) enable managers to obtain important information about animal populations. To use these methods, individually numbered **leg bands** are placed on migratory game birds, usually just prior to the hunting season, and hunters are relied upon to report the band number, date, and location of harvest of banded birds they recover. Banding information is used to identify the distribution of harvest and harvest areas associated with different breeding areas, to estimate harvest rates and relative vulnerabilities to harvest of different gender and age cohorts, and to estimate age- and gender-specific survival rates (Smith et al. 1989b).

Banding has been particularly important in the management of waterfowl populations and their harvests. An operational **duck-banding** program has been in place in Canada and the United States for >5 decades (Smith et al. 1989b, Blohm 2006). Information from banding has been increasingly incorporated into harvest management, particularly for mallards. Large-scale banding programs also provided much of the information used to manage mourning doves in the United States (Dunks et al. 1982, Tomlinson et al. 1988).

A recently completed national strategic harvest-management plan for **mourning doves** (Anonymous 2005) emphasized the need for survival and harvest rate information for this important game species. During 2003–2005, a large-scale banding effort was conducted to provide the founda-

tion for an operational long-term banding program in all states where mourning doves are hunted, as called for in the national strategy (Otis et al. 2008).

An important aspect of banding studies is to estimate band reporting rates. In the mid-1990s, the **U.S. Bird Banding Laboratory** began issuing bands inscribed with a toll-free phone number, in addition to the mailing address that had been inscribed previously, which hunters could use to more easily report band recoveries. More recently, the Bird Banding Laboratory has had a web address inscribed on bands, in addition to the toll-free phone number for reporting bands. Recent analyses indicate these changes have resulted in substantially higher band reporting rates (Royle and Garretson 2005, Otis et al. 2008, Zimmerman et al. 2009).

Developing Regulations

Governmental Roles in Regulating Hunting

Primary federal authority and responsibility for migratory birds was established after the signing of the **Convention for the Protection of Migratory Birds** by representatives from the United States and Great Britain (for Canada) in 1916. The **Migratory Bird Treaty Act** of 1918 implemented the convention in the United States (U.S. Fish and Wildlife Service 1988). This Act was later amended to incorporate similar treaties with Mexico (1936), Japan (1972), and Russia (1976). In North America, compliance with these treaties is the responsibility of the Minister of Environment in Canada, Secretary of the Interior in the United States, and Director General de Flora y Fauna Silvestre in Mexico.

The migratory bird conventions between the United States and Canada and the United States and Mexico **define migratory game birds** as those species belonging to the following families: **Anatidae** (ducks, geese, and swans), **Rallidae** (rails, gallinules, and coots), **Gruidae** (cranes), **Charadriidae** (plovers and lapwings), **Haematopodidae** (oystercatchers), **Recurvirostridae** (stilts and avocets), **Scolopacidae** (sandpipers, phalaropes, and allies), and **Columbidae** (pigeons and doves; U.S. Fish and Wildlife Service 1988). The treaties allow take of migratory birds only between 1 September and 10 March each year, and constrain hunting to seasons not exceeding 3.5 months in any one region. The treaty between the United States and Canada was amended in 1995 to allow for subsistence take of birds, including some species not originally designated as game birds, in Alaska and Canada outside normal hunting seasons; the amended treaty was formally implemented in the United States in 1999.

Under the Migratory Bird Treaty Act, the **Secretary of the Interior** authorizes when hunting of migratory game birds is permitted, and adopts regulations for this purpose, or imposes closed seasons if hunting is incompatible with population status. These regulations must be based on the status and distribution of migratory game birds and must be updated annually. This responsibility has been delegated

to the U.S. Fish and Wildlife Service, Department of the Interior.

Information from monitoring programs about bird distribution and migration pathways and increased state involvement in migratory game bird management efforts led in 1947 to the division of the United States into 4 administrative **Flyway Councils** (Fig. 33.1) for establishing annual hunting regulations (Hawkins et al. 1984). Through these Councils, representatives from state and federal agencies in the United States, as well as from Canada and Mexico, have major roles in coordinating management activities and developing annual hunting regulations for migratory game birds (U.S. Fish and Wildlife Service 1988).

Annual Regulations Process

Extensive and elaborate processes have been developed for setting regulations for migratory game birds to allow involvement by multiple levels of government, follow legal requirements for consultation with the public, and use of annually updated monitoring information (Blohm 1989). In the United States, federal regulations are considered either “basic” or “annual” (U.S. Fish and Wildlife Service 1988). Basic regulations generally remain the same from year to year, and include constraints such as methods of take and ammunition types that can be used in hunting. Basic regulations are generally tied to safety issues and general views about ethical hunting practices.

Annual regulations are subject to frequent change and are usually tied more closely to the status of hunted populations. Annual regulations are further divided into either “framework” or “special” regulations. **Framework regulations** are the main tools used to adjust harvest levels at flyway or continental scales, and include framework dates (the earliest opening and latest closing dates), season length, and bag limits (U.S. Fish and Wildlife Service 1988). **Special regulations** that modify framework regulations are intended to influence harvest or hunter opportunity at finer spatial scales or for individual species. Examples include **season**

Fig. 33.1. Waterfowl flyways and boundaries of the 4 waterfowl Flyway Councils in the United States.

splits (dividing the total hunting-season length in a state into 2 or 3 nonconsecutive segments), **zoning** (delineating a state into separate areas in which regulations can be set independently), **area closures** (reducing overall harvest of a species by prohibiting hunting in major concentration areas), **special seasons** (allowing take of particular species outside the regular season), and **bonus birds** (birds of lightly harvested species added to the regular daily bag limit [U.S. Fish and Wildlife Service 1988, Ladd et al. 1989, Nichols 1991]). Special regulations usually are not changed annually, but have been controversial because they add complexity to the regulatory process and often occur at spatial scales at which population responses cannot be adequately measured using existing monitoring programs.

The regulatory process in the United States involves a series of meetings and consultations beginning in January and ending in late September each year (Box 33.8). The director of the U.S. Fish and Wildlife Service appoints a **Migratory Bird Regulations Committee**, which is responsible for recommendations on regulations. This committee meets in January to review current regulations and identify important issues. Each of the 4 Flyway Councils meet in late March and again in July to formulate recommendations for regulations. The Migratory Bird Regulations Committee meets in June to recommend regulations for “early” seasons, which begin in September and include most **webless** (nonwaterfowl) species, and again in late July or early August to develop proposed regulations for “late” season regulations, which begin near 1 October and include most waterfowl. Representatives from each Flyway Council participate in these deliberations. Throughout this series of meetings,

results of population and harvest monitoring programs are reviewed as they become available to help clarify the decision-making process. **Early season** recommendations are published for public comment in July, so final federal guidelines and state regulations can be selected before 1 September. Final federal frameworks for **late seasons** are published in mid-September, following a public comment period, and are adopted as law by the end of September.

Final regulations enacted by states may be the same or more restrictive, but not more liberal, than applicable federal regulation frameworks. Within each Flyway, states generally attempt to design hunting seasons that coincide with typical patterns of migration chronology. For example, northern states typically begin seasons as early as federal frameworks allow, whereas southern states attempt to provide hunting opportunity as late as possible.

The annual process for developing migratory game bird regulations in **Canada** requires final proposals for any changes to be made by early March (Canadian Wildlife Service Waterfowl Committee 2002). Thus, results from annual breeding population, production, and breeding habitat surveys for the current year are not available. The **Canadian Wildlife Service of Environment Canada** reviews hunting regulations and recent trend data for game bird populations annually, with comments from the provinces, territories, and other stakeholders. During November and December, Canadian Wildlife Service personnel review biological information and develop recommendations for hunting regulations for the following year. In January, the Canadian Wildlife Service issues proposed regulations and solicits public comments. After this consultation period, final regulation

Box 33.8. SCHEDULE FOR THE ANNUAL PROCESS OF SETTING MIGRATORY GAME BIRD HUNTING REGULATIONS IN THE UNITED STATES, AND ASSOCIATED POPULATION AND HARVEST MONITORING PROGRAMS

Regulations process	Month	Monitoring
U.S. Fish and Wildlife Service regulations Committee (SRC) meets to identify issues	January	Midwinter waterfowl and crane surveys
Flyway Councils develop recommendations	February	Parts Collection Survey wing bees
	March	Hunter Questionnaire Surveys; banding analysis for duck harvest and survival rates
	April–May	Breeding waterfowl and habitat, dove call-count, and woodcock singing-ground surveys
SRC meets to recommend “early” season regulations	June	Harvest survey results available
Flyway Councils develop recommendations	July	Waterfowl production surveys
SRC recommend “late” season regulations	August	Preseason duck banding
“Early hunting” seasons begin	September	Autumn surveys for sandhill cranes, greater white-fronted geese (<i>Anser albifrons</i>)
“Late” hunting seasons begin	October	

proposals are submitted to **Parliament**, and in June final hunting regulations, adjusted if necessary to account for public comment, are passed into law.

Adaptive Harvest Management

In 1995, the U.S. Fish and Wildlife Service, in cooperation with the 4 flyway Councils, implemented an **adaptive harvest management** approach for setting duck hunting regulations in the United States (Box 33.9). With this approach, key sources of uncertainty are explicitly incorporated into modeling and decision-making processes used to select regulations. Thus, management can be used as a tool to help reduce uncertainty about the managed system (Walters 1986, Lancia et al. 1996, Lee 1999).

The adaptive harvest management process is currently used in setting regulations for 3 populations of mallards. **Midcontinent mallards** are defined as those mallards breeding in the traditional breeding survey area (except AK) and the states of Minnesota, Wisconsin, and Michigan; these mallards are harvested primarily in the Mississippi and Central flyways. **Eastern mallards** breed in Ontario and Quebec, Canada, and the northeastern United States and are harvested primarily in the Atlantic Flyway. **Western mallards** breed and are primarily harvested in the Pacific Fly-

way. For each of these populations, sets of alternative population models have been developed that describe competing hypotheses about the effects of harvest on annual survival (i.e., additive versus compensatory mortality) and the effect of mallard abundance on reproductive rate (i.e., density-dependent reproductive success). Alternative “packages” of framework regulations have been developed for each flyway, with expected mallard harvest rates associated with each package. The harvest management objective for all 3 populations is to maximize cumulative (i.e., sustainable) harvest over the long term. For midcontinent mallards, this objective is constrained to avoid regulations that could be expected to result in subsequent population sizes below an established objective.

Approaches such as are used in adaptive harvest management force managers to specify and reach consensus on harvest management objectives, and to formally acknowledge fundamental disagreements about the influence of different management actions on achieving those objectives. This approach also provides a process for objectively making decisions about regulations in the face of these disagreements (Johnson and Williams 1999, Humburg et al. 2000, Johnson and Case 2000). Although adaptive harvest management is focused on optimal management performance, the approach

BOX 33.9. FEATURES OF ADAPTIVE HARVEST MANAGEMENT FOR MALLARD POPULATIONS IN THE UNITED STATES

Key components of adaptive harvest management (Johnson et al. 1993, Williams and Johnson 1995, Johnson 2001) include

1. a set of alternative models describing population responses to harvest and uncontrolled environmental variation;
2. a measure of reliability (probability or weight) for each model;
3. a limited set of regulatory alternatives (season lengths, bag limits, and framework dates) that differ in their expected harvest rates; and
4. an objective function or mathematical description of the objective(s) of harvest management.

These components are used in a stochastic optimization procedure to derive an optimal harvest policy, which is used to identify the appropriate regulatory alternative for population levels and probabilities associated with the alternative population models (Johnson et al. 1997). The setting of annual hunting regulations then involves a 4-step process:

1. Each year the optimal regulatory alternative is identified based on duck breeding populations and resource conditions, and on current model weights.
2. Once the regulatory decision is made, model-specific predictions for subsequent breeding population size are calculated.
3. When monitoring data are available, model weights are updated based on how well the population size predicted by each alternative model agrees with the observed population size.
4. The new model weights are used to start a new iteration of the process.

Over time, this iterative process of updating model weights and optimizing regulatory choices should identify which model is the best predictor of changes in population size.

also allows for learning about the underlying systems involved in and affected by harvest management (Johnson et al. 2002).

Harvest Management of Overabundant Species

A **primary goal** of harvest management for migratory game birds in North America continues to be **prevention** of overharvests that result in significant population declines. Within this constraint, hunting has often been used to reduce or control the density of birds on local scales. However, in recent decades, several continental populations of geese in North America have grown rapidly (Ankney 1996). In this case, the intent of harvest management is the large-scale reduction of populations to address environmental and economic damage caused by these overabundant birds. **Articles of the 1999 amended Migratory Bird Treaty** between the United States and Canada address this situation by allowing these governments to “provide for and protect habitat necessary for the conservation of migratory birds” and to “take appropriate measures to preserve and enhance the environment of migratory birds” (U.S. Fish and Wildlife Service 2001:6). The amended treaty also authorizes “permitting the take of migratory birds that, under extraordinary conditions, become seriously injurious to agriculture or other interests” (U.S. Fish and Wildlife Service 2001:6).

During the last half of the 20th century, some populations of **light geese** (snow geese [*Chen caerulescens*] and Ross’ geese [*C. rossii*]) in North America grew rapidly and are now causing widespread habitat damage on their arctic and subarctic breeding areas (Batt 1997). In the United States, managers first attempted to reduce this population growth by increasing bag limits and extending the hunting season length for light geese to 107 days, the maximum allowed by the Migratory Bird Treaty Act. However, due to continued increases in light goose numbers and low hunter success, the harvest rate on light geese actually declined. In 1999, the U.S. Fish and Wildlife Service authorized new methods of take for light geese (electronic calls and unplugged shotguns) and established a conservation order that permitted take outside the dates established for hunting seasons by the Migratory Bird Treaty Act. Similar regulatory approaches are being used in Canada. The purpose of these efforts is to reduce light goose populations to sustainable levels and stop the spread of habitat deterioration. If current regulatory approaches are not effective, more aggressive population reduction efforts may be warranted (Batt 1997, U.S. Fish and Wildlife Service 2007).

Similarly, in recent years, populations of Canada geese that nest and reside predominantly in the United States (i.e., **resident Canada geese**) have increased dramatically, and conflicts with people, including personal and public property damage, are increasing in many areas (Ankney 1996, U.S. Fish and Wildlife Service 2005a). Expanded hunting methods and the use of a conservation order for take of res-

ident Canada geese have been implemented to reduce numbers and influence the distribution of these geese throughout their range.

Future Directions

Management of migratory game bird harvests in the United States and Canada has changed dramatically over the past century. Federal governments have primary authority in regulating harvests, but elaborate systems have been developed to encourage suggestions and interactions with state, provincial, and territorial governments, as well as other stakeholders. Extensive monitoring programs have been developed to assess the status of many populations and their harvests. These systems have led to an annual process where managers work cooperatively to review available data and attempt to establish hunting regulations that result in harvest levels consistent with population management objectives.

A major goal of migratory game bird management has been to predict the influence of hunting regulations, and resulting harvests, on the future size of bird populations. Over time, this goal has led to a greater emphasis on the use of objective biological information in making management decisions. More recently, there has been explicit recognition that managers will need to contend with uncertainties about the status of bird populations and the consequences of harvest management actions. **Adaptive management approaches** can be used to explicitly account for (and work to reduce) these uncertainties, while trying to achieve management objectives. It seems likely the pursuit of improved understanding of the effects of harvest on migratory game bird populations will continue.

Measures of success in harvest management include greater agreement among managers and stakeholders on harvest management goals, and an improved understanding of the effectiveness and limitations of different management actions in achieving these goals. The recent focus on harvest management objectives, combined with declining trends in hunter participation, has led to a renewed emphasis on understanding and addressing the expectations and interests of migratory bird hunters (Enck and Ringelman 2006, Witter et al. 2006). As approaches toward harvest management of migratory game birds continue to evolve in North America, we expect future developments will include

1. greater focus and resolution of the **priorities and specific objectives** (both biological and sociological) of harvest management;
2. continued efforts to expand and refine the **accuracy and precision of monitoring** programs for priority species and populations (with debates over the spatial, temporal, and ecological scale of harvest management objectives helping drive the scale of monitoring efforts);

3. increased use of **mathematical models** to objectively drive harvest management decision-making processes (in relation to explicit, agreed-upon objectives);
4. increased emphasis on **reducing uncertainty** about important biological mechanisms that drive population dynamics, and the influence of harvest on these mechanisms, for key harvested populations; and
5. increased efforts to increase or at least stabilize declines in **hunter participation**, by incorporating human dimensions information directly into the development of harvest management strategies.

Meeting these challenges will require greater commitments of resources, communication, and cooperation among managers, at all governmental levels. However, the long history of migratory bird management in North America has helped set the stage for success in these efforts.

MANAGEMENT OF BIG GAME HARVESTS

In contrast to harvest management of most upland game and waterfowl populations, management of **big game harvest** is often more complex and contentious, primarily because of the ability of hunters to differentiate among gender and age classes before selecting an animal to harvest, and the variety of weapons used to harvest large mammals. Additional complicating factors include potential for extensive **damage** to private property (agricultural and horticultural depredations, wildlife–vehicle collisions) and **non-consumptive values** (viewing, “charismatic megafauna”). These factors hinder application of theoretical harvest strategies to practical harvest management, as does the difficulty of obtaining extensive, long-term data sets needed to apply theoretical harvest models (Langvatn and Loison 1999).

Management of large mammal populations is often viewed as a 4-step, linear process (Strickland et al. 1994): (1) **inventory** (identify current or potential population status), (2) **define goals and objectives** (identify desired population status), (3) **develop strategies to achieve objectives**, and (4) **evaluate** how well strategies met objectives. Given adequate quantitative data, the process is theoretically and intuitively quite simple. However, in practice, defining population goals and objectives and developing harvest strategies and regulations are extremely complex processes requiring continuous stakeholder input and involving sociopolitical influence. Further, obtaining adequate inventory information is often challenging because of financial and logistical constraints.

Inventory

The initial step in big-game harvest management typically involves estimating current population status, as well as biological capacity to produce and sustain a given species. For wildlife agencies, inventory should be based on geographi-

cal areas containing relatively discrete populations or groups of demographically similar populations, but smaller scale management programs will likely be constrained by land-ownership boundaries. These **management units** can be based on **geographic features** (e.g., watersheds, mountain ranges), political boundaries, or some combination thereof. **Political boundaries** are often more appropriate for areas with relatively homogenous habitats and species distributions (such as white-tailed deer in eastern North America), whereas geographic features better define annual ranges of migratory populations occupying diverse habitats in the West. Definition and refinement of appropriate boundaries are enhanced by research on seasonal ranges, migration patterns, and population responses to environmental factors. **Management units** or subdivisions used as hunt area boundaries should be readily distinguishable by hunters to avoid confusion, enhance compliance with legal requirements, and increase the probability that harvest strategies will be successful.

Depending on species and habitats, **inventories** may be designed to estimate population abundance (e.g., sightability surveys for elk; Samuel et al. 1992) or provide an index to population status (e.g., trend surveys), as well as to determine age and gender ratios (see Chapter 8, Volume 1). Agencies in western North America often conduct surveys from **aircraft** where habitats and congregation of animals on winter ranges enhance observation. Use of aircraft as a survey platform is less effective for relatively uncommon species (e.g., carnivores) or in areas typified by dense forest canopies or widely distributed animal populations (e.g., eastern white-tailed deer). In these situations, managers most often rely on indirect measures of population status. Rabe et al. (2002) reviewed survey methods for several big game species in western states and recommended that managers design surveys to directly **estimate population size**, incorporate **random sampling** methods (with habitat stratification as appropriate), and **estimate survival** of (at least) adult females and young. **Gender and age ratios** are important data, but should be used in concert with independent information regarding population status (Caughley 1974, 1977; McCullough 1994; but see Bender 2006).

Allocation of resources for inventory is a significant and important challenge; when prioritizing effort, managers should strive to collect accurate information for fewer populations rather than inaccurate information for many populations (Rabe et al. 2002). **Computer modeling** can be applied to estimate population status between periodic surveys or extrapolate to areas or populations that are not surveyed. However, managers must be acutely aware of the limitations and appropriate applications of computer modeling (White 2000a). Development of rigorous, statistically sound inventory programs is crucial to effective management, as well as defense of data and potential challenges (sometimes legal) to associated management actions. In addition to cost and

logistic considerations of aircraft-based surveys, managers and administrators must consider personnel safety when employing aerial surveys, particularly in mountainous terrain.

Harvest Surveys

Estimating harvest is an obvious component of any harvest system and harvest data are typically the most accurate and easily obtained information available to managers. Harvest data are important inputs to population models and calculations for determining future big game harvest strategies. At one extreme, **harvest surveys** may entail recording data for each deer killed on a hunting lease, whereas surveys conducted by wildlife agencies estimate harvest across multiple species, seasons, weapon types, and management units. Typical data collected include **number** of animals harvested by **gender and age** class (or a surrogate for age such as antler or horn characteristics), **hunter effort** (e.g., days hunted), **location** (e.g., management unit, county), **date** of harvest, and **weapon** used. Because harvest data are so important to assessing past strategies and predicting outcomes of proposed strategies, harvest surveys must be based on statistically sound procedures and applied at scales appropriate to the data collection.

Agencies apply a variety of **methods to estimate harvest**: check stations, mandatory checks of harvested animals, report cards, random mail or telephone surveys, toll-free telephone service (Rupp et al. 2000), and more recently, Internet-based reporting. There also has been a recent trend toward **mandatory reporting** (with multiple reporting tools) for all licensed big-game hunters in several states, in some cases to address concerns of constituents who questioned validity of sample-based survey results.

Methods that require hunters to physically present animals to management agency personnel provide opportunities for managers to collect measurements and biological samples, verify harvest information, and interact with hunters. However, these methods can be labor-intensive and expensive, do not provide a direct measure of hunter effort, and may be logistically challenging in jurisdictions with long seasons or multiple big-game seasons. Conversely, remote survey methods can be designed to economically estimate harvest statistics and precision with a sample-based approach, but may be more prone to bias or errors associated with distortion of reported information. Reporting errors and omissions can be reduced with toll-free telephone and Internet-based surveys by requiring legitimate answers to all survey questions before accepting reports. Regardless of techniques used, managers need to recognize and address potential reporting bias (e.g., **nonresponse**). Carpenter (2000) presented reviews and recommendations for harvest survey techniques.

Development of Harvest Strategies

Harvest theory for most big game species in the order Artiodactyla is generally based on the concepts of biological

carrying capacity (K) and density-dependent population growth (Caughley 1977, McCullough 1979), where population growth follows the logistic growth curve until reaching limitations imposed by habitat. As populations approach K, population growth declines to the point where losses (deaths, emigration) equal gains (births, immigration; i.e., $\lambda = 1$). **Density dependence** assumes that productivity decreases or mortality increases as resources (e.g., forage) become limited. Populations are most productive near the inflection point of the growth curve, approximately 50% of K (McCullough 1979; but see Macnab 1985), and this is the point at which harvest can be maximized. Big game species in the order Carnivora tend to be longer lived and less productive than ungulates. Therefore, harvest management for large carnivores must be adjusted to match population performance.

Unfortunately, determination of K for wild populations is very difficult and K often changes through time due to changes in habitat and weather, particularly in more variable environments such as the arid and semiarid West. For some species, managers can **monitor attributes** of populations or individuals (e.g., net recruitment, yearling body weight or antler size) to estimate population status relative to K. For example, managers in Georgia gauge relative white-tailed deer density based on main beam length of yearling bucks within broad habitat categories (Georgia Department of Natural Resources 2003). Other surrogate measures of animal density, such as parasite loads or vehicle collision rates, have been suggested as possible indices. Alternatively, estimates of K may be derived from appropriate measurements of ungulate effects on habitat, such as amount of browsing on important forage species, but actually estimating K with this approach requires extensive effort and an extraordinarily high level of understanding of system dynamics (see Chapters 16–18, Volume 1). More often, characteristics of vegetation or habitat condition are included as indices or objectives for population management.

Although **biological carrying capacity** is an intuitively attractive concept upon which to base harvest management, practical management of big game populations in most of North America is more likely to be based on **social carrying capacity (SCC)**. Social carrying capacity is determined by human tolerance for wildlife population levels, or perhaps more accurately, tolerance for damage, nuisance, or threats to human safety caused by wildlife. In many cases, SCC is well below biological carrying capacity, particularly in situations where large mammals congregate on or near private land where conflict with human interests is likely (e.g., winter ranges on private land used for livestock production, suburban areas). For example, McCaffery (1989) stated that deer density objectives based on farmer tolerance were approximately 22–30% of estimated biological carrying capacity in agricultural areas of Wisconsin.

Somewhat paradoxically, when SCC approximates K/2, managers may find themselves in a position to reach goals

of **maximum sustained yield**. However, when SCC is widely disparate from $K/2$, conflicts typically arise among hunters, wildlife agencies, agricultural interests, and other stakeholders. This is a common scenario in large mammal management and emphasizes the need to develop goals and objectives that are acceptable to the majority of stakeholders. Patterson et al. (2000) provided a thorough review of human dimensions and conflict resolution associated with wildlife management.

Management goals are typically broad, subjective statements about the desired future condition of a population. For example, the current goal statement for mule deer in Idaho is "Abundant mule deer occupying healthy habitats ensuring a rich recreational, cultural, and public heritage for current and future generations" (Idaho Department of Fish and Game 2008a:iv). Within the framework of such a goal, specific, measurable objectives are established to reach the goal. Goals and objectives, as well as subsequent strategies and regulations, must have wide public and political support for management programs to be successful.

Management objectives may include a variety of components ranging from population characteristics to measures of conflict (Table 33.4). The influence of SCC is emphasized by the fact that conflict management was the most frequently identified management objective for mule deer (see Table 33.4); conflict management is likely an even more frequent component of harvest management objectives for elk. Additional management objectives may include mortality rates, hunter success, hunter density, harvest density (no. of animals harvested/km²), and measures of hunter satisfaction. Objectives related to hunting opportunity may be fur-

ther subdivided among hunter groups (e.g., by weapon type or age).

Sideboards for objectives are initially limited by biological realities. For example, total population should not exceed K , some minimum number of animals is necessary to prevent extirpation, and a minimum ratio of males is necessary to ensure fertilization of females in polygynous species. Within these biological constraints, there are diverse arrays of potential management objectives that are essentially a matter of social desires. However, public wishes are rarely consistent across user groups and managers are often forced to act as mediators and develop objectives that provide a balance among **competing interests** (e.g., providing annual hunting opportunity while also providing opportunities to harvest mature males). As such, management tends to depart from the realm of biology and enter the realm of human dimensions.

Developing Regulations

Once management objectives have been determined, the next step is developing regulations that will achieve objectives, preferably within a specified timeframe. A wide variety of harvest regulations and season structures are applied across jurisdictions and species (Table 33.5). Local **tradition** and history often play important roles in determining existing and potential big-game harvest systems, which can inhibit development of alternative or innovative approaches.

Like management objectives, development of regulations is largely a matter of **social desire**. Managers are responsible for identifying appropriate harvest levels by gender and age class that will meet management objectives, but how and when those animals are harvested are not biological considerations. Thus, input from hunters, landowners, and other stakeholders is critical to establishing effective regulations. In this process, the manager's role is to provide technical expertise and information about anticipated effects of harvest strategies and regulations, but final recommendations should be based on public desires.

Regulations should be easily understood by hunters and **enforceable**. The concept of **fair chase** is integral to developing harvest regulations, but the definition of fair chase varies within and among hunters and nonhunters, across political boundaries, and over time. For example, use of bait and dogs to hunt deer are commonly accepted practices in some southeastern states, whereas these methods are shunned for deer (but accepted for black bear [*Ursus americanus*]) hunting in some western states.

Managers should be cognizant of traditions and social aspects of hunting when developing regulations because regulation changes may have unintended consequences. For example, to enhance hunting opportunity for mature bull elk, managers in western states often limit the number of permits available for mature bulls in specific management units. Unless a general-season opportunity for another component of

Table 33.4. Objectives applied to mule deer management in western states (USA) and provinces (Canada)

Management objective	Jurisdiction
Population trend	AK, AZ, ID, KS, MT, NE, NV, ND, SD, SK, TX, YK
Population abundance	AB, AZ, CO, ID, MT, ND, OR, SD, SK, TX, UT, WY
Preseason buck:doe ratio	ND, SD, SK, TX
Postseason buck:doe ratio	AB, AZ, CO, ID, MT, NE, NV, OR, TX, UT, WY
Buck age structure	AZ, KS, MT, NE, NV, SD, TX
Antler composition of harvested bucks (e.g., % 4-point)	AZ, ID, MT, NV, OR, TX
Fawn:doe ratio	AZ, MT, NV, SK, TX
Hunter days	AK, AB, AZ, ID, KS, NV, ND, SD, YK
Habitat considerations	AK, AB, AZ, CO, ID, KS, MT, NV, SD, TX, UT, WY
Min. or max. buck harvest	AK, MT, NE
Min. or max. doe harvest	NE
Conflict management	AB, CO, ID, KS, MT, NE, NV, ND, SD, SK, TX, UT, WY

Table 33.5. Components of hunting regulations for big game species and expected effects

Regulation	Characteristics
Unlimited entry "general season"	Maximizes participation, reduces success, control of harvest is low
Limited entry "permit seasons"	Restricts participation, increases success, maximizes control of harvest
Common opening date	Disperses hunters across more area
September season	Rutting males more vulnerable, nonrutting species less vulnerable
Firearms season in October	Deer in rut more vulnerable, animals more vulnerable if concentrated on winter ranges
Long season	Allows more opportunity for harvest, especially if weather conditions are favorable
Short season	Concentrates harvest and hunters, reduces differential vulnerability of gender or age in harvest
Weekend openings	More hunters participate on opening day
Weekday openings	May spread participation, decrease vulnerability
Either gender season	Increases harvest of younger males, encourages harvest of some females
Male only	Reduces survival of males, allows populations to respond to limiting factors other than hunting
Antler or horn restrictions	Hunter numbers may decline, reduces survival of targeted males, may increase illegal kill
Legal firearm or bow	Maximizes opportunity
Primitive weapons	Reduces opportunity and participation
Archery	Lowest opportunity

Modified from Strickland et al. (1994).

the population is made available (e.g., spike-only bull) in the same unit, this approach likely displaces hunters who traditionally hunted the area and may have done so for several generations. This kind of regulatory approach may have serious consequences for **hunter recruitment** and retention and epitomizes the trade-offs inherent in developing management objectives and specific harvest regulations.

In situations where human conflict with big game species is spatially or temporally localized, managers may be able to increase SCC (i.e., tolerance) by implementing harvest strategies designed to dissuade wildlife from occupying specific areas. For example, in Idaho managers have defined hunt-area boundaries that encompass only private land, or land in or immediately adjacent to agricultural production, and instituted seasons for antlerless deer and elk that coincide with periods of **crop depredation**. Such approaches can be effective in allowing landowners to help control large mammal conflict on their property, but effectiveness can be diminished if some landowners do not allow hunting and, thus, create refuges.

To provide a framework for evaluation, managers should attempt to implement regulations that are consistent and stable over long enough periods to encompass the normal variability of hunting conditions. Changing season length and timing annually will virtually eliminate the possibility of estimating effects of different season structures. Application of this concept is particularly important for seasons that account for the majority of harvest (e.g., general, centerfire-weapon seasons for deer or elk).

An often neglected aspect of the regulation process is **evaluation**. Few rigorous analyses of common harvest regulations have been conducted. If managers cannot reliably predict effects of changes in season length, timing, or other regulations, the regulation development process often breaks

down to subjective debate among hunters, managers, administrators, and others. **Retrospective analyses** of past harvest regulations (if consistent over time) is a first step to increasing understanding, but ideally, harvest regulations should be modified and monitored in an experimental framework to elucidate cause-and-effect relationships. Implementing large-scale experiments to examine big-game harvest regulations is logistically and politically challenging, but necessary for improving long-term harvest management. Few such large-scale experiments have occurred in North America, but Montana Fish, Wildlife and Parks (2001) recently adopted an adaptive harvest-management program for mule deer.

Deer

White-tailed deer are the most commonly hunted big game species in North America and mule deer are an iconic species of high importance in the West. However, because of extreme differences in habitat, populations, and distribution, current harvest management of the 2 species varies considerably. Whitetails are ubiquitous through most of their eastern range and have increased in recent decades to the point many harvest management programs are challenged by an inability to achieve adequate female harvest (Riley et al. 2003a). Conversely, **mule deer** populations in many western states are below desired levels and harvest occurs under relatively restrictive frameworks.

For both species, there appears to be an increasing proportion of hunters who desire the opportunity to harvest "mature" bucks. The recent development of some forms of **Quality Deer Management** (QDM) programs for white-tailed deer is representative of this trend. However, as applied by agency deer managers, QDM is a holistic management system consistent with the principles of sustained yield management. In short, QDM is designed to reduce deer pop-

ulations to ICC and reduce harvest of young bucks (sometimes through min. antler size regulations), thereby increasing buck:doe ratios and increasing average age of bucks. Quality deer management programs on private lands typically include various habitat enhancement practices designed to increase carrying capacity, and attract and hold deer on the managed property. Miller and Marchinton (1995) and Harper (undated) described guidelines and implementation of QDM.

From an agency perspective, it is important to place QDM in the appropriate context: eastern whitetail populations are generally considered **overabundant**, have been linked to numerous social and ecological problems (Decker 1987, deCalesta 1994), and exhibit extremely skewed gender ratios such that yearlings may account for $\geq 80\%$ of harvested bucks. Thus, whitetail managers do not consider QDM a form of **trophy management** (Harper undated), but rather a program to restore balance among whitetail populations, available habitat, and SCC. In contrast to most mule deer managers, Harper (undated) apparently defined mature bucks as 2.5 years and sometimes 3.5 years old. However, regardless of intent, there are likely hunters who confuse QDM for whitetails with simply producing greater opportunity to harvest large, mature (typically ≥ 4.5 -yr-old) mule deer bucks. Consequently, there are frequent requests for regulations that reduce mule deer buck harvest in some way to increase the proportion of mature bucks in the future. Implementing some form of minimum **antler point restriction** (APR), shortening seasons, or reducing hunter numbers, are among the most common suggestions.

Elk

In many ways, **elk** harvest management has come to parallel mule deer management in recent years. As elk populations generally increased through the 1970s to 1990s, managers shifted from relatively intensive harvest of predominately males to more aggressive female-harvest strategies in attempts to address agricultural depredations and balance elk populations with available habitat. However, at the same time, elk productivity in several areas was declining, possibly in a density-dependent response to high population levels. Concurrent reductions in hunter access or shifts in elk behavior contributed to difficulty in achieving female harvest. The combination of these factors led to situations where many managers faced large standing crops of unproductive elk. Decreased productivity and increased use of private land by elk in many areas have created significant management challenges. Current elk managers often implement harvest strategies designed to reduce harvest rates for bulls (particularly mature bulls) and optimize cow harvest spatially and temporally to reduce conflict with agricultural interests.

Harvest management for bull elk differs from most other species because of breeding chronology. Most elk breeding

occurs before 1 October and, thus, before the traditional time for most harvest seasons. Conversely, most mule deer breeding occurs in mid-November, after harvest seasons. Therefore, equal postseason male:female ratios may provide for substantially different ratios during breeding seasons.

ACCESS RESTRICTIONS FOR MANAGING ELK HARVEST

Much research effort has been directed to assessing **effects of roads and motorized vehicle access** on big game species behavior and harvest rates, particularly for elk (see Rowland et al. 2005). The vast majority of this literature has concluded elk avoid areas near roads open to motor vehicles and elk vulnerability to harvest increases with increases in road density (Rowland et al. 2005). A large array of landscape variables affect the magnitude of road effects on elk, but restricting motorized access is viewed as an effective management tool for reducing elk harvest rates and improving elk habitat.

As with other **regulations**, managing motorized access is not without controversy. Average age of hunters and use of off-highway vehicles are both increasing, and many hunters have grown accustomed to, and demand, varying levels of motorized access for at least part of their hunting efforts. Conversely, hunters using other forms of access (e.g., foot travel, livestock) may be bitterly opposed to excessive motorized access.

Most land is not under the management authority of wildlife agencies; therefore, **access** regulation is most often part of a cooperative management approach with state and federal land management agencies. Access management may include seasonal road closures during hunting seasons, limitations on the kind of vehicles allowed, or limitations on use (e.g., game retrieval allowances). Managers need to work with the appropriate land management agency during their travel-management planning process to incorporate access restrictions that match harvest management objectives. In at least one case, a state wildlife agency has attempted to regulate motorized access under their authority to regulate method of take. Thus, in several management units in Idaho, hunters may not use motorized vehicles to hunt (including travel to hunting areas) unless traveling on a road open to full-sized vehicles. This regulation is designed to reduce off-road motorized access, thereby reducing harvest rates and improving hunt quality.

Bear

Black bear (and **mountain lion** [*Puma concolor*]) harvest management is often challenging because managers must generally rely on indirect indices of population status. Harvest regulations are frequently designed to emphasize harvest of males and reduce harvest of females. Because of relatively long maternal dependence, females with young are typically excluded from harvest. Use of dogs or bait for hunting bears

are controversial, but may promote selective harvest of males. Litvaitis and Kane (1994) found that hunters using dogs and bait harvested males at greater rates than still or stalk hunters, but the difference in selectivity among methods in east-central Idaho has been small or nonexistent in recent years (Idaho Department of Fish and Game 2008b). A common practice is adjusting season length based on relationship of indices (e.g., gender and age composition of harvested animals) to established objectives. Because of behavioral changes associated with denning chronology (emergence timing, hunter access related to snowpack), harvest levels and (to some extent) gender ratios can be adjusted through season length and timing. In some cases, total or female harvest quotas are imposed to limit harvest. Harvest quotas can be effective tools, but considerable effort is required to implement and monitor effective quota systems.

Other Big Game Species

Ungulate species such as **mountain sheep** (*Ovis canadensis*, *O. dalli*), **mountain goat** (*Oreamnos americana*), and to some extent, **moose** (*Alces alces*) and **pronghorn antelope** (*Antilocapra americana*) tend to occur in more fragmented habitats, have more restricted ranges, or be more vulnerable to harvest than deer and elk in North America. Smaller, fragmented populations are more likely to exhibit population variability (possibly including local extirpation), so more conservative harvest strategies are appropriate. For some species, this may become increasingly important in the face of predicted climate change. Harvest for these species is typically regulated by limiting hunter numbers through some form of lottery or by implementing a **harvest quota** (harvest seasons end when a specified number of animals are killed).

Many jurisdictions have applied horn-size minimums for mountain sheep harvest (e.g., three-quarter curl, full curl) to ensure adequate numbers of mature rams are available for breeding, and promote the take of **trophy** rams. The recent trend, however, has been conversion to any-ram bag limits because harvest rates in most jurisdictions are very low and biologically insignificant, hunting opportunities are extremely rare, sublegal loss should be reduced, and there is an increasing belief that agencies need not dictate attributes of **hunt quality** (i.e., what constitutes a trophy). As demand for mountain sheep for translocation programs has declined in recent years, a few jurisdictions have implemented ewe harvest seasons when local populations exceeded objectives (Jorgenson et al. 1993).

Mountain goat populations typically display low productivity due to late primiparity and low recruitment (Festa-Bianchet et al. 1994, Côté and Festa-Bianchet 2001). Mountain goats are sexually dimorphic, but because differences are small and many hunters lack experience (hunting opportunities are very rare), either-gender bag limits prevail (but many jurisdictions provide educational materials and en-

courage harvest of males). Therefore, harvest objectives for native mountain goat populations are generally very conservative, usually <5% of estimated adults.

Population Responses to Hunting

White-Tailed Deer

In contrast to many big game species, the challenge for whitetail managers is increasingly finding ways to increase harvest, particularly for females. Because of heavily skewed gender ratios in many whitetail populations, minimum antler conformation regulations (points, spread) can be effective in increasing average age of bucks (e.g., increase age at harvest for most bucks from 1.5 yr to 2.5 yr).

Many whitetail populations occur in relative stable environments; therefore, principles of sustained yield management based on density dependence can be applied with more certainty than in more variable systems. Perhaps the greatest challenges for many whitetail managers derive from long traditions and staunchly held beliefs of constituent groups. That existence of a book titled *Deer Wars* (Frye 2006) attests to the impact of these influences.

Mule Deer

For **mule deer**, minimum APRs are generally effective at reducing buck mortality and increasing total buck:doe ratios, but have almost invariably failed to increase mature (≥ 4.5 -yr-old) buck:doe ratios or absolute number of mature bucks compared to areas without APRs (Erickson et al. 2003). Failures of minimum APR regulations have been attributed to unlawful or accidental take of sublegal bucks and the shift of hunting pressure to older-age-class bucks (Erickson et al. 2003).

Effects of altering **season length** are somewhat equivocal and are typically confounded by the concurrent change in season timing. In general, reducing the number of days available to hunt has a negligible effect on total harvest and tends to increase complaints regarding high hunter density. A potential cause for the lack of effect on harvest may be related to average **hunter effort**. For example, if the average hunter spends 4 days hunting, season length would likely have to be reduced to <4 days to effectively reduce hunter effort.

There are several effective means to reduce buck harvest and, thus, increase average buck age. Limiting **hunter numbers** is the most direct and effective means of reducing harvest, but also the most costly in terms of hunter opportunity, flexibility, and tradition; and perhaps ultimately, in terms of hunter recruitment and retention, and associated support of hunting. Further, limiting hunter numbers in some management units will very likely displace hunters to adjacent units, negatively affecting hunt quality and populations in those areas. Managing **hunter success** through regulation of season timing, weapon type, motorized access, or maxi-

mum APRs may allow managers to maintain opportunity while reducing harvest.

Some hunters and scientists have questioned whether high removal rates of mature bucks or maintenance of low buck:doe ratios may negatively influence genetic diversity or population productivity. Erickson et al. (2003) discussed effects on genetics and concluded potential for modification of genetic diversity through selective harvest of large males in free-ranging deer populations was very low. Extremely high harvest rates on males resulting in very low buck:doe ratios could reduce the diversity of male genetic material passed to offspring, but the long-term effects on genetic diversity are unknown.

Research to date has failed to demonstrate a biologically meaningful relationship between gender ratios and subsequent age ratios in mule deer (Erickson et al. 2003). Changes in mule deer buck:doe ratios were inconsequential to subsequent changes in fawn:doe ratios in Colorado (White et al. 2001, Bishop et al. 2005, Bergman et al. 2009). Further, there does not appear to be a threshold below which postseason mule deer buck ratios (within ranges observed in ID and MT) can be linked to reduced fawn production or winter survival (M. Hurley, Idaho Department of Fish and Game, unpublished data). Thus, altering harvest management to increase buck ratios for the explicit purpose of increasing productivity is unwarranted (White et al. 2001).

Effects of female harvest depend on adult female natural mortality rates and fawn recruitment to breeding age. Numerous recommendations and generalizations exist for allowable adult female harvest rates. These proposed rates may serve as guidelines, but managers need to determine appropriate harvest rates based on population-specific demographic data and population monitoring.

Elk

Noyes et al. (2005) demonstrated changes in breeding chronology, but not pregnancy rates, based on age of breeding bull elk (in a semi-free-ranging population) and theorized that higher bull ratios (and, thus, greater average age of bulls) could lead to increased calf survival and long-term fitness. However, research on free-ranging elk populations has not discerned important relationships between bull:cow ratios and subsequent calf:cow ratios (White et al. 2001, Bender et al. 2002, Hamlin and Ross 2002). Although direct effects of bull:cow ratios on calf recruitment have not been documented, some scientists suggest there may be long-term advantages to maintaining reasonable numbers of mature bulls in exploited populations (Noyes et al. 2005).

Several **regulatory approaches** have proven successful in increasing bull:cow ratios. Moving centerfire-weapon seasons out of the rut typically reduces bull harvest rates, particularly for mature bulls. Maximum APRs (i.e., spike-only) apparently contributed to increased bull ratios in northeast-

ern Oregon. Managers in Idaho were able to increase bull ratios by implementing a somewhat complex season system that was designed to attract hunters to hunt in seasons where they would be less successful for adult bulls because of weapons allowed, season timing, and bag limits (compared to centerfire-weapon, any-bull seasons; B. Compton, Idaho Department of Fish and Game, unpublished data). Similar to responses observed for mule deer, minimum APRs are not effective in increasing mature bull survival (Matthews and Coggins 1993, Biederbeck et al. 2001).

EFFECTS OF HUNTING ON ELK BEHAVIOR

Elk responses to hunting pressure have been a topic of high interest among hunters and managers. Archery and centerfire-weapon seasons during the rut, long season structures extending from August through January (or later), and motorized access have all received scrutiny. Human hunting activities that increase elk energy expenditures are generally viewed negatively, but effects to productivity or survival are difficult to quantify. Elk may move long distances in response to disturbance from hunters, but movements are obviously quite variable and depend on many factors.

Proffitt et al. (2009) found that changes in elk group size and movements during hunting season varied with habitat and gray wolf (*Canis lupus*) activity. Conner et al. (2001) showed that elk moved to private land (refuges) in response to opening of archery seasons, but the magnitude of response varied depending on topography and migration characteristics. Ability to achieve **antlerless harvest** for elk populations that cause conflict with agricultural interests has become problematic for many managers because elk have apparently become more prone to occupying areas that serve as refuges. Whether this behavior is learned, or results from swift response to environmental cues, is unknown. Regardless of the mechanism, Hamlin (2007) described movement patterns of elk (equipped with global positioning system units) and indicated that some elk are apparently very adept at avoiding harvest via use of refuge areas.

Bear

Trends in gender and age composition of harvested bears provide useful tools for monitoring effects of hunting on black bear populations. As harvest rates increase, average age of males declines and the proportion of females in the harvest increases. If females comprise $\leq 35\%$ of harvested bears and average age of males is ≥ 4 , the population is likely stable (Beecham and Rohlman 1994). However, changes in these characteristics may lag population changes. The combination of this lag in response time and low reproductive rates means managers generally need to manage to prevent overharvest. Refuge areas, either designated or resulting from limited hunter access or effectiveness, may serve as repopulation sources for more heavily hunted areas because young

males tend to travel long distances to find vacant habitat (Beecham and Rohlman 1994).

Other Big Game Species

Harvest of **bighorn sheep** rams in most jurisdictions tends to be quite conservative and ram:ewe ratios are maintained at relatively high levels. Until recently, manipulation of populations that were assumed to be near K took the form of capture for translocation to unoccupied habitats. Some bighorn sheep populations appear to be essentially limited by large-scale die-offs caused by respiratory disease and subsequent reduced productivity. In some cases, populations that formerly served as important translocation sources declined significantly after die-offs and remain at very low levels (Idaho Department of Fish and Game 2008c). Harvest can replace translocation removal, but because uncertainty exists about the role of density dependence in die-offs, the benefits of sustained ewe harvest are questionable.

Native **mountain goat** populations display little or no compensatory response to population reductions, making populations sensitive to female harvest (Kuck 1977, Côté et al. 2001). Conversely, some introduced populations have displayed higher productivity and compensatory responses to harvest (Swenson 1985). Harvest rates should be based on individual herd dynamics. In general harvest rates should be more conservative when periods between inventories increase, populations are small (50–100), or harvest of females is high (>25–30%).

Sustained Yield Management

As discussed previously, under assumptions of the logistic model for population growth, **maximum sustained yield** (MSY) is achieved when populations are at approximately $K/2$. Nine principles of sustained yield management have been identified (Box 33.10). Additionally, several theoretical models have been examined for maximizing yield over time, but most of these models require very accurate estimates of population size and performance and are, thus, perhaps better suited to smaller scale or very intensive management systems.

Threshold harvesting is the practice of harvesting only the number of animals (by gender and age class) exceeding a predetermined level necessary for maintaining a specific population size. Sæther et al. (2001) demonstrated that modeled threshold harvesting of moose in Scandinavia could provide greater sustained yield over the long term than **proportional** (removing a fixed proportion by gender and age class) or **fixed harvesting**. However, the predicted annual gain was modest and annual variation in permitted harvest was high, including years in which very little harvest would be permitted. From a practical standpoint, implementation of a threshold harvest strategy in North America would likely be socially and politically unacceptable.

BOX 33.10. PRINCIPLES INVOLVED IN BEHAVIOR OF EXPLOITED POPULATIONS

1. Any exploitation of an animal population reduces its abundance.
2. Below a certain exploitation level, populations may be resilient and increase their survival and/or production rates and growth rates to compensate for the individuals removed.
3. When populations are regulated through density-dependent processes, exploitation rates (up to some level) will tend to increase productivity and reduce natural mortality of the remaining individuals.
4. Exploitation rates above the maximum sustained yield level will reach a point at which extinction will occur if exploitation is continued.
5. Age composition and the number of animals remaining after exploitation are key factors in the dynamics of exploited animal populations.
6. If a population is stable in numbers, it must be reduced below that density to generate a harvestable surplus.
7. For each density to which a population is reduced, there is an appropriate sustained yield.
8. For each sustained yield, there are 2 density levels at which it can be harvested.
9. The maximum sustained yield may be harvested at only one density, about one-half of resource-based carrying capacity (McCullough 1979).

From Silliman and Gutsell (1958) and Caughley (1976).

For most North American big game populations, harvest strategies will be largely determined by accuracy of population data and population status relative to objectives. Where population size is well documented and managers can regulate hunter numbers, calculating harvest levels that will achieve objectives is a relatively straightforward process. Harvest will invariably fluctuate as a result of uncontrollable factors such as weather conditions during the hunt and other environmental stochasticity, but this framework allows for adjustment in future harvest levels that will continuously move the population toward objectives.

Care should be taken in developing harvest systems designed to achieve MSY. Management for MSY has received criticism and, for some species, been blamed for overharvest

(see Macnab 1985). In systems characterized by large variability in weather and habitat conditions, density-dependent population responses may be overshadowed by these stochastic processes, thus reducing appropriate yield levels. Small overestimates of population size or important demographic variables could lead to excessive harvest. When possible, harvest rates should be matched to current, empirical demographic characteristics of each population. If managers must resort to using average or published demographic data, initial management outcomes should be closely monitored or modeled to determine whether population response is consistent with assumed variable values.

Future Directions

Managers charged with management of big game harvest will face a number of challenges in future years. For most wildlife agencies, there appears to be a widening gap between revenue and expenses related to monitoring big game populations. For example, hourly rates for helicopter surveys in Idaho increased 35–50% over the last 5 years, whereas fees to hunt deer and elk increased approximately 10%. Further, availability of appropriate survey platforms (i.e., “bubble-type” helicopters) and pilots experienced in wildlife surveys have declined in some regions. Therefore, managers will likely need to be innovative in applying alternate population monitoring strategies and increase reliance on population modeling between survey efforts.

An old deer manager once described a rather axiomatic reality of mule deer management: “Deer go up, deer go down, hunters complain.” As **demographic** characteristics of hunters change (aging constituency), their motivations, expectations, and abilities also change. Public and hunter **attitudes** toward harvest management of big game, particularly with regard to carnivores, “trophy” management, and fair-chase issues, continue to change over time and generate considerable controversy. Shifts in **landownership** and management and loss of habitat have reduced hunter access and created de facto refuges in many areas. Harvest managers will need to monitor these important sociological changes and adapt harvest management strategies accordingly (Carpenter 2000).

Encroachment of human development on habitats occupied by large mammals (and vice versa) lead to increasing conflicts (damage and nuisance complaints), which may degrade public valuation and appreciation of these species, potentially reducing public support for management programs (Lutz et al. 2003). Thus, managers will need to be increasingly cognizant of implications of these scenarios, and incorporate conflict management in goal- and objective-setting processes for large mammal populations (e.g., Decker et al. 2005).

SUMMARY

Harvest management is constantly evolving, primarily because information on species biology is improving and the landscapes occupied by many wildlife species are continually changing. Additionally, public and hunter attitudes toward harvest management of big game continue to change over time and often generate substantial controversy. Anthropogenic effects on habitats occupied by large mammals can lead to increasing conflicts, which may reduce public appreciation of these species and possibly reduce public support for management programs (Lutz et al. 2003). As interest of nonhunters in wildlife populations and management increases, the importance of managing biologically defensible harvests also will increase. Gutiérrez (1994) argued that professionals are at a crossroads in game bird management and the direction taken will affect the future of game bird hunting. This observation most likely applies to all hunted species. Monitoring populations and harvests will become more critical to managers attempting to implement appropriate harvest regulations. Further, changing landscapes will alter at least some, and perhaps many, wildlife populations. Approaches to harvest management for some of these populations also will likely have to change. Managing the harvest will continue to be a difficult and sometimes frustrating effort for many wildlife professionals. Nevertheless, management decisions backed by sound science and rigorous data collection will alleviate some of these difficulties.

Identification and Management of Wildlife Damage

KURT C. VERCAUTEREN,
RICHARD A. DOLBEER,
AND ERIC M. GESE

INTRODUCTION

WILDLIFE MANAGEMENT is often thought of in terms of protecting, enhancing, and nurturing wildlife populations and the habitat needed for their well-being. However, many species at one time or another require management actions to reduce **conflicts** with people, other wildlife species, or other resources. Examples include an airport manager modifying habitats to reduce gull (family Laridae) activity near runways, a forester poisoning pocket gophers (family Geomyidae) to increase tree seedling survival in a reforestation project, or a biologist trapping an abundant predator or competing species to enhance survival of an endangered species. These are just a few of many examples (e.g., Fig. 34.1).

Wildlife-damage management is an increasingly important part of the wildlife profession because of expanding human populations and intensified land-use practices. Wildlife damage in the United States approximates **\$22 billion** (hereafter, all currency given in U.S. dollars) in losses annually (Conover 2002). Concurrent with this growing need to reduce wildlife–people conflicts, public attitudes, and environmental regulations are restricting use of some of the traditional tools of control such as toxicants and traps. Agencies and individuals carrying out control programs are being scrutinized more carefully to ensure that their actions are justified, environmentally safe, humane, and in the public interest. Thus, wildlife-damage management activities must be based on sound economic, ecological, and sociological principles, and carried out as positive, necessary components of overall wildlife management programs.

Wildlife-damage management programs can be thought of as having 4 parts: (1) problem definition, (2) ecology of the problem species, (3) management methods application, and (4) evaluation of management effort. **Problem definition** refers to determining the species and numbers of animals causing the problem, the amount of loss or nature of the conflict, and other biological and social factors related to the problem. **Ecology** of the problem species refers to understanding the life history of the species, especially in relation to the conflict. Management methods **application** refers to taking the information gained from parts 1 and 2 to develop an appropriate management program to alleviate or reduce the conflict. **Evaluation** of management effort permits an assessment of the reduction in damage in relation to costs and impact of the management effort on target and nontarget populations. Emphasis is often placed on **integrated** wildlife-damage management, whereby several damage management methods are used in combination and coor-

Fig. 34.1. Tupper; (F) photo by U.S. Animal and Plant Health Inspection Service, Wisconsin.

minated with other management practices being used at that time.

This chapter focuses on techniques related to parts 1 (problem definition) and 3 (management methods application). Each major section on groups of wildlife species has 3 parts: (1) **assessment** of damage, (2) **identification** of damage by individual species, and (3) management **techniques**, which is an elaboration of those listed under each of the species.

LEGAL REQUIREMENTS FOR MANAGEMENT

Capturing or Killing Wildlife Species

Before action is taken to control or manage wildlife damage, it is important to understand the **laws** regarding both target and nontarget wildlife species. The management of most wild mammals, reptiles, and amphibians in the United States and Canada is the responsibility of the individual states and provinces. The capture, possession, or killing of these vertebrates to control damage or nuisance situations is regulated by state or provincial laws. The main exception for mammals, reptiles, and amphibians in the United States regards endangered species that are regulated federally by the Endangered Species Act of 1973, as amended.

Migratory birds, in contrast to other vertebrates, are managed in North America at the federal level under the **Migratory Bird Treaty Act** of 1918. The treaty has been amended several times to include formal agreements between the United States, Canada, Mexico, Japan, and Russia. Federal regulations in the United States and Canada require that a depredation permit be obtained from the U.S. Fish and Wildlife Service and Canadian Wildlife Service, respectively, before any person may capture, kill, possess, or transport most migratory birds to control depredations. No federal permit is required merely to frighten or herd depredating birds other than endangered or threatened species, and bald (*Haliaeetus leucocephalus*) or golden eagles (*Aquila chrysaetos*).

Birds in the Families Phasianidae (e.g., grouse spp., ptarmigan spp., wild turkey [*Meleagris gallopavo*]) and Odontophoridae (quail spp.) are considered **nonmigratory** and are regulated at the state and provincial level. Furthermore, birds **introduced** to the United States, such as house sparrows (*Passer domesticus*), pigeons (*Columba livia*), European starlings (*Sturnus vulgaris*), and monk parakeets (*Myiopsitta monachus*), have **no federal protection**. Furthermore, a federal permit is not required in the United States to control yellow-headed (*Xanthocephalus xanthocephalus*), red-winged (*Agelaius phoeniceus*), tri-colored (*A. tricolor*), rusty (*Euphagus carolinus*), and Brewer's blackbirds (*E. cyanocephalus*), or cowbirds (*Molothrus* spp.), all grackles (*Quiscalus* spp.), crows (*Corvus* spp.), and magpies (*Pica pica*), when they are committing or about to commit depredations upon ornamental or shade trees, agricultural crops, livestock, or wildlife, or when they are concentrated in such numbers and manner as to constitute a health hazard. However, federal provisions do not circumvent any state laws or regulations, which may be more, but not less, restrictive.

In summary, anyone contemplating the capture or killing of a vertebrate species for damage management must first determine the state or provincial regulations for that species. For most birds and all federally endangered species, federal regulations also must be followed.

Environmental Protection Agency Registration of Chemicals

The **Federal Insecticide, Fungicide, and Rodenticide Act** (FIFRA), as amended, requires all pesticides and other chemicals used in controlling or repelling organisms in the United States to be approved and registered by the **Environmental Protection Agency** (EPA). The registration process is complex and costly, not only for new products, but also for previously registered products being reviewed and reevaluated (Goldman 1988). Products federally registered under Section

3 of FIFRA may not be available for use in all states, because many have their own registration requirements that might be more restrictive. Some products have Section 24C registrations that are valid only for specific states that have localized problems. Occasionally, products are available temporarily in specific localities for emergency use under Section 18 provisions of FIFRA. Finally, many of the registered compounds, such as vertebrate toxicants, are classified as **Restricted Use** pesticides. These products can only be used by, or under the direct supervision of, a certified pesticide applicator. Each state has its own certification requirements. Thus, anyone contemplating use of chemicals in wildlife-damage management must determine the status of, and requirements for use of, those chemicals in their particular locality. Jacobs (1994) provided a comprehensive list of registered chemicals for wildlife-damage management.

BIRD DAMAGE

Damage Assessment

Birds annually destroy many millions of dollars' worth of agricultural crops in North America. The greatest loss appears to be from **blackbirds** feeding on ripening corn (*Zea mays*); a survey in 1993 conservatively estimated a loss of 285,000 metric tons worth \$30 million in the United States (Wywiałowski 1996). Blackbird damage to sunflowers (*Helianthus* spp.) in the upper Great Plains states was estimated at \$8 million in 1980 (Hothem et al. 1988). Damage by various bird species, especially **European starlings**, to fruit crops such as cherries (*Prunus* spp.), grapes (*Vitis* spp.), and blueberries (*Vaccinium* spp.) can be severe in localized areas (Dolbeer et al. 1994a, Pimentel et al. 2000). **Fish-eating birds** can cause major losses at fish-rearing facilities and affect sport fishing (Glahn and Brugger 1995, Shwiff et al. 2008). Economic losses from bird **strikes to aircraft** are even more substan-

tial than losses to agriculture crops, with >\$600 million annually for U.S. civil aviation (Fig. 34.2; Dolbeer et al. 2009) and \$100 million for military aircraft (Conover et al. 1995).

Unlike most mammals, which are secretive when causing damage, birds are often highly visible and the damage is usually conspicuous. For these reasons, **subjective estimates** often overestimate losses as much as 10-fold (Weatherhead et al. 1982). Thus, **objective estimates** of bird damage to agricultural crops are important to accurately define the magnitude of the problem and to plan appropriate, cost-effective control actions (Dolbeer 1981).

To estimate losses to birds in agricultural crops, one must devise a sampling scheme to select the fields to be examined, and then determine the plants or areas to be measured in the selected fields (Stickley et al. 1979). For example, to objectively estimate the amount of blackbird damage in a ripening corn or sunflower field, the estimator should examine ≥ 10 locations randomly spaced in the field. If a field has 100 rows and is 300 m long, the estimator might walk staggered distances of 30 m along 10 randomly selected rows (e.g., 0–30 m in row 9, 31–60 m in row 20, etc.). In each 30-m length, the estimator should randomly select 10 plants and estimate the damage on each plant's ear or head. Bird damage to corn can be estimated by measuring the length of damage on the ear (De Grazio et al. 1969) or by visually estimating the percent loss of kernels (Woronecki et al. 1980) and converting to yield loss per hectare. Fruit loss can be estimated by counting the numbers of undamaged, pecked, and removed fruits per sampled branch (Tobin and Dolbeer 1987). Sprouting rice (*Oryza sativa*) removed by birds can be estimated by comparing plant density in exposed plots to that in adjacent plots with wire bird enclosures (Otis et al. 1983). The seeded surface area of sunflower heads destroyed by birds can be estimated with the aid of a plastic template (Fig. 34.3; Dolbeer 1975).

Fig. 34.2. Number of reported bird ($N = 87,416$) and terrestrial mammal ($N = 1,912$) strikes to civil aircraft, USA, 1990–2008. Additionally, 299 and 100 strikes involving bats and reptiles, respectively, were reported, for a total of 89,727 strikes by all species of wildlife. From Dolbeer et al. (2009).

Fig. 34.3. A template used for evaluating bird damage to sunflowers.

Losses of agricultural crops to birds can be estimated indirectly through avian bioenergetics. By estimating the number of birds of the depredating species feeding in an area, the percentage of the agricultural crop in the birds' diet, the caloric value of the crop, and the daily caloric requirements of the birds, one can project the total biomass of crop removed by birds on a daily or seasonal basis (Weatherhead et al. 1982, White et al. 1985, Peer et al. 2003).

Species Damage Identification

Most bird damage occurs during daylight hours, and the best way to identify the species causing damage is by observation. However, the presence of a bird species in a location receiving damage does not automatically prove the species guilty. As one example, large, conspicuous flocks of common grackles (*Q. quiscula*) in sprouting winter wheat (*Triticum aestivum*) fields were found, after careful observation and examination of stomach contents, to be eating corn residue from the previous crop. Smaller numbers of starlings were removing the germinating wheat seeds (Dolbeer et al. 1979). As another example, detailed research showed that great blue herons (*Ardea herodias*) at catfish farms primarily fed on diseased, dying fish (Glahn et al. 2002). Below, the characteristics of damage for various groups of birds are described.

Gulls

Several **gull species** have adapted to existing in proximity to people, taking advantage of landfills and open trash containers for food. For example, a survey in 1994 revealed $\geq 15,000$ nesting ring-billed (*Larus delawarensis*) and herring gulls (*L. argentatus*) in >30 colonies on roofs in U.S. cities on the Great Lakes (Dwyer et al. 1996). Besides causing structural damage to roofs, gulls increasingly cause problems in urban areas by begging for food, defacing property, and contaminating municipal water supplies (Belant 1997). Gulls are a serious threat to flight safety at airports (Fig. 34.4), repre-

Fig. 34.4. A Cessna 500 Citation crashed in a woodlot shortly after take-off from Wiley Post Airport, Oklahoma City, Oklahoma on 4 March 2008. Analysis of organic remains recovered from the aircraft by a U.S. Department of Agriculture biologist under the direction of the National Transportation Safety Board indicated the aircraft had struck at least one American white pelican (*Pelecanus erythrorhynchos*) during the initial climb (Dove et al. 2009). All 5 people on board were killed. Photo by U.S. Department of Agriculture.

senting 25% of the bird strikes with civil aircraft causing damage, 1990–2008 (Dolbeer et al. 2009). In rural areas, gulls sometimes feed on fruit crops and farm-reared fish and ducklings, and compete with threatened bird species for nest sites. **Control techniques** include habitat manipulation, screening and wire grids, mechanical and chemical frightening agents, toxicants, shooting, and nest destruction.

Blackbirds and European Starlings

The term “**blackbird**” loosely refers to a group of about 10 species of North American birds, the most common of which are the red-winged blackbird, common grackle, and brown-headed cowbird (*M. ater*). The European starling, a species introduced to North America in the late 1800s, superficially resembles native blackbirds and often associates with them. Together, blackbirds and European starlings constitute the most abundant group of birds in North America, comprising a combined population of >1 billion (Dolbeer 1990).

Blackbird damage to ripening corn, sunflowers, and rice can be serious (Dolbeer 1999, Blackwell et al. 2003). Much of this damage is done in late summer during the milk or dough stage of seed development. The seed contents of corn are removed, leaving the pericarp or outer coat on the cob. Blackbird damage to sprouting rice in the spring can be serious in localized areas.

Starling depredations on grain and fruit crops and impact on livestock health cost American agriculture an estimated \$800 million annually (Pimentel et al. 2000). Starlings foraging at feedlots in winter can cause substantial losses

(Glahn et al. 1983, Linz et al. 2007a) and disease concerns (LeJeune et al. 2008). Although contamination of livestock feed by starling feces is often a concern of farmers, a study indicated that this contamination did not interfere with food consumption or weight gain of cattle and pigs (Glahn and Stone 1984). Starlings can seriously damage fruit crops such as cherries and grapes (Dolbeer et al. 1994a).

Perhaps the greatest problem caused by blackbirds and starlings is their propensity to gather in large, nocturnal roosting **congregations**, especially in winter (Dolbeer et al. 1997). The noise, fecal accumulation, and general nuisance caused by millions of birds roosting together near human habitations can be significant (White et al. 1985). Roosting birds near airports can create a safety hazard for aircraft; and roost sites, if used for several years, can become focal points for the fungus that causes **histoplasmosis**, a respiratory disease in humans (Tosh et al. 1970). **Control techniques** include habitat manipulation, cultural practices (e.g., resistant crop varieties), proofing and screening, lasers, mechanical and chemical frightening agents, repellents, toxicants, trapping, and shooting.

Pigeons and House Sparrows

Pigeons and house sparrows are urban and farmyard birds whose droppings deface and deteriorate buildings. Around storage facilities, they consume and contaminate grain. Pigeons and sparrows may carry and spread various diseases to people, primarily through their droppings (Weber 1979). As occurs with congregations of blackbirds and starlings, droppings that are allowed to accumulate over several years may harbor spores of the fungus that causes **histoplasmosis**. Sparrows build bulky grass nests in buildings, drain spouts, and other sites, where they can cause fire hazards or other problems. Flocks of pigeons at airports pose a hazard to departing and arriving aircraft (Dolbeer and Wright 2009). **Control techniques** include screening and proofing, overhead wires, trapping, toxic and stupefying (alpha-chloralose) baits, shooting, and chemical reproductive inhibitors (pigeons).

Crows, Ravens, and Magpies

Crows, ravens (*C. corax*), and **magpies** are well-known predators of eggs and nestlings in other birds' nests. In certain situations, these species kill newborn lambs or other livestock by pecking their eyes (Larsen and Dietrich 1970). Magpies sometimes peck scabs on freshly branded cattle.

Crows occasionally damage agricultural crops such as sprouting and ripening corn, apples (*Malus* spp.), and pecans (*Carya illinoensis*). Most of this loss is localized and minor. Crow damage to apples can be distinguished from damage by smaller birds by the deep (up to 5 cm), triangular peck holes (Tobin et al. 1989). Tree-roosting congregations of crows in urban areas cause nuisance problems because of noise and feces (Gorenzel et al. 2002). **Control techniques** include

mechanical frightening devices, distress calls, lasers, shooting, trapping, chemical frightening agents, and toxicants.

Hérons, Egrets, and Cormorants

These species sometimes concentrate at fish-rearing facilities and cause substantial losses (Dorr and Taylor 2003). Salmon (*Salmo* spp.) smolts released in rivers in the north-eastern United States have suffered heavy depredation by **double-crested cormorants** (*Phalacrocorax auritus*). This species also has caused serious losses at commercial fishponds in the southern United States (Glahn and Brugger 1995). Nighttime observations are sometimes necessary to determine the depredating species, because some of these species will feed at night. **Control techniques** include habitat modification, screening, overhead wires, frightening devices, and shooting.

Raptors

The **raptors** most often implicated in predation problems with livestock (primarily poultry and game-farm fowl) are red-tailed hawks (*Buteo jamaicensis*), great-horned owls (*Bubo virginianus*), and goshawks (*Accipiter gentilis*; Hygnstrom and Craven 1994). Unlike mammalian predators, raptors usually kill only 1 bird/day. Raptor kills usually have bloody puncture wounds in the back and breast. **Owls** often remove the head. Raptors generally pluck birds, leaving piles of feathers. Plucked feathers that have small amounts of tissue clinging to their bases were pulled from a cold bird that probably died from other causes, and was simply scavenged by the raptor. If the base of a plucked feather is smooth and clean, the bird was plucked soon after dying. Raptors have large territories and are not numerous in any one area; therefore, the removal of 1 or 2 individuals will generally solve a problem.

Golden eagles occasionally kill livestock, primarily lambs (sheep) and kids (goats) on range. This predation can be locally severe in sheep-producing areas from New Mexico through Montana (Phillips and Blom 1988). Close examination is needed to identify an eagle kill. Eagles have 3 front toes opposing the hind toe, or hallux, on each foot. The front talons normally leave punctures about 2.5–5.0 cm apart in a straight line or small "V," and the wound from the hallux will be 10–15 cm from the middle toe. In contrast, mammalian predators usually leave 4 punctures or bruises from the canine teeth. Talon punctures are usually deeper than tooth punctures, and there is seldom any crushing of tissue between the talon punctures. If a puncture cannot be seen from the outside, one can skin the carcass to determine the pattern of talon or tooth marks. Often a young lamb is killed with a single puncture from the hallux in the top of the skull and punctures from the 3 opposing talons in the base of the skull or top of the neck (O'Gara 1978b, 1994).

Raptors, especially red-tailed hawks and kestrels (*Falco sparverius*), are frequently attracted to grassland areas at airports to hunt for rodents and large insects (Fig. 34.5; McIlveen et al. 1993, Garland et al. 2009). These birds can cause serious damage to aircraft when ingested into engines (Dolbeer and Wright 2009). **Control techniques** include proofing and screening, habitat modifications, modified herding techniques, frightening devices, trapping and translocation, and shooting.

Vultures

Population increases of turkey (*Cathartes aura*) and black (*Coragyps atratus*) vultures in North America since the 1970s have resulted in various conflicts with humans. Both species can cause **nuisance** problems when roosting on structures or in trees in urban areas (Avery et al. 2006). Because of their size (1.8–2.3 kg), vultures soaring near airports pose a threat to aircraft (Dolbeer and Wright 2009). Black vultures will prey on newborn livestock (Milleson et al. 2006).

Woodpeckers

Woodpeckers (family Picidae) at times cause damage to buildings with wood siding, especially cedar (*Cedrus* spp.) and redwood (*Sequoia sempervirens*; Fig. 34.6 [Evans et al. 1983, Belant et al. 1997]). The birds peck holes to locate insects, store acorns, or establish nest sites. They also damage utility poles (Tupper 2009). **Sapsuckers** (*Sphyrapicus* spp.) attack trees to feed on the sap, bark tissues, and insects attracted to the sap. This feeding can sometimes kill the tree or degrade the quality of wood for commercial purposes (Ostry and Nicholls 1976). Woodpeckers occasionally annoy homeowners by knocking on metal rain gutters and stovepipes to proclaim

Fig. 34.5. Red-tailed hawk utilizing grasslands between runways for capturing prey and, thus, creating potential for airstrikes. Photo by U.S. Animal and Plant Health Inspection Service, Minnesota.

their territories. **Control techniques** include exclusion, sticky repellents, live traps, snap traps, shooting, and frightening devices.

Ducks, Geese, and Sandhill Cranes

Damage by **ducks** (family Anatidae) and **cranes** (*Grus canadensis*) to swathed or maturing small-grain crops during the autumn harvest is a serious, localized problem in the northern Great Plains region (Knittle and Porter 1988). Damage occurs from direct consumption of grain and from trampling, which dislodges kernels from heads.

Canada (*Branta canadensis*) and snow **geese** (*Chen caerulescens*) grazing on winter wheat and rye (*Secale cereale*) crops

Fig. 34.6. Two acorn woodpeckers (*Melanerpes formicivorus*), shown feeding from acorn granaries. Buildings, fence posts, and utility poles have all been shown to provide ideal substrate for acorn woodpecker granaries. In places where human structures have encroached on woodpecker habitat, woodpeckers have found that human structures can provide excellent storage facilities for acorns. Photo by S. Tupper.

can reduce subsequent grain and vegetative yields (Kahl and Samson 1984, Conover 1988). Canada geese also can be a serious problem to sprouting soybeans (*Glycine max*) in spring and in fields of standing corn in autumn. Canada geese have adapted to suburban environments in the past 30 years, creating **nuisance** problems around parks and golf courses through grazing and defecation (Smith et al. 1999). Canada geese are the most serious bird **threat to aircraft** in North America (Dolbeer and Wright 2009, Dolbeer et al. 2009). **Control techniques** include mechanical frightening devices, lure crops, hunting, trapping and transplanting, overhead wires, capture with drug (alpha-chloralose), nest destruction, and chemical reproductive inhibitors (Canada geese).

Management Techniques

Modifications of Habitat and Cultural Practices

Habitat and cultural modifications can be implemented in many situations to make roosting, loafing, or feeding sites less attractive to birds. Although the initial investment of time and money may be high, these modifications often provide long-lasting relief. **Thinning** or pruning vegetation can cause roosting birds such as blackbirds and starlings to move, often increasing the commercial or aesthetic value of the trees or marsh at the same time (Micacchion and Townsend 1983, Leitch et al. 1997). Gull activity at airports can be reduced by **eliminating** standing **water** and prohibiting **landfills** in close proximity. The U.S. Federal Aviation Administration's policy is that solid-waste disposal sites should not be located within 3 km of any runway used by turbine-powered aircraft (Cleary and Dolbeer 2005).

The use of **lure or conservation crops**, where waterfowl or blackbirds are encouraged to feed, is sometimes cost-effective in reducing damage to nearby commercial fields of grain and sunflowers where **bird-frightening programs** are in place (Cummings et al. 1987, Linz et al. 2007b). **Bird-resistant cultivars** of corn, sunflower, and sorghum (*Sorghum* spp.) have shown effectiveness in reducing damage. For example, varieties of sweet and field corn with ears having long, thick husks difficult for blackbirds to penetrate sustain less damage than do varieties with ears having short, thin husks (Dolbeer et al. 1988a, 1995). Certain varieties of cherries are more vulnerable to bird damage than other varieties (Tobin et al. 1991). Use of endophytic fescue (*Festuca* spp.) turf grass may reduce grazing by geese (Washburn et al. 2007). Planting crops so that they do not mature unusually early or late also can reduce damage by blackbirds (Bridgeland and Caslick 1983). **Control of insects** in cornfields can make those fields less attractive to blackbirds and reduce subsequent damage to the corn crop (Dolbeer 1990).

Proofing and Screening

Plastic netting is cost-effective in excluding birds from individual fruit trees or high-value crops such as blueberries or grapes (Fuller-Perrine and Tobin 1993). **Netting** or wire screen-

ing can be used to exclude birds from rafter areas of airport hangars, undersides of bridges, fish hatcheries, and vent openings of buildings. **Ledges** on buildings designed or retrofitted at a 45° angle will prevent bird perching or nesting. Electrically **charged wires** or arrays of wire or **plastic spikes** installed on ledges and other sites can prevent birds from perching.

Parallel strands of monofilament lines or wires strung at 2.5–12-m intervals over ponds, landfills, and other structures can reduce gull activity (Blokpoel and Tessier 1984, Belant and Ickes 1996). **Monofilament lines** at 30–60-cm intervals repelled house sparrows from feeding sites (Agüero et al. 1991). Gulls and house sparrows are reluctant to fly through these strands even though the spacing is larger than their wingspans. **Overhead lines** also have excluded birds from fish hatcheries. Recommended spacing between wires is 60 cm for mergansers (*Mergus* spp.) and 30 cm for great blue herons (Salmon and Conte 1981). Heavy **plastic (polyvinyl chloride [PVC]) strips** hung from open doorways will help exclude starlings and other birds from buildings (Johnson and Glahn 1994).

Frightening Devices

Many **sonic and visual devices** are marketed, or home-made, to frighten birds. Birds usually **habituate** to such devices, no matter how effective they may be initially. Thus, 2 important rules are (1) never rely solely on one type of device for frightening, and (2) vary the use of devices by altering the timing and location of their use. The use of selected lethal control with **shotguns** can enhance the efficacy of frightening devices (Baxter and Allan 2008). Frightening devices are only as effective as the person deploying them.

Probably the most widely used frightening device is the **propane cannon**, which produces a loud explosion at timed intervals (Fig. 34.7; Washburn et al. 2006). Several models are marketed, including ones with automatic timers, remote activation, and rotating barrels. To be effective in frightening birds from crops, at least one cannon should be used for each 2 ha and the cannons should be moved every few days. An occasional shotgun patrol to reinforce the exploders is important (Dolbeer 1980), using either live ammunition or shell crackers. **Shell crackers**, fired from a 12-gauge shotgun, shoot a projectile that explodes 50–75 m away. Other pyrotechnic devices for frightening birds include **rockets and whistle bombs** (Cleary and Dolbeer 2005).

Recorded **alarm and distress calls** of birds broadcast over a speaker system sometimes work well to frighten birds (Bomford and O'Brien 1990). Some airports have speakers mounted on vehicles, from which personnel can broadcast these amplified calls for bird species frequently encountered during runway patrols. Shooting at birds with a shotgun is often used to reinforce the distress calls. These calls are commercially available for many bird species (Schmidt and Johnson 1983).

Fig. 34.7. Propane cannons used to alleviate damage caused by a variety of wildlife species. Photo by U.S. Animal and Plant Health Inspection Service, Wisconsin.

Ultrasonic devices emitting sounds with frequencies above the level of human hearing (20,000 Hz) are marketed for bird control in and around buildings. However, objective field tests have not demonstrated effectiveness of ultrasonic devices in repelling birds (Woronecki 1988). Most birds detect sounds in about the same range of frequencies as do humans.

Flags, helium-filled balloons with and without eyespots, and **hawk-kites** suspended from balloons or bamboo poles have been used with some success to repel birds from various sites (e.g., Conover 1984, Seamans 2002). **Mylar flags**, 15 cm \times 1.5 m in size, are used to keep geese from agricultural crops and gulls from loafing sites (Heinrich and Craven 1990, Belant and Ickes 1997); 10 flags/4 ha are recommended. Reflecting tape made of Mylar, strung in parallel lines at 3–7-m intervals, reduced blackbird numbers in agricultural fields (Dolbeer et al. 1986). Dead vulture (*Cathartes aura*, *Coragyps atratus*) and crow effigies suspended from structures or trees have caused abandonment of vulture and crow roosts (Seamans 2004, Avery et al. 2008b). **Inflatable human effigies** have been used to disperse cormorants from aquaculture facilities (Stickley et al. 1995). **Lasers** have been effective in dispersing Canada geese, cormorants, crows, and other species from nighttime roosting sites (Blackwell et al. 2002, Gorenzel et al. 2002). **Trained dogs and birds of prey** (falconry) are sometimes used at airports, landfills, and other sites to disperse various bird species (Cleary and Dolbeer 2005).

Blackbird roosts containing up to several million birds can be moved by use of a combination of devices, particularly recorded distress calls, shell crackers, rockets, and propane cannons (Mott 1980). **Strobe lights** placed in the roost also are helpful. The operation should begin before sunset, when the first birds arrive, and end at dark. People with shotguns and shell crackers should be stationed on the prime-

ter of the roost to intercept flight lines as they enter the roost. Three to five nights of harassment may be required to achieve complete dispersal. If not done as a part of the dispersal program, the habitat of the roost should be altered (e.g., tree thinning) after dispersal is achieved to discourage the roost from reforming. **Compressed air** has been used to disperse starling roosts in urban areas where loud, explosive noises were unacceptable (White et al. 2005).

Repellents

Birds have a poor sense of smell and taste in general, and repellents based on these senses are usually not effective (Rogers 1974, Belant et al. 1998b). For example, naphthalene crystals, although registered as an **odor repellent** for starlings, pigeons, and house sparrows in indoor roosts, have not been effective in field trials (Dolbeer et al. 1988b). **Taste repellents** used as seed treatments to prevent consumption of germinating seeds also are of questionable value (Heisterberg 1983).

In contrast, chemicals that produce illness or adverse physiological response upon ingestion (i.e., **conditioned aversion**) appear to work well as bird repellents (Rogers 1974). Methiocarb, a carbamate insecticide, is a condition-aversive repellent that has been used as a seed treatment for corn (applied as a powder to the seed at planting) and as a spray treatment for ripening cherries and blueberries (Dolbeer et al. 1994a). Another condition-aversive repellent, anthraquinone, has shown effectiveness in repelling geese from feeding on turf (Dolbeer et al. 1998, Blackwell et al. 1999). Formulations **containing methyl anthranilate**, a chemical that irritates the trigeminal nerve in birds, has had some success as a repellent (Belant et al. 1995).

Traps

European starlings and certain blackbird species often can be captured in **decoy traps**. A decoy trap is a large (e.g., 6 \times 6 \times 1.8-m) poultry-wire or net enclosure containing 5–20 decoy birds, food, water, and perches. Birds enter the trap by folding their wings and dropping through an opening (0.6 \times 1.2 m) in the cage top covered with 5-cm \times 10-cm welded wire to reach the food (cracked corn, millet) below. Decoy traps have been used to reduce local populations of starlings near cherry orchards (Bogatich 1967), to remove cowbirds from the nesting area of the endangered Kirtland's warbler (*Dendroica kirtlandii*; Kelly and DeCapita 1982), and to capture blackbirds for banding and research purposes. Pigeons and house sparrows can be captured in various **walk-in or funnel traps** (Corrigan 1989). **Mist nets** can be used to remove house sparrows around barns and small farm plots (Plesser et al. 1983).

Various trapping techniques are used to capture raptors, including **bal-chatri traps**, harnessed pigeons, **Swedish goshawk traps**, **bow nets**, and **padded leg-hold traps** (Bloom 1987). Raptors often become wary to one trapping technique,

requiring the use of 2 or 3 different techniques before successfully capturing some birds. Golden eagles preying on livestock can be captured for translocation with a **net gun** fired from a helicopter (O'Gara and Getz 1986).

Shooting

Shooting can be effective in reducing local populations of depredating or hazardous birds (Dolbeer et al. 1993). For example, a skilled shooter with an air rifle (pellet gun) can efficiently remove pigeons roosting and nesting inside buildings. For large populations of flocking birds, shooting may have little impact on the overall population (Dolbeer 1998), but can enhance efforts to repel birds from areas needing protection (Dolbeer et al. 2003, Baxter and Allan 2008, Taylor and Strickland 2008). This concept has been promoted in Wisconsin through a hunter referral program in which farmers allow goose hunters to shoot in agricultural fields experiencing chronic damage (Heinrich and Craven 1987).

Reproductive Control

Development of effective methods for reducing populations of overabundant nuisance bird species using contraception has been difficult to implement because of the lack of a safe, approved **avian contraceptive**. Since 2005, however, nicarbazin has received regulatory approval in the United States for use as a bait-delivered means to decrease hatchability of resident Canada goose and feral pigeon eggs (Bynum et al. 2007, Avery et al. 2008a). As with toxicants (discussed below), the challenge is delivering the proper dosage of bait to the target population. **Egg oiling** is another technique to inhibit hatching in Canada geese and gull populations (Cumming et al. 1997, Blackwell et al. 2000).

Toxicants and Capture Agents

The use of **toxic baits** to kill pest birds without harming nontarget organisms requires patience and a thorough understanding of the habits and food preferences of the target species. Prebaiting for several days with untreated bait is critical to enhance bait acceptance, to assess the amount of toxic bait to be used, and to assess possible nontarget hazards. Other nearby sources of preferred food should be restricted as much as possible during the prebait period. Strict control must be maintained over the toxic bait. Dead birds should be collected at least daily and buried in an approved location.

DRC-1339 is an EPA-registered toxicant incorporated into poultry pellets and marketed as Starlicide Complete® (Earth City Resources, Bridgeton, MO) for killing starlings at feedlots and poultry yards. DRC-1339, incorporated into bread baits, also is registered for killing certain gull species that compete with threatened bird species for nest sites (Seamans and Belant 1999). DRC-1339 affects the renal and circulatory systems, killing the bird 24–72 hours after ingestion.

Avitrol® is an EPA-registered frightening agent. The active ingredient, 4-aminopyridine, when ingested in small doses, causes the affected bird to emit distress calls while flying in erratic circles. The affected bird usually dies within 0.5 hours, but its initial behavior can act to frighten other birds away. Avitrol is registered for use on pigeons, gulls, house sparrows, starlings, and blackbirds around structures and nesting and roosting sites; for European starlings in feedlots; for gulls at airports; and for blackbirds in corn and sunflower fields. Avitrol-treated bait is usually diluted 1:10 or 1:99 with untreated bait so that only a portion of the birds feeding is affected (Woronecki et al. 1979).

Alpha-chloralose is a drug that can be mixed with corn or bread baits to immobilize and capture nuisance waterfowl, coots (*Fulica* spp.), and pigeons. Birds typically become immobilized 30 minutes after ingesting bait and fully recover 4–24 hours later (Woronecki et al. 1992). Alpha-chloralose is restricted by the U.S. Food and Drug Administration for use by biologists of Wildlife Services, U.S. Department of Agriculture (Belant et al. 1999).

UNGULATES

Damage Assessment

In North America, ungulates associated with damage to resources are typically members of the **deer** (Cervidae) and **swine** (Suidae) **families**. They include native species such as white-tailed deer (*Odocoileus virginianus*), mule deer (*O. hemionus*), and Rocky Mountain elk (*Cervus canadensis nelsoni*), as well as introduced species like fallow deer (*Dama dama*), red deer (*C. e. barbarus*), feral swine (*Sus scrofa*), and feral goats (*Capra hircus*). Populations of some species of ungulates, primarily white-tailed deer (Côté et al. 2004), elk (Bradford and Hobbs 2008), and feral swine (Gipson et al. 1998, Ditchkoff and West 2007), have been increasing steadily in recent decades. **Overabundant populations** of ungulates commonly cause a variety of types of damage at local, regional, and landscape scales. Ungulates damage plants in natural, agricultural, forestry, and urban settings, resulting in losses in billions of dollars each year (Fig. 34.8; Conover 2002). Ungulates also can transmit diseases to livestock and humans and threaten human safety when involved in collisions with vehicles—including airplanes. Repair costs associated with **deer-vehicle collisions** exceed \$1.6 billion annually (Conover 2002).

Cervids feed on various agricultural crops, especially soybeans, corn (see Fig. 34.8B), and alfalfa (*Medicago* spp.). Yield reductions in soybean fields are most severe when feeding occurs during the first week of sprouting (deCalesta and Schwendeman 1978), and corn yield is affected most when feeding occurs during the silking-tasseling stage (Hygnstrom et al. 1991). When food-stressed, cervids also may feed on and contaminate stored crops, imposing risk for disease transmission to livestock (VerCauteren et al. 2003b).

Fig. 34.8. Urban and rural damage caused by ungulates includes (A) deer browse resulting in deformation of individual trees by browsing, (B) crop damage by deer, (C) rooting by feral swine, and (D) stripping of bark through antler rubbing by elk. (A) Photo by S. Hygnstrom; (B) photo by G. Clements; (C) photo by T. Campbell; (D) photo by G. Clements.

Furthermore, increasing ungulate densities around stored feed increases the potential for disease transmission within and among species.

Cervids damage fruit and ornamental trees, as well as trees planted for timber production, by browsing (see Fig. 34.8A) and antler-rubbing (see Fig. 34.8D; Maas-Hebner et al. 2005). **Browsing** buds of fruit trees during the first year following planting has the greatest effect on fruit production; thus, this is the most important time to exclude deer (i.e., Mower et al. 1997). Similar browsing on nursery plants and in Christmas-tree plantations can diminish market values (Scott and Townsend 1985). Browsing of hardwood saplings and young Douglas-fir (*Pseudotsuga menziesii*) trees in regenerating forests can result in long-term effects (i.e., Horsley et al. 2003), including reduced growth rates, misshapen trees, and even plantation failures. **Antler-rubbing**, to remove velvet and hone sparring skills for the mating season (rut), can damage or kill trees. On larger spatial scales, overabundant populations of cervids can have deleterious effects on entire biotic communities (deCalesta 1994, Waller and Alverson 1997, Wisdom et al. 2006).

Feral swine include escaped domestic swine that have reverted to living in the wild and exotic wild boar that were introduced, as well as hybrids of the two (Mungall 2000). Annual costs associated with feral swine damage alone were estimated at \$1.5 billion (Pimentel et al. 2005). Unlike other ungulates that are strictly herbivorous, feral swine are omnivorous. Feral swine consume mast and seedlings, thereby affecting forest regeneration. **Rooting** by feral swine accel-

erates erosion and facilitates the spread of exotic plant species that thrive in disturbed environments (Seward et al. 2004). Biological, physical, and chemical properties of soil also can be altered through rooting and defecation (Moody and Jones 2000). Besides being destructive to vegetation, feral swine can be predatory and pursue wildlife (Roythe 1995, Seward et al. 2004) and domestic animals (Choquenot et al. 1997). Feral swine are effectual reservoirs of an array of diseases (i.e., Williams and Barker 2001, Meng et al. 2009) that could be transmitted to domestic swineherds through interactions that have been documented to occur between wild and domestic populations (Wyckoff et al. 2005). Feral swine also wallow in and around water sources, thereby increasing potential for disease contamination (Atwill et al. 1997, Jay et al. 2007).

Species Damage Identification

Cervids

Identification of cervid damage is not difficult, because the culprits are often observed causing damage. In addition, their **tracks** are readily identifiable. Cervids lack upper incisors and, therefore, leave a rough, shredded break on the twigs and stems they browse. Vegetation fed upon by rodents and lagomorphs, however, shows a neat, sharp-cut edge. Evidence of browsing damage higher than rodents or lagomorphs can reach also is indicative of cervid damage (taking into account that these smaller animals can cause damage higher on vegetation when standing on snow). **Mule and white-tailed deer** damage typically occurs from ground level to

1.8 m and they seldom browse on branches >2.5 cm in diameter. **Moose** (*Alces alces*) and **elk** damage can reach 3 m in height and they will use their incisors to scrape the bark of aspen (*Populus tremuloides*) trees. In the autumn, male cervids rub the velvet from their antlers, often removing tree bark in the process. Scarring is generally confined to the trunk up to 1 m high for mule and white-tailed deer and up to 2 m for elk.

Feral Swine

Rooting by feral swine is readily visible, because they turn over soil in search of roots and tubers, and in the process cause damage to yards, pastureland, crops, and native habitats. Depending on the number of swine present, rooted areas can exceed an acre (0.40 ha) in size and damage can be several feet deep. **Mud-covered rubs** on nearby trees and power poles (see Fig. 34.8C) are common indicators of swine activity. Predation by feral swine can be difficult to ascertain because complete consumption often occurs. Identification must often be made by locating other signs of swine presence such as tracks, rubs, or rooting.

Management Techniques

The public generally approves of **nonlethal** management techniques, especially in urban settings, where traditional hunting may not be considered safe, yet damage levels are high. Although population reduction through lethal means is often necessary to reduce ungulate damage to tolerable levels, many nonlethal strategies may have a role in a comprehensive ungulate management program. However, limited effectiveness and high cost of nonlethal strategies frequently make them economically impractical, even when used in conjunction with lethal strategies. Frequently, the efficacy of nonlethal techniques is directly correlated to the level of motivation of the targeted individuals. For example, a simple frightening device employing sound and lights or a single strand of electric fence may be a sufficient deterrent to minimize deer use of a minimally desired resource; however, strongly motivated deer can breach a 2.1-m-high woven-wire mesh fence. The management technique chosen for a scenario under one level of motivation may have a different degree of success in dissimilar scenarios. Thus, the

level of motivation of the targeted individuals must be considered prior to implementation of any nonlethal technique.

Habitat and Food Modifications

Reduction of permanent cover in a localized area can effectively manage damage by reducing ungulate carrying capacity, though it also destroys habitat important to other wildlife. Selecting plants that are less palatable or are resistant to ungulate damage can minimize ungulate damage to plantings in urban areas. Craven and Hygnstrom (1994) present a list of common plants and their susceptibility to damage. Agricultural crops should be harvested as early as possible to minimize the time during which they are susceptible to damage. **Lure crops** can be used to draw ungulates away from more valuable crops (Schwab et al. 2001), but providing this additional forage could lead to higher densities, resulting in increased damage. Similarly, feeding and baiting ungulates ultimately leads to increased local damage. **Supplemental feeding** can result in higher reproductive and survival rates, and lead to congregated and tame populations (Doenier et al. 1997). It also makes the ungulate population more susceptible to diseases (Davidson and Nettles 1997, Garner 2001), some of which can be spread to other species of wildlife and livestock.

Exclusion

Frequently, the only long-term, nonlethal method to effectively minimize ungulate damage is **fencing**. Many fence designs are available (Fig. 34.9), although an effective yet low-cost design has yet to be perfected. Fencing provides protection in 1 of 3 ways: (1) as a physical barrier, (2) as a psychological barrier, or (3) as a combination of 1 and 2. The standard deer fence, a 2.4-m-high woven-wire fence, is a physical barrier and greatly reduces the possibility of an animal passing through, over, or under it. Conversely, a single- or double-strand electric poly-tape fence acts as a psychological barrier through aversive conditioning. **Conditioning** occurs when an animal attempts to breach the fence and receives a powerful electric shock. This training can be expedited with the use of bait such as peanut butter applied directly to the fence (i.e., Porter 1983). Some fences, such as a 2.4-m-high, 11-strand high-tensile electric fence, increase the efficacy of the barrier by incorporating both concepts.

Fig. 34.9. Examples of fence types for ungulate control: (A) multistrand, electrified high-tensile steel, (B) 2-strand, electrified poly-rope for hogs, (C) high, woven-wire mesh, (D) high polypropylene mesh, (E) baited, electrified poly-tape, and (F) slanted, electrified poly-rope. (A) Photo by M. Lavelle; (B) photo by D. Hewitt; (C) photo by J. White; (D) photo by J. White; (E) photo by U.S. Animal and Plant Health Inspection Service, Wisconsin; (F) photo by K. VerCauteren.

Broad classes of **fence designs** include woven-wire mesh, high-tensile, poly-mesh, and electrified poly-tape or poly-rope (VerCauteren et al. 2006a; Table 34.1). Variables to be considered when deciding on the most appropriate fence design to construct include (1) level of protection desired, (2) seasonality of the resource being protected, (3) physical ability of the target species, (4) motivation to breach, (5) behavioral characteristics, (6) costs associated with constructing and maintaining the fence, (7) longevity of the fence, and (8) possible negative effects of erecting a fence (VerCauteren et al. 2006c). While fencing may have the potential to eliminate damage, its expense may make it cost-prohibitive, especially in situations where the value of the resource being protected is low and the area to be protected is large (VerCauteren et al. 2006b), such as with many agricultural crops. In addition, size, shape, and perimeter of the area influence the amount of fencing required and, thus, the cost (Conover 2002).

Alternatives to fencing that provide protection for individual trees or tree parts include: **tree cylinders**, **tree wraps**, and **bud caps** (deCalesta and Witmer 1994). These devices reduce damage by preventing access to the roots, stems, vegetation, and growing points until plants are no longer highly vulnerable to serious damage. One benefit of these damage reduction tools is that they do not completely exclude animals from large portions of their habitat; thus, they may be preferred in some settings. One must consider number of plants (usually tree seedlings) and size of area being protected, because at \$5/seedling protected (Kimball et al. 2008), individual plant protection expenses may approach the expense of fencing. Chicken-wire **cylinders**, photodegradable polypropylene cylinders, and a variety of flexible mesh **sleeves** can effectively protect seedlings (i.e.,

Taylor et al. 2006). Protective cylinders provide protection only until the terminal bud protrudes from the top of the cylinder, becoming accessible to ungulates. It may be advantageous to apply bud caps at this time.

A variety of fence designs have been used to minimize damage caused by feral swine. Sturdy wire mesh is reliable and effective as long as it is tight to the ground. Fence also must be rigid enough to deter swine from climbing over it. An evaluation of electrified poly-rope for excluding feral swine proved promising (see Fig. 34.9B; Reidy et al. 2008). Traditional 0.86-m rigid-wire **hog panels** are quite effective in controlling the movements of feral hogs. Similar to cervids, feral swine (when not especially motivated) can be deterred simply by adding a single strand of **electrified wire** offset from an existing fence (Hone and Atkinson 1983).

The weakest link in a potentially effective fence is most often the gate, which must be closed to be effective. Considerable research into alternatives to traditional gates for deer has been conducted with varying results (Fig. 34.10). **Automatically closing gates** (see Fig. 34.9A and D; VerCauteren et al. 2009), **electrified mats** (see Fig. 34.9C; Seamans and Helon 2008), and **active** (see Fig. 34.9B; VerCauteren et al. 2009) and **passive cattle-guard type devices** (i.e., Peterson et al. 2003b) have been evaluated with mixed success.

Frightening and Hazing

Propane cannons, flashing **lights**, shell crackers, and other **sonic devices** used near a resource can provide temporary relief from ungulate damage (Gilsdorf et al. 2002). Ungulates adjust or **habituate** to frightening devices rather quickly, and these devices are generally not effective for an entire growing season. Recent research has evaluated the efficacy of **animal-activated** frightening devices, with mixed results

Table 34.1. Fence types including cost, height, efficacy level, longevity, and level of required maintenance

Fence type	Cost	Height (m)	Efficacy	Longevity (yr)	Maintenance
Woven-wire mesh	>6.00	3.0	High	30–40	Low
Chain link	>6.00	2.4	Moderate–high	30–40	Low
Polypropylene mesh	4.00–6.00	2.3	Moderate–high	10–20	Medium
Electrified poly-rope (9-strand)	4.00–6.00	1.8	Moderate	20–30	Medium
Welded-wire mesh	4.00–6.00	3.0	High	20–30	Low
Plastic snow fence	4.00–6.00	2.1	Moderate–high	5–10	Medium
Modified woven-wire with 2-strand barbed-wire	4.00–6.00	2.4	Moderate–high	20–30	Medium
Modified woven-wire with 5-strand high-tensile	4.00–6.00	2.4	Moderate–high	20–30	Medium
Barbed-wire (18-strand)	2.00–4.00	2.4	Moderate	20–30	Medium
Nonelectrified 15-strand high tensile	0.50–2.00	2.4	Moderate	20–30	Medium
New Hampshire (electrified, offset 3-strand)	0.50–2.00	1.0	Low	20–30	High
Slanted 7-strand electrified high-tensile	0.50–2.00	1.5	Moderate	20–30	High
Penn State 5 (5-strand electrified high-tensile)	0.50–2.00	1.1	Moderate	20–30	High
Electrified 2-strand poly-tape	0.50–2.00	0.9	Low	5–10	High
Nonelectrified 8-strand high-tensile	0.50–2.00	1.8	Low	20–30	High
Peanut butter–baited electric	0.50	1.1	Low	10–20	High

(i.e., Belant et al. 1998a; Gilsdorf et al. 2004a, b; Beringer et al. 2003). **Infrared beams** or passive infrared sensors activate these new devices when triggered by ungulate-sized animals. Beringer et al. (2003) significantly reduced soybean damage with a deer-activated system that randomly played **sounds** chosen to frighten ungulates (i.e., aggressive dogs, barrages of gunshots, ungulate distress calls) and included an illuminated **human effigy**. Conversely, this same device minus the illuminated effigy was insufficient at protecting corn during the silking–tasseling stage from deer (Gilsdorf et al. 2004b).

Lasers, which are effective in dispersing some bird species, also are ineffective in dissuading deer (VerCauteren et al. 2003a, 2006a). A frightening device that provided physical stimuli deterred deer from using cattle feed (Fig. 34.11; Seward et al. 2007), suggesting that targeting the sense of touch can improve efficacy. Studies directed at using frightening devices to alleviate feral swine damage are lacking; thus, none can be recommended.

Dogs as a Deterrent

Dogs within the perimeter of an invisible fencing system that surrounds agricultural crops have been shown to reduce damage by deer (Beringer et al. 1994) and several producers are actively using dogs to protect orchards and annual crops (Curtis and Rieckenberg 2005, VerCauteren et al. 2005b). Dog selection, training, and care are important components to the success of this strategy. The use of dogs also has the potential to reduce transmission of disease in wild ungulates to livestock (VerCauteren et al. 2008).

Repellents

A variety of repellents has been evaluated to assess their ability to reduce ungulate damage (El Hani and Conover

1997, Wagner and Nolte 2001, MacGowan et al. 2004). There are 3 general categories of repellents: (1) odor, (2) contact, and (3) systemic. **Odor repellents** are ostensibly designed to repel animals from an area and either mimic predator odors (e.g., human or coyote [*Canis latrans*] hair) or are repugnant (e.g., mothballs, bone tar). Apfelbach et al. (2005) discussed the variability in efficacy of predator odors on mammalian prey species. Recent research suggests that so-called “**fear repellents**” (i.e., those associated with predator odors) reduce browsing by altering the palatability of the plant (Kimball and Nolte 2006). **Contact repellents** are applied directly to the targeted resource and are later ingested by the offending animal (i.e., Kimball et al. 2008). They function by

Fig. 34.11. Animal-activated frightening devices used to reduce disease-transmission risks between deer and livestock are being designed and evaluated. Photo by N. Seward.

changing the hedonic quality of the treated food item and/or causing illness (aversive conditioning). **Systemic repellents** are incorporated into plants, either naturally (e.g., tannins), by supplementation (e.g., selenium), or through genetic manipulation.

Although repellents should not be expected to eliminate damage (Craven and Hygnstrom 1994), they can be relatively inexpensive and effectively provide short-term protection. Repellents are most effective on vegetation during the dormant season, but results are frequently inconsistent. Even under optimal conditions, some damage usually occurs. As with other nonlethal techniques, factors such as ungulate population density, availability of alternate foods, target plant species, weather, repellent concentration, and duration of the problem can influence the effectiveness of repellents.

The history of pesticide regulations has compromised the effectiveness and marketing of repellents. In 1978, amendments to the **Federal Insecticide Fungicide and Rodenticide Act** gave the Environmental Protection Agency the option to waive data submission requirements for efficacy of pesticides. The EPA took advantage of this provision except for certain public health uses (Jacobs 2002). In 1982, the waiver was extended to all vertebrate pesticide products, but within 2 years, data submission requirements for public health uses were fully reinstated with the added proviso that the waiver applied only to the submission of data and that EPA could request efficacy data for any product at any time. Armed with this option, the agency began to require submission of efficacy data for reregistration of products claimed to repel vertebrate pests; the efficacy of many such products had been in question for several years. The **Office of Pesticide Programs** reversed this policy in 1995, except for products making claims to repel pests of public health significance (Jacobs 2002). The result of these legislative actions is that efficacy data are not required for most products making claims to repel vertebrate pests, because these products are not typically labeled for public health uses (Jacobs 2002). As a result, there are many repellents currently on the market and many are not effective.

Fertility Control

Considerable effort has been expended to develop fertility control agents (contraceptives) for, and methods of delivery to, ungulates. **Contraceptives** for wildlife have potential to be a complementary tool for population management in scenarios where current nonlethal management techniques are ineffective or unacceptable. There are several contraceptive strategies including chemosterilants, immunocontraceptives, intrauterine devices, and surgical procedures that can all effectively result in decreased reproduction. Initially, Knipling (1959) proposed the principle that undesirable wild animal populations may be controlled with the use of **sterility-causing** agents. Shortly thereafter, Greer et al. (1968) field tested several methods on elk. Over the following 40+

years, much research was directed at the same goal, with an array of species, and using a variety of strategies. Researchers at the National Wildlife Research Center have explored an array of chemical and immunologically based contraceptives for wildlife (Mauldin and Miller 2007). Early immunocontraceptives proved inefficient and expensive because they required a booster or second shot (i.e., Walter et al. 2002). Recent developments in single-shot fertility-control methods (Hernandez et al. 2006, Locke et al. 2007) have received a great deal of attention and EPA registrations are being pursued. Orally delivered contraceptives, as well as live-vector (bacterial or viral) delivery, are being explored further (i.e., Fagerstone et al. 2002, Conner et al. 2007). However, it is unlikely that fertility control will become a viable stand-alone ungulate management strategy (Dolbeer 1998, DeNicola et al. 2000) beyond maintaining relatively small closed populations (Ruthberg et al. 2004).

Removal

Regulated, managed **hunting** in rural settings is the most practical and effective method of managing overabundant deer populations and controlling damage (Fig. 34.12A). It also is the most ecologically, socially, and fiscally responsible method. Some states have special depredation permits that can be issued to landowners to remove cervids in areas where they are causing damage outside the normal hunting season, if sufficient control cannot be achieved during the hunting season. Well-managed hunting also can be effective for reducing burgeoning deer numbers in urban settings (i.e., McDonald et al. 2007). Several case studies have outlined strategies to ensure the success of deer hunts in areas that also are densely populated with humans (McAninch 1995, VerCauteren and Hygnstrom 2002, Warren 2002). **Archery** hunting, under specific restrictions (e.g., earn-a-buck tags), can be a useful tool in an integrated management program to keep urban deer populations in check (Kilpatrick et al. 2004). Professional **sharpshooters** also have been employed effectively to reduce deer numbers (Fig. 34.12B) in areas where public hunting was not considered safe (i.e., DeNicola et al. 2000, DeNicola and Williams 2008).

In damage management situations, **live capture** and relocation of ungulates is generally a poor option, though it is sometimes mandated by safety considerations or sensitive public-relations issues. Ungulates can be captured with various designs of cage traps (see Fig. 34.12C), corral traps, rocket nets, drop nets, or via remote chemical immobilization, and then **euthanized or relocated**. It is important to realize that there are problems with holding animals humanely in captivity until they can be transported somewhere for release, and finding suitable release sites also is difficult. In many instances, shooting is a more effective and practical option. In areas such as arboretums, where shooting is normally prohibited, the use of skilled sharpshooters under permit is probably preferable to live capture (Ishmael

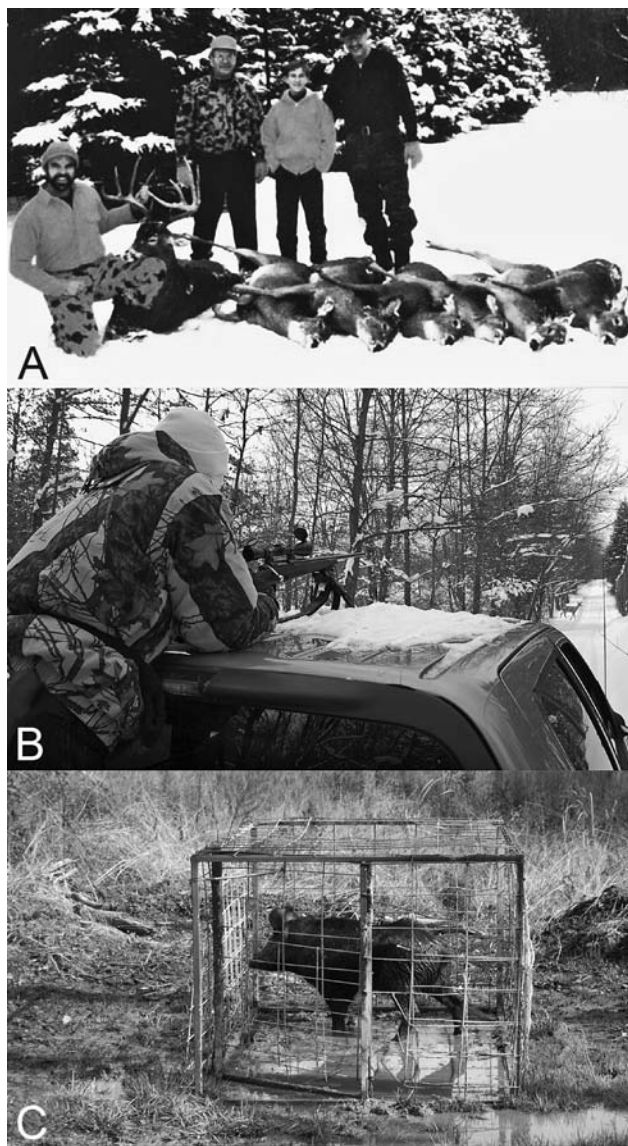

Fig. 34.12. Population control methods for ungulates include (A) well-managed hunting, (B) sharpshooting, and (C) trapping for euthanasia. (A) Photo by S. Hygnstrom; (B) photo by K. Malcom; (C) photo by M. Lavelle.

and Rongstad 1984, DeNicola and Williams 2008). Additional lethal tools such as **snares** and **toxicants** are occasionally recommended for limited use in specific situations and warrant further exploration.

RODENTS AND OTHER SMALL MAMMALS

Damage Assessment

Rodents and other small mammals are often not readily observed causing damage, and their damage is frequently difficult to measure and quantify. Likewise, accurate estimates of monetary losses of much of this damage are difficult to ascertain. Damage assessments indicate rodents and non-

predatory small mammals cause tremendous annual losses of food and fiber. Conover (2002) estimated the value of rodent damage to agriculture in the United States could be as high as **\$7 billion annually**. In the timber industry, **American beaver** (*Castor canadensis*) and **pocket gophers** cause the most damage. Miller (1987b) surveyed forest managers and natural resource agencies in 16 southeastern states and estimated annual wildlife-caused losses, primarily attributed to beaver, to be \$11.2 million on 28.4 million ha. Comparatively, in 1998, Louisiana expended \$2 million to control **nutria** (*Myocastor coypus*; Bounds and Carowan 2000). Other types of damage include losses of sugarcane (*Saccharum officinarum*) to **rats** (*Rattus* spp.), orchard damage by **voles** (*Microtus* spp.), and decreased forage quantity on rangelands caused by rodents and **lagomorphs** (rabbits and hares). In households, house mice (*Mus musculus*) are the primary species conflicting with humans.

Quantifying losses to evaluate efficacy of rodent-control techniques can be challenging. Most research compares plots where resources are protected to those with no protection, or agricultural production in areas with no rodents to areas with rodents. However, loss estimates must be converted to dollar losses to compare cost–benefit evaluation of control programs (VerCauteren et al. 2002a). Conversion to dollars is often difficult, given vast areas involved and variability in rodent populations. These considerations and the complexity of damage situations make it easy to realize the need for better monitoring techniques, damage assessment methods, and control effort evaluation.

Species Damage Identification

Most rodents and small mammals are nocturnal, secretive, and not easily observed. Often the investigator must rely on sign, such as **tracks**, **trails**, **tooth marks**, **feces**, or **burrows** to identify the species responsible for damage. Trapping may be necessary to make a positive identification of damage-causing rodents and, frequently, more than one species is involved. Characteristics of the damage may provide clues to the species involved. In orchards, for example, major stripping of roots is usually caused by pine voles (*Microtus pinetorum*), whereas damage at the root collar or on the trunk up to the extent of snow depth is most often caused by meadow voles (*M. pennsylvanicus*). Rats gnaw stalks of sugarcane until they are hollowed out between the internodes, but usually not completely severed. Rabbits (*Sylvilagus* spp.), in contrast, usually gnaw through stalks, leaving only the ring-shaped nodes. Damage to plants can generally be grouped as (1) root damage—pocket gophers and pine voles, (2) trunk debarking—meadow voles, squirrels (family Sciuridae), porcupines (*Erethizon dorsatum*), woodrats (*Neotoma* spp.), rabbits, and mountain beavers (*Aplodontia rufa*), (3) stem and branch cutting—beavers, rabbits, meadow voles, mountain beavers, pocket gophers, woodrats, squirrels, and porcupines, (4) needle clipping—mice, squirrels, mountain beavers, porcupines, and rabbits, and (5) debudding—red squirrels (*Tam-*

iasciurus hudsonicus and *T. douglasii*) and chipmunks (*Tamias striatus* and *Eutamias* spp.). These characteristics can aid in identification of the responsible species, but positive identification should be made either by species-specific sign (e.g., tracks, feces) or by capture of individuals.

Bats

Bats, the only mammals capable of true flight, eat vast quantities of insects. Only a few of the 190 species of bats in North America cause problems. Problems primarily occur when they form roosts or maternity colonies **in human dwellings** or structures. Those most commonly encountered in pest situations are: little brown bat (*Myotis lucifugus*), big brown bat (*Eptesicus fuscus*), Mexican free-tailed bat (*Tadarida brasiliensis*), pallid bat (*Antrozous pallidus*) in the Southwest, and the Yuma myotis (*M. yumanensis*) in the West (Greenhall 1982, Frantz 1986). Species identification may be difficult, but is important because several bat species are threatened or endangered and protected by state and federal laws.

Besides seeing bats, their presence also can be evidenced in buildings by noise (squeaking, scratching) and a distinctive pungent odor of accumulated feces and urine. Bat feces are readily differentiated from those of rodents by odor, insect content, and ease with which they are crushed. Many people are fearful of bats and panic in their presence. Bats can carry and transmit **rabies**, although 0.05% of bats are thought to be rabid (Fitzgerald et al. 1994). However, because infected bats may exhibit weakness or paralysis, they are often unable to fly or roost and, therefore, pose a greater risk of contact with humans and domestic animals. Where bat colonies are allowed to persist, fecal deposits accumulate, and the fungus that causes **histoplasmosis** can develop. **Damage management techniques** involve education to overcome phobias, habitat modifications (1-way valve devices on structures after young reach flight stage, and construction of artificial roosts), repellents (naphthalene), and traps.

Beaver, Muskrat, and Nutria

A decline in traditional trapping combined with increased restrictions on use of specific trap designs are resulting in proliferation of beaver populations in parts of the United

States. Burrowing aquatic rodents, as agents of disturbance, can alter habitats in positive and negative ways. **Beaver**, **muskrat** (*Ondatra zibethicus*), and **nutria** are aquatic rodents that can cause damage in and around natural and human-created wetlands. Due to their burrowing habits, they cause damage to manmade dams, levees, and irrigation canals. The presence of these species is evidenced by the damage they cause and by their tracks, droppings, and trails. Beaver and muskrat are native to North America and nutria was introduced from South America. The regulations regarding control of these species vary from state to state.

Beaver damage is easily identified by the distinctive, cone-shaped tree stumps that result from their gnawing (Fig. 34.13D). Other beaver sign includes dams, lodges, bank burrows, and green sticks with the bark freshly peeled off. Beaver eat a wide variety of plant species, but are usually locally selective, which can result in overexploitation of preferred species (Fitzgerald et al. 1994). Damage caused by beaver results from feeding behavior (tree cutting) and their efforts to control water levels (dam building; Miller and Yarrow 1994). Beaver girdle and fell large-diameter trees to access the branches, contributing to losses in timber value (Fitzgerald et al. 1994). They also cause flooding of roads, dwellings, and other human property.

The most serious damage caused by **muskrats** is wash-outs and cave-ins of pond dams, levees, and irrigation canals. They also can cause severe damage to grain, such as rice, and to garden crops growing near water. Their cone-shaped huts of aquatic material projecting 0.5–1.0 m above the water surface, feeding platforms of aquatic vegetation, and burrow entrances indicate muskrat presence. Their burrow entrances, 13–17 cm in diameter, are much smaller than those of nutria. Muskrat and nutria are smaller than beaver and do not build dams or plug culverts.

Nutria can cause significant damage to rice and sugarcane, especially in fields adjacent to Gulf Coast marshes (LeBlanc 1994). They may severely impede cypress (*Taxodium distichum*) regeneration (Conner and Toliver 1987) and damage wooden structures and floating marinas. Nutria also have been implicated as a threat to the persistence of coastal marshes (Ford and Grace 1998). The presence of nutria can

Fig. 34.13. Examples of rodent damage: (A) tree damage in orchards by voles, (B) damage to underground cables by pocket gophers, (C) soil cast left by pocket gophers, and (D) beaver damage to trees. (A) Photo by U.S. Animal and Plant Health Inspection Service, Wisconsin; (B) photo by U.S. Animal and Plant Health Inspection Service, Wisconsin; (C) photo by U.S. Animal and Plant Health Inspection Service, Wisconsin; (D) photo by N. Seward.

be verified by identification of scat, which has distinctive parallel lines running along its length (LeBlanc 1994).

Beaver, muskrat, and nutria can be infected with several pathogens and internal and external parasites that can be transmitted to humans (e.g., Davidson and Nettles 1997). Proper water-treatment measures should be taken before drinking water in regions where these species occur. Permissible **damage management techniques** vary by state and include habitat modification (explosives for dams, drain devices in dams or culverts), exclusion, traps (live traps accompanied by translocation, Conibears, footholds), snares, and shooting.

Deer and White-Footed Mice

Deer and white-footed mice (*Peromyscus maniculatus* and *P. leucopus*, respectively) are common and widely distributed throughout North America (Timm and Howard 1994). These mice are nocturnal, active year-round, and their populations may show large fluctuations. Their cheek pouches give them the capacity to carry 3–5 times more food than other species of mice and may increase their efficiency in exploiting small, particulate food items that are patchily distributed (Vander Wall and Longland 1999). *Peromyscus* can be significant seed predators (Sullivan 1978), and in some areas direct seeding for reforestation has failed because of their foraging activities. Their effects on reforestation have caused a shift to the use of hand-planted seedlings in many areas. *Peromyscus* also can cause significant losses to corn seedlings in conservation tillage systems, but this damage may be offset by their consumption of harmful insects and weed seeds (Clark and Young 1986, Johnson 1986). *Peromyscus* invade homes, where they eat stored food and damage upholstered furniture or other materials that are shredded for use in nest building. Trapping with snap or live traps is the best method to identify the species present. **Damage management techniques** for *Peromyscus* include habitat and food modifications, exclusion, traps (snap traps and live traps), repellents, and toxicants. Species of *Peromyscus* are the primary reservoirs of the **Sin Nombre hantavirus** (Corrigan 2001), which is the cause of an often-fatal pulmonary syndrome in humans.

Ground Squirrels

Ground squirrels, genus *Spermophilus*, are important pest species in north-central and western North America, causing serious economic losses to agricultural and range resources. Belding's (*S. beldingi*), California (*S. beecheyi*), rock (*S. variegatus*), and Richardson's (*S. richardsonii*) ground squirrels are all considered pests in at least part of their range (Marsh 1994a, Johnson-Nistler et al. 2005). They can inflict serious damage to pastures, forage crops, rangelands, vegetable gardens, and grain, fruit, or nut crops.

A careful search of an area showing damage will reveal opened seed hulls and caches. They often live in colonies or concentrate in localized areas (Marsh 1994b). As a group,

ground squirrels are widely recognized for their ability to achieve high population levels in suitable habitats (Giusti et al. 1996). Ground squirrel burrows can collapse irrigation levees, increase erosion, damage farm machinery, and cause injury to livestock and humans. Ground squirrels also predate nests of ground-nesting birds (Renfrew and Ribic 2003), including those of waterfowl (Sargeant and Arnold 1984, Marsh 1994a).

Ground squirrels are diurnal and easily observed (Marsh 1985a). They hibernate and estivate and show major dietary shifts during the year (Marsh 1985a, 1986). Effective control strategies must consider these factors. Ground squirrels are extremely adaptable, so indirect control through habitat modification, exclusion, or use of chemical and visual repellents has limited, if any, benefit in most situations (Whisson et al. 2000). Ground squirrels carry several zoonotic diseases, including **plague**. In plague-endemic areas, ground squirrel control should be combined with ectoparasite control (Marsh and Howard 1982). **Damage management techniques** include habitat modification (exclusion, burrow ripping, and flooding), toxicants, fumigants, traps (live traps, size no. 0–1.5 foothold traps, snap traps), and shooting.

Marmots

Marmots (*Marmota* spp.), also known as **woodchucks**, can cause damage to a variety of crops and forage production may be markedly reduced by marmot feeding and trampling (Marsh 1985a). Damage to crops such as alfalfa, soybeans, beans (*Phaseolus* spp.), squash (*Cucurbita* spp.), and peas (*Pisum* spp.) can be costly and extensive. They damage fruit trees and ornamental shrubs by gnawing or scratching woody vegetation (i.e., Swihart and Picone 1994). Damage often occurs on farms, in home gardens, orchards, nurseries, around buildings, and occasionally on dikes (Bollengier 1994). Their burrows, often positioned along field edges, can cause damage to farm machinery and injure livestock, and burrows can compromise the structural integrity of irrigation ditches, resulting in loss of water. In suburban areas, burrows under buildings or in landscaped areas cause problems (Marsh and Howard 1982). The presence of marmots is easily ascertained by direct observation of animals and burrows. During periods of forage growth, vegetation around burrows is noticeably shorter than in surrounding areas. Occupied burrows can be identified in spring by presence of dirt pellets ranging from marble to fist size. **Damage management techniques** include frightening devices, fumigants, traps (e.g., Conibear traps, foothold traps, live traps) and shooting.

Voles

Voles, also called meadow mice, field mice, and pine mice, cause extensive damage to forests, orchards, and ornamentals by gnawing bark and roots (Sullivan et al. 1987, O'Brien 1994). In North America, there are 19 species of voles, 4 of

which are of pest significance. They are the most prolific of all rodent species and probably the most important item in the food chain among secondary consumers (Corrigan 2001). Tree or shrub damage usually occurs under snow or dense vegetation. The bark is gnawed from small trees near the root collar and up the trunk to the snow surface (see Fig. 34.13A). Voles gnaw through small trees or shoots up to 6 mm in diameter. Some vole species also cause extensive damage to root systems and this damage may not be detected until spring, when it is reflected in condition of new foliage. Voles and other rodents thrive in no-till agricultural settings and cause a great deal of damage (Witmer et al. 2007). Voles can damage field and garden crops as well, and when vole populations are high, losses can be severe (Clark 1984, Marsh 1985a). They also are carriers of **bubonic plague and tularemia**.

Vole populations are characterized by 3 levels: (1) low, (2) high, and (3) irruptive (Johnson and Johnson 1982). In North America, population peaks occur about every 4 years, although not in explosive numbers and not predictably (Johnson and Johnson 1982). Voles are active throughout the year. Their presence is most easily ascertained by searching for their runways and burrow systems. In orchards, these can be found by pulling the grass and other debris from the bases of trees. Gnawing on trunks and roots of trees is not as uniform as that of other rodents. Tooth marks can be at all angles, even on small branches, and may vary from light scratches to channels 3 mm wide, 2 mm deep, and 10 mm long. In hay crops, runways with numerous burrow openings, clipped vegetation, and feces can be detected in dense vegetation. **Damage management techniques** for voles include habitat modification (provision of alternative foods), exclusion, toxicants, and traps (snap traps).

Moles

There are 7 species of **moles** (representing 5 genera) in North America; 4 of these species have distributions restricted to the Pacific Northwest and West Coast of the United States (Yates and Pedersen 1982). Moles feed primarily on soil invertebrates, especially earthworms and grubs (insect larvae). Vegetation can comprise up to 20% of the diet of some species of moles. Although they damage crops and ornamentals, they are most detrimental to turf areas (Marsh 1996). They are active year-round. Voles and mice also use burrows of moles and can be responsible for some damage attributed to moles (Henderson 1994a).

Moles can usually be detected by mounds of soil brought up from extensive tunnels dug in search of food and by raised soil of surface burrows. Shallow tunnels of moles can be confused with those of pocket gophers, but moles typically leave volcano-shaped mounds composed of clods of soil and their burrow plugs are at the peaks of the hills. **Gophers** leave fan-shaped mounds with the burrow plug near the base of the mound (Henderson 1994a). Generally, go-

phers produce larger mounds than moles, but the Townsend's mole (*Scapanus townsendii*) can produce up to 4 mounds/day (Yates and Pedersen 1982). The burrowing activity of moles may reduce production of forage crops by undermining and smothering vegetation and by exposing root systems to drying. Forage production in pastures can be reduced 10–50% by burrowing activity (Yates and Pedersen 1982). Their surface burrows also can plug harvesting machinery and contaminate hay and silage. The burrowing activity of moles can extensively damage lawns and golf greens. **Damage management techniques** include habitat modification (soil compaction, flooding), exclusion, chemical repellents, insecticides (to reduce the moles' primary food source), fumigants, toxicants, and traps.

Pocket Gophers

Thirteen species of **pocket gophers** (*Geomys* spp., *Pappogeomys castanops*, and *Thomomys* spp.) occur in the United States. They can cause substantial damage to agricultural crops, lawns, rangeland, and tree plantings. Gophers feed primarily on underground portions of plants and trees. Root crops such as potatoes, sweet potatoes, beets, parsnips, turnips, and carrots are favorite foods, as are field crops such as alfalfa and clover (Marsh 1998). Damage is often undetected until a tree shows aboveground signs of stress, by which time the damage may be lethal. Pocket gophers also may damage plastic irrigation lines in agricultural settings, as well as underground pipes and cables (see Fig. 34.13B). In rangeland, soil disturbance and mound building by pocket gophers results in increased plant diversity, favoring annual and invasive species. They also can reduce the carrying capacity of rangeland for livestock. Gopher mounds can cause equipment breakage and increase wear of haying machinery. Furthermore, their burrows can cause substantial losses of irrigation water, especially in flood-irrigated crops (Marsh 1998).

Pocket gophers are a major impediment to reforestation in the western United States (Crouch 1986). They damage trees by stem girdling and cutting, root clipping, and exposing roots to drying (Case and Jasch 1994). In winter, pocket gophers often forage aboveground by tunneling through snow. Extensive aboveground girdling is easy to detect. Damage to roots may go unnoticed until seedlings fall over and become discolored (Nolte et al. 2000).

Fan-shaped soil mounds, in contrast to the conical mounds of moles, easily identify pocket gopher presence. Burrow entrances are typically plugged. Aboveground debarking damage caused by pocket gophers shows small tooth marks, differing from the distinct broader grooves left by porcupines and the finely gnawed surface caused by meadow voles. Gophers sometimes pull saplings and vegetation into their burrows. Gophers also fill some of their snow tunnels with soil, forming long, tubular "soil snakes" that remain after the snow melts (see Fig. 34.13C). **Damage management techniques** include habitat modification (flood irrigation,

crop rotation), cultural practices (plastic mesh cylinders to protect seedlings, protective coverings for pipes and cables), fumigants, toxicants, and traps.

Prairie Dogs

There are 5 species of **prairie dogs** (*Cynomys* spp.) in North America. The Mexican (*C. mexicanus*; endangered) and Utah (*C. utahensis*; threatened) prairie dogs are federally listed. Prairie dogs live in colonies that are easily identified by conical mounds around burrow entrances and by the presence of these highly visible rodents. Populations were reduced greatly by intensive control and conversion of habitat to agriculture in the early to mid-1900s. In recent years, populations have been expanding, commensurate with reduced control efforts.

Prairie dogs damage rangelands and pastures by clipping vegetation for food and nesting material and by clearing cover from the vicinity of burrows (Hygnstrom and Virchow 1994). Their activity not only reduces available forage, but also can alter species composition of vegetative communities in favor of forbs. Competition with cattle is minimal and, in some situations, beneficial effects of prairie dogs may offset competition. Thus, each conflict situation should be evaluated individually (Fagerstone 1981). Crops planted near prairie dog colonies can receive serious damage from feeding and trampling. In addition, damage to irrigation systems is common and **American badgers** (*Taxidea taxus*) digging for these rodents can cause even greater damage. The burrows and mounds created by prairie dogs can increase soil erosion and drainage of irrigation water, and cause damage to farm machinery.

Prairie dogs serve as a reservoir for **bubonic plague** (Hygnstrom and Virchow 1994) and are often responsible for periodic outbreaks (Witmer et al. 2003). Prairie dog colonies also provide habitat for other species such as the endangered black-footed ferret (*Mustela nigripes*). Reestablishment of black-footed ferret populations may be hampered by the occurrence of plague outbreaks (Hanson et al. 2007). It is a violation of federal law to poison a prairie dog town when ferrets are present (Hygnstrom and Virchow 1994).

In recent years, prairie dogs have thrived in urban areas that were historically prairie dog habitat. Damage in these environments includes degradation of community open space, clipping of landscape vegetation, and encroachment into residential yards. Populations in urban areas can increase the probability of bubonic plague transmission to pets. **Damage management techniques** include habitat modification (e.g., deferred grazing), exclusion, fumigants, toxicants, traps (foot-hold and Conibear), and shooting.

Rabbits and Hares

Rabbits and hares (*Lepus* spp.; family Leporidae) can damage or destroy landscape plantings, gardens, agricultural crops, and rehabilitated rangeland. In winter, leporids may strip

bark from and debud fruit trees, conifers, and other trees and shrubs (Craven 1994). Populations of hares show large fluctuations and, during peak densities, hares can severely damage vegetation and compete with livestock for forage. Stems clipped by rabbits and hares have a clean, oblique, knife-like cut. Rabbits and hares usually clip stems ≤ 6 mm in diameter at a height not > 50 cm above the ground. Repeated clipping will deform seedlings. Leporids can often be observed at damage sites along with their tracks, trails, and droppings.

Rabbits are known vectors of **tularemia**, a zoonotic disease, and they may carry larvae of several ascarid roundworms that can produce disease if uncooked, infected meat is ingested by humans (Davidson and Nettles 1997). **Damage management techniques** include rabbit “drives” or “roundups,” use of ferrets, habitat modification, exclusion, chemical repellents, traps, snares, and shooting (Smith et al. 2007).

Tree Squirrels

Tree squirrels can be grouped into 3 categories: (1) large tree squirrels (gray [*Sciurus carolinensis*], fox [*S. niger*], and tassel-eared [*S. aberti*]), (2) pine squirrels (red and Douglas), and (3) flying squirrels (northern [*Glaucomys sabrinus*] and southern [*G. volans*]; Jackson 1994b). Squirrels eat plants and fruits, dig up newly planted bulbs and seeds, strip bark and leave from trees and shrubs, invade homes, and consume bird eggs (Hadidian et al. 1987, Jackson 1994b). Squirrels also can cause problems by traversing power lines, gnawing on them, and shorting out transformers.

Squirrels often can be observed at the damage site. Damage to conifers is indicated by green, unopened cones scattered on the ground under mature trees and by accumulated cone scales and “cores” at feeding stations. Bark stripping can be observed in trees and bark fragments are often found on the ground, as are the tips of twigs and small branches. These activities may interfere with natural reseeding of trees that are important to forestry, particularly in ponderosa pine (*Pinus ponderosa*) forests, where pine squirrels may remove 60–80% of the cones in poor to fair seed years (Jackson 1994b). **Damage management techniques** include cultural practices (trimming limbs near buildings and transformers), exclusion, frightening devices, chemical repellents, toxicants, traps (Conibear, foothold, and live traps), and shooting.

Woodrats

Woodrats, also called pack rats, brush rats, or trade rats, are attracted to human food supplies in buildings and will remove small objects such as utensils and other items, sometimes leaving sticks or other objects “in trade.” There are 9 species of woodrats in the United States, several of which have become significant pests in suburban and semirural developments in the Southwest (Corrigan 2001). They often

construct conspicuous stick houses in cabins, unused vehicles, rocky outcroppings, or in upper branches of trees (Marsh and Howard 1982, Salmon and Gorenzel 1994). They will shred mattresses and upholstery for nesting material.

Woodrats are agile climbers and consume fruits, seeds, and green foliage of herbaceous and woody plants. They clip small branches and strip and finely shred patches of bark for their nests. Their damage may be confused with that of tree squirrels and porcupines; however, woodrats leave a relatively smooth surface with a few scattered tooth marks and tend to litter the ground beneath the tree less than tree squirrels. Woodrats have been involved in epizootics of **plague** and have been infected with **tularemia**. At least 6 species of woodrats have been identified as reservoirs of **trypanosomes** (parasitic blood-infesting protozoa) that cause **Chagas disease** (Corrigan 2001). Some subspecies of woodrats are endangered; therefore, one should check local regulations before undertaking control efforts. **Damage management techniques** include exclusion, chemical repellents, toxicants, traps (snap and live traps), and shooting.

Commensal Rodents

The 3 species of **commensal rodents** (those that live primarily around human habitation) are Norway rats (*Rattus norvegicus*), roof or black rats (*R. rattus*), and house mice. These omnivorous rodents consume millions of bushels of grain each year in the field; on the farm; in the grain elevator, mill, store, and home; and in transit. They also waste many more millions of bushels by contamination. One rat can eat approximately 9–18 kg of feed/year and probably contaminates 10 times that amount with its urine and droppings (Timm 1994a, b). Pimentel (2007) estimates the number of rats on farms in the United States at 1.5 billion, causing damage in excess of \$27 billion annually.

Besides consuming plant products, commensal rodents feed on poultry chicks and occasionally attack adult poultry, wild birds, newborn pigs, lambs, and calves. In buildings and vehicles, rodents gnaw electrical wires, creating a serious risk to human safety (Corrigan 2001) and sometimes starting fires. Their gnawing also causes considerable property damage. Extensive damage to foundations and concrete slabs sometimes results when rats burrow under buildings. Burrowing into dikes and outdoor embankments causes erosion. Health departments annually report hundreds of human babies bitten by rats. Many viral and bacterial diseases are transmitted to humans by rodent feces- and urine-contaminated food and water. Among the diseases, rats may transmit to humans or livestock are **plague**, **murine typhus**, **leptospirosis**, **trichinosis**, **salmonellosis**, and **ratbite fever**.

Signs of commensal rodents include gnawing, droppings, tracks, burrows, and darkened or smeared areas along walls where they travel. Reviews of problems caused by these species and methods of control are provided by Timm (1994a, b), Hygnstrom and VerCauteren (1995), and Corrigan (2001).

Damage management techniques include tracking powder, habitat modification, cultural practices (sanitation), exclusion, fumigants, toxicants, and traps (snap and multiple-catch traps).

Management Techniques

There are 2 general categories of control related to rodents and other small mammals: **nonlethal and lethal**. Many traditional methods of wildlife-damage management are lethal; however, these methods are increasingly being questioned by society based on humaneness and target specificity. Presently, we lack ability to alleviate many wildlife damage problems in effective and economical ways using only nonlethal techniques (Conover 2002). Wildlife researchers specializing in damage management are expending considerable effort to develop nonlethal means to reduce damage. The following section briefly reviews control techniques commonly used to manage populations of rodents and small mammals. An **Integrated Pest Management (IPM)** approach is recommended for control of rodents and other small mammals. The IPM concept favors timely and strategic incorporation of a combination of cost-effective control techniques to reduce the impact of species on valuable resources.

Habitat Modification and Cultural Practices

All animals are dependent on food and shelter; therefore, elimination of one or both of these requirements will force them to move from the immediate area. This method of control, where practical, is the most desirable and usually has the most permanent effect in reducing small mammal damage. However, other species often are dependent upon the same habitat. **Modifications of the habitat** can result in greater adverse effects to desirable nontarget species and natural communities than careful use of a registered toxicant or other control tool. Modifications also can create situations that contribute to other species becoming pests.

Many rodents and small mammal pests can be discouraged from using areas by removal of brush and woodpiles, weeds, and other debris. Commensal rodent control can be greatly facilitated by removal of harborage, garbage, and refuse. Squirrel interference with power transformers may be reduced if vegetation near power poles is managed (Hamilton et al. 1987). Mountain beaver populations in silvicultural areas may be decreased by removing surface shelter such as stumps, logs, and brush piles (Cafferata 1992). High populations of muskrats in sugarcane are associated with debris remaining in fields after harvest (Steffen et al. 1981).

Davis (1976) reported that pine vole damage in an apple orchard was reduced by mowing 3 times/year, clearing vegetation from under the trees, removing pruned branches, restricting distribution of fertilizer and, after harvest, inspecting and cleaning vulnerable parts of the orchard. Control of pine voles with anticoagulant baits was enhanced in apple orchards cultivated 2 or 3 times/year (Byers 1976). Byers

(1984), however, found that **cultural controls** (combinations of mowing, cultivation, and herbicide application) were much more expensive than application of **toxic baits** and offered no advantages in vole control. Evaluation of large-scale use of **diversionary foods** to reduce vole damage provided promising results (Sullivan and Sullivan 2008).

Various **mechanical methods** have been developed to prevent beaver from stopping water flow through culverts (Roblee 1987). Water levels behind beaver dams can be manipulated by installing a perforated pipe or a 3-log drain (Miller and Yarrow 1994) through the dam. Muskrat damage to farm-pond dams can be reduced by maintaining a 3:1 slope on the water side of the dam, a 2:1 slope on the outer face, and a top width of 2.4 m (Miller 1994).

Provision of **alternative foods** can reduce conifer seed loss to mice in forest regeneration projects (Sullivan and Sullivan 2008) and may be useful in reducing loss of agricultural crop seedlings in no-tillage fields (Hygnstrom et al. 2000) and orchards (Sullivan and Sullivan 1988). Pocket gopher infestations in logged areas can be reduced by prompt regeneration and minimal site preparation. Selective cutting, when feasible, can be used in areas with high potential for gopher infestations (Crouch 1986). Use of insecticides to reduce numbers of soil invertebrates can protect turf from nine-banded armadillos (*Dasypus novemcinctus*) and moles, but damage may initially increase due to increased food-searching by animals already present (Henderson 1994a).

Exclusion

Exclusion involves installation of barriers that prevent access by pest species into structures or areas, or elimination of their physical contact with specific objects. Rodent-proofing of structures is achieved most economically if incorporated into construction plans. Corrigan (2001) provides detailed suggestions on how to accomplish rodent-proof construction. Basically, openings or sites where rodents might create openings are protected with wire mesh, sheet metal, or concrete, providing long-term protection. **Steel sheathing** also has been incorporated into underground power- and telephone-line wiring to provide protection from gnawing rodents.

Exclusion is a necessary part of an effective program to remove bats from structures. Final closure of entrances to the structure should not be made until all young have reached the flight stage. At that time, these openings can be closed with a **1-way door** that permits bats to leave the structure, but prohibits reentry.

In small orchards, rodent and rabbit damage can be eliminated by wrapping trees with hardware cloth or burlap that is buried 5 cm deep around the tree base. **Plastic seedling protectors** will protect conifer seedlings from rodents and rabbits. These plastic net-tubes are placed over seedlings at planting. Some allow branches to grow through the netting and provide protection for the terminal bud for 3–5 years as the terminal leader grows through the tube. A 0.6-m-wide

expandable metal band placed around tree trunks 2 m above the ground will keep squirrels out of individual trees. Branches should be trimmed within 2 m of the ground or buildings. **Fences** made of 1.2–2.5-cm-mesh net wire 0.7–1.0 m high can protect small areas against nonclimbing rodents and small mammals. Lower edges of fences should be buried with an “L” shape on the outside of the fence to prohibit burrowing under the fence. Both **visual and physical barriers** are commonly used in attempts to minimize prairie dog town expansion in urban settings, though efficacy is often minimal and costs range from \$1/m to \$5/m and \$30/m to \$60/m, respectively (i.e., Merriman et al. 2004, Foster-McDonald et al. 2006, Witmer et al. 2008b).

Frightening Devices

Frightening devices may deter rodents and small mammals from localized areas for short periods. These devices are designed to frighten animals by targeting their visual or auditory senses. **Visual repellents** (e.g., eyespots, predator effigies, Mylar) were designed to repel birds, although some of these visual devices also may affect mammals (Mason 1998). **Sonic devices** include distress calls, pyrotechnics (e.g., live ammunition, shell crackers, firecrackers), propane cannons, and sirens. Numerous **ultrasonic devices** are available commercially, but (like most frightening devices) are ineffective in alleviating damage over the long term (Shumake 1997). Limited research with frightening devices has been conducted on rodents and small mammals (i.e., Koehler et al. 1990).

Biological Management

Exploration into methods of **biological management** has received increased attention and evaluation (Hygnstrom et al. 1994). A variety of techniques, including agents of **disease or predators**, to control populations of small mammals have been evaluated. In the 1950s, *Myxoma* virus was used to control United Kingdom rabbit populations, resulting in 99% mortality (Lees and Bell 2008). Rabbit haemorrhagic disease has been viewed as a cost-effective tool in the successful reduction of rabbit populations in Australia (Vere et al. 2004, Henning et al. 2005). Various other **pathogens** including **protozoa** (Jäkel et al. 2006), **bacteria** (Kaboodvandpour and Leung 2007), and **viruses** (Hood et al. 2000) have been examined as potential tools for mammalian pest control with variable results. Protecting rice crops by applying *Sarcocystis singaporensis* protozoa was determined to be more cost effective than applying zinc phosphide (Jäkel et al. 2006). Although agents of disease may be an effective tool in population reduction, they may have adverse effects on regional biodiversity or even widespread ecological effects that must first be assessed. Species specificity also is an underlying concern of using disease-causing agents as a tool, because susceptibility may be unknown.

Use of predatory species to alleviate damage by pest species has been more widespread with insect pests, though

also has application with birds and mammals. **Ferrets** (*Mustela putorius furo*) have been used effectively in the capture of rabbits, though often for recreational purposes. Using ferrets for large-scale rabbit reductions in some areas has resulted in the establishment of feral ferret populations, which can result in widespread damage as well. **Mongoose** (family Herpestidae) have historically been used to control rats in sugarcane fields around the world, with questionable success. On the Hawaiian Islands, and other islands, mongoose introductions for rat control backfired and resulted in the demise of many species of birds, lizards, frogs, and snakes (Pitt and Witmer 2006). The common domestic **farm cat** (*Felis catus*) was traditionally employed for its abilities in **rodent control**, though also proficient in capture of nonpest species such as songbirds. The deployment of domestic cats was actually conducted in 1960 on Borneo in attempts to control rodent populations (Harrison 1965). The installation of **raptor perches** adjacent to areas in which rodent control is desired provides additive reduction in rodent numbers (Fig. 34.14; Hall et al. 1981, Murua and Rodriguez 1989, Witmer 2009).

Fertility Control

The use of **fertility control** measures, including the use of chemical and immunological agents to provide reproductive inhibition on rodents and other small mammals, has been the focus of several studies (Mauldin and Miller 2007). Development of an effective method of delivery for the agent to rodents or small mammals is a challenge in itself. For example, Nash et al. (2007) achieved nearly 50% reduction in prairie dogs with the use of an oral contraceptive delivered in enticing baits for 10 consecutive days in the field. Additionally, viral-vectored immunocontraceptives are in development, and may eventually be registered for a variety of pest species (Hood et al. 2000). As with any application of fertility control measures on pest species, an initial population reduction action would be the first step. In a case with

many commensal rodents, invasive species, and other pest species the desire to sustain a population may not be the goal; thus, the development of a lethal tool may be more appropriate.

Repellents

Several compounds have been registered for use as small-mammal **repellents** (Jacobs 1994); however, definitive efficacy data for most are lacking (Mason 1998), as is information on why some chemicals repel offending animals. Repellents are most effective when applied directly to foods with the intent of reducing consumption (Mason 1998). **Chemical repellents** for rodents are grouped into 3 categories: (1) **sensory irritants**, (2) **semiochemical odors** (e.g., predator urines), and (3) those that produce **conditioned taste-avoidance** behavior (Clark 1998, Mason 1998).

Specific semiochemicals found in predator excreta apparently induce fear and, thus, area avoidance by certain prey species. For example, Swihart and Picone (1994) achieved a 98% reduction in gnawing by woodchucks on apple trees through the application of bobcat (*Lynx rufus*) urine. Sullivan and Crump (1984) also had positive results in the use of predator scents to deter hare feeding on lodgepole pines (*Pinus contorta*). Sullivan et al. (1988) hypothesized that a reduction in damage by voles following the application of **predator scents** may have been due, in part, to increased predator activity in response to the application.

Use of some area repellents, such as naphthalene or paradichlorobenzene, in structures is often limited because the vapors cannot be prevented from permeating areas occupied by people. The efficacy of repellents applied to plants or seeds are affected by availability of natural foods and ability to withstand weathering. **“Bitter” chemicals** (e.g., thiram, denatonium benzoate, denatonium saccharide, sucrose octaacetate) are not necessarily perceived by animals as such, and are not inherently repellent to herbivores. Commercially available repellents for deer (Mason et al. 1999) and experimental formulations (Figueroa et al. 2008) emitting sulfur odors and volatile fatty acids effectively deter rabbits and potentially other mammalian species from feeding on tree seedlings.

Repellents that act by inducing taste-avoidance behavior function by producing smell or taste aversions, or gastrointestinal malaise. Those claimed to work because they are perceived as bitter by humans probably are either ineffective or are paired with some other compounds that cause illness or distress (Mason 1998, Nolte 1999). Some repellents create a burning sensation (e.g., capsaicin). **Capsaicin** encased within utility cables provided protection from gnawing by pocket gopher and rats (Shumake et al. 1999, 2000). Various taste sensations (bitter, sour, sweet, etc.) affect animals differently, or may have no effects. **Thiram**, the most widely used taste repellent, can be applied to trees, tree seeds, seedlings, bulbs, and shrubs to protect them from rodents and moles.

Fig. 34.14. Fabricated raptor perches constructed to facilitate predation of rodents by raptors in areas where rodent population-management tools are needed. Photo by G. Witmer.

Thiram should not be used on plant parts eaten by humans or domestic animals. Fruit trees must be sprayed only in the dormant season. Innovative work into the stimulation of satiation receptors has potential to minimize damage caused by rats (Cotterill et al. 2005).

Fumigants

Fumigants registered for rodent control include smoke-producing gas cartridges, aluminum phosphide, chloropicrin, and methyl bromide (Corrigan 2001). When inhaled, fumigants are lethal and are used to kill burrowing mammals. When fumigants are used, all burrow openings should be closed after introduction of the pesticide. **Active ingredients** in gas cartridges are a combination of sulfur, nitrate, charcoals, or phosphorous compounds, which, when ignited, produce carbon monoxide and other gases. These gases asphyxiate rodents in their burrows (Corrigan 2001).

Aluminum phosphide is a fumigant available in tablets or pellets that produces toxic phosphine gas when exposed to atmospheric moisture, and this gas is flammable or explosive at some concentrations. **Chloropicrin** is typically used as an additive to fumigants to provide an exposure warning (like sulfur is added to natural gas). Its only other registered rodent uses are in empty grain and potato storage bins to control rats and mice. **Methyl bromide**, because it has been documented to deplete atmospheric ozone (Ristaino and Thomas 1997), will not have its registration renewed. Hygnstrom and VerCauteren (2000) evaluated effectiveness of 5 fumigants (aluminum phosphide, gas cartridge, methyl bromide, chloropicrin, and a methyl bromide–chloropicrin mixture) for managing prairie dogs; all reduced burrow activity by 95–98%. Jacobs (1994) provides information on specific fumigants.

Toxicants

Toxicants are the most common method used to control damage-causing populations of rodents and other small mammals. Toxicants require little labor and can kill large numbers of animals over large expanses of land (Pascal et al. 2008). Damage reduction is the goal of any control program and must be the final measure of efficacy. Efficacy of a control program may be increased by using several toxicants in combination or by periodically alternating those used. This strategy aids in avoiding development of resistance to the primary toxicant (Marsh 1988).

One disadvantage of toxicants is that they usually are not species-specific (Conover 2002). Potential hazards to nontarget species must be considered when toxicants are used. Hazards associated with use of a toxicant are not necessarily related to toxicity of the compound, but are more often associated with how they are applied. Hazards to nontarget wildlife can be reduced by properly selecting toxicants, bait composition and formulation techniques (including bait color, size, shape, texture, and hardness), and bait delivery systems

(Marsh 1985b). Some toxicants may be absorbed by plants and pose a risk to herbivores (Conover 2002). To reduce environmental hazards, the EPA closely regulates registration and monitors risks of toxicants (Erickson and Urban 2004), approving only those that decompose rapidly and do not pose a significant threat to other species. Above- and below-ground carcass searches can be conducted to evaluate efficacy and nontarget mortalities of the management effort (Witmer et al. 1995, VerCauteren et al. 2002b).

Toxicants are classed as either anticoagulants or non-anticoagulants. Historically, anticoagulants were considered multidose or chronic toxicants, and nonanticoagulants as single-dose or acute toxicants. New-generation anticoagulants, however, can be effective in a single feeding and some new nonanticoagulants need to be ingested by individuals of the target species over several days (Marsh 1988). **Baits** come in a variety of forms including food, block, pellets, loose meal, seeds, packets, liquids, tracking powder, and nontoxic monitoring blocks.

Numerous toxicant formulations are registered for use in commensal rodent control around farm buildings and in noncrop areas; however, fewer are available for use in crops. Development of registrations for in-crop use of toxicants, particularly anticoagulants, is a high-priority research area. However, use of toxicants is expected to decline as alternative methods of reducing damage are developed (Fagerstone and Schafer 1998).

Anticoagulants are chemicals that disrupt the normal clotting process of blood. Death in poisoned rodents results from internal hemorrhaging and damage to capillaries (Corrigan 2001). There are 2 classes of anticoagulants, first-generation (multiple-dose) and second-generation (single-dose). First-generation anticoagulants typically require several consecutive doses to kill, while second-generation anticoagulants cause death after a single dose. First-generation anticoagulants generally require ingestion for 3–14 consecutive days to be effective. **Bait shyness** is generally not a problem because animals do not associate ill effects with bait consumption. However, bait delivery procedures must consider the need for making toxicants available over several consecutive days. Warfarin was the first, most widely used, of the “rat poisons” for many years (Corrigan 2001). Despite a popular misconception that warfarin is no longer used because mice and rats have developed a physiological resistance to it, in actuality, its patent has expired and newer pesticides more profitable for manufacturers have displaced the older pesticides. **Physiological resistance** to warfarin and other first-generation anticoagulants is actually a minor problem. Such resistance usually only occurs after continuous use at the same site for several years and can be overridden by switching temporarily to another rodenticide, such as zinc phosphide. Nevertheless, manufacturers and marketers of the second-generation anticoagulants, which are effective against rodents resistant to the first-generation compounds, have

touted this effectiveness against resistant rodents in their sales pitch. Chlorophacinone and diphacinone are other first-generation anticoagulants still widely used, but neither is effective against rats resistant to warfarin. Vitamin K is an antidote for first-generation anticoagulants.

The **active ingredients** brodifacoum, bromadiolone, and difethialone comprise the most popular second-generation anticoagulants used in the United States (Corrigan 2001). These anticoagulants are highly toxic to rodents and a single feeding on baits with an active ingredient concentration as low as 0.005% can result in death (Marsh 1988). Currently, all second-generation anticoagulants are effective against warfarin-resistant rodents.

Anticoagulants can be obtained in prepared baits or purchased as concentrates for mixing with fresh bait. Baits should be placed where rodents feed, drink, or travel. For anticoagulants that require multiple ingestions, bait stations purchased from pesticide supply houses or constructed from wood or metal, are particularly useful in protecting the bait from weather and nontarget species (Fig. 34.15). Some baits come in packets that are gnawed open by rodents and others are available in moisture-resistant paraffin blocks. Several anticoagulants are registered for use in **tracking powders**, which are dusted into burrows and along runways where house mice or Norway rats travel. Rodents ingest the anticoagulant by licking the toxic dust from their feet and fur.

Toxicants with different modes of action provide an obvious answer to anticoagulant resistance. The 3 most common nonanticoagulant baits used in the structural pest management industry are zinc phosphide, cholecalciferol, and bromethalin. **Zinc phosphide** is an effective, acute toxicant that has been in use for >50 years with minimal nontarget

hazards (to humans and other nontarget species), though several instances of unintentional intoxication in food-stressed turkeys have been documented recently (Poppenga et al. 2005). A key to success with zinc phosphide is prebaiting to establish a feeding routine. For some species of field rodents, such as **prairie dogs**, it is the only pesticide currently registered for use (Fagerstone and Schafer 1998). Hygnstrom et al. (2000) found that zinc phosphide pellets applied in-furrow at planting reduced corn yield loss and zinc phosphide has since been registered for this use. Hygnstrom et al. (1994) also provides species-specific baiting strategies using zinc phosphide. **Cholecalciferol** (vitamin D3) is both a single- and multiple-feeding toxicant effective on commensal rodents (Marshall 1984). No secondary hazards have been associated with its use (Marsh 1988). **Bromethalin** also is effective on **rats**, including those resistant to warfarin.

Strychnine is another nonanticoagulant acute rodenticide used to control pocket gopher and some ground squirrel populations to reduce damage to forest seedlings, agricultural crops, and home landscaping (Fagerstone and Schafer 1998). Due to regulatory and court actions, its former widespread use has now been restricted to underground applications (in pocket gopher and ground squirrel burrows).

Removal

Live traps are often used to capture mammals of all sizes without harm (Fig. 34.16). They are an excellent option to use in residential areas or to relocate rodents and other small mammals causing damage. Various homemade designs can be constructed of wire mesh or wood, or wire mesh and plastic models can be purchased commercially. Certain models can be used to capture a variety of species, while others are species-specific. Some designs have doors at both ends, permitting visibility through the trap, thereby reducing trap shyness. Suggested baits, which depend on the species being trapped, include apple slices, sunflower seeds, peanut butter, and rolled oats. **Multiple-capture live traps** for nutria have potential to increase trapping efficiency and provide another tool to gain control of burgeoning invasive species (Witmer et al. 2008a).

Foothold traps are manufactured in several sizes and designs (Fig. 34.17). Traditional foothold traps are commonly used for beaver, muskrat, and nutria control, while smaller sizes are used to capture tree and ground squirrels, rats, and marmots. Use of foothold traps, body-gripping traps, and snares is controversial; however, when properly used they are effective and valuable wildlife management tools. Some states prohibit their use, whereas others permit only traps with padded or offset jaws. Like other types of traps, there is potential to capture nontarget species. This danger can be lessened by using proper trap sizes, pan tension devices, breakaway mechanisms, species-specific baits, and selecting trap locations that target the habits of the species being trapped (Conover 2002).

Fig. 34.16. Live traps come in a variety of sizes and styles for almost any mammalian species. *Photo by M. Lavelle.*

Body-gripping traps, primarily **Conibears** (see Fig. 34.17E), are used in water sets for beaver, muskrat, and nutria. Manufactured in a variety of sizes, they have the humane feature of killing quickly. These traps have a pair of opposing, heavy-gauge rectangular rods that close like scissors when triggered, killing the animal with a quick body blow. Conibear traps are lightweight and easy to use. They can be placed at entrances of burrows and lodges and in dams, runs, and slides. Care should be taken when large Conibear traps are used due to the potential hazard to pets, children, and nontarget species. Some states prohibit the use of dry-land sets.

Body-gripping traps also are available for moles and pocket gophers. For moles, the trap is placed over a section of the burrow that has been intentionally collapsed or compressed by the broad trap pan. The trap is activated when a mole, traveling the runway, pushes up on the compressed roof, trips the trigger pan, and is caught by the loops or scis-

sor action of the jaws. The **harpoon trap** is set in a similar fashion, but a spring-loaded harpoon spears the mole. For gophers, traps are placed into the exposed laterals or main tunnels of the burrow system. The openings can then either be left exposed or covered.

Snap traps are most commonly used for controlling rats and mice, and are used regularly in houses and other buildings. Advantages to using snap traps include reduced danger to children or pets compared to some chemicals, easy recovery of killed animals, and no contaminants. Obstacles such as boxes or boards can be used to direct rodents to traps. **Preferred baits** include a mix of peanut butter and rolled oats, a small piece of bacon or apple, or a raisin. Snap traps can be used outdoors to capture small field rodents when only a few animals are involved, or to capture animals for identification or population ecology studies.

Beaver can be captured as effectively with snares as with Conibear or foothold traps (Weaver et al. 1985). **Snares** cost and weigh less than traps. Depending on whether the snare has a **stop-lock device** to restrict tightening, the behavior of the captured animal and the length of time it has been held, as well as the part of the anatomy that is being held, the animal may or may not die before it can be found and released. Snares also are effective in controlling small populations of rabbits. Animals must be traveling a well-defined trail or using a specific entrance such as a hole in a fence. Snares are made of a loop of lightweight wire or cable incorporating a **locking device** to prevent the animal from backing off the tension in the cable. Snares can be set to kill the captured animal or to hold it by the leg or neck. Research is being conducted to make snares more species-selective. State wildlife regulations should be checked to ascertain legality of snare usage.

Shooting can be a selective method of eliminating individual pest mammals. Small-bore shotguns, rifles, and air guns are effective firearms. Some animals can be shot most effectively at night by using a spotlight with a red lens or night-

Fig. 34.17. Examples of several types of traps, including foothold (B, C, D, and F), snares (A and G), and body-gripping trap (E).

Photo by M. Lavelle.

vision equipment. Shooting is especially useful in controlling animals with low reproductive rates, such as porcupines. Local wildlife codes must be reviewed before shooting is used. Shooting at night, in particular with a spotlight, is not legal in some states.

CARNIVORES AND OTHER MAMMALIAN PREDATORS

Damage Assessment

Depredations of livestock by mammalian predators have been a concern to livestock producers for many centuries. In the United States, 224,200 sheep and lambs were estimated to have been lost to predators in 2004 (Agricultural Statistics Board 2005). Losses to predators represented 37% of total losses to all causes and resulted in loss of \$18 million to farmers and ranchers. In 2004, depredations of sheep and lambs were mainly caused by coyotes (60%), dogs (*Canis lupus familiaris*; 13%), mountain lions (*Puma concolor*; 6%), and bears (*Ursus arctos horribilis* and *U. americanus*; 4%). Cattle and calf losses to predators in the United States totaled 190,000 head during 2005 with an estimated loss of **\$92.7 million** (Agricultural Statistics Board 2006). Losses to predators accounted for only 5% of total losses. **Coyotes** caused 51% of predator losses to cattle and calves, followed by **dogs** (11%). Losses of poultry to predators, although not well documented, also are believed to be substantial (Andelt and Gipson 1979). Not only do predators directly kill livestock, but changes in livestock behavior (Kluever et al. 2008) also should be considered.

Predation by coyotes, wolves (*Canis lupus*), bears, and mountain lions can be a significant mortality factor for many ungulate species, mainly white-tailed deer, mule deer, black-tailed deer (*O. h. columbianus* and *O. h. sitkensis*), moose, caribou (*Rangifer tarandus*), and elk (*Cervus canadensis*; Linnell et al. 1995, Ballard et al. 2001). Predation on neonatal ungulates with losses >50% of the fawn cohort is commonly documented, especially in areas with coyotes (Barrett 1984, Hamlin et al. 1984, Whittaker and Lindzey 1999). Whether predation is a factor regulating ungulate populations, and whether predator control can enhance ungulate populations, continues to be a matter of debate among scientists (Connolly 1978, Messier 1991, Sinclair 1991, Boutin 1992, Ballard et al. 2001) and remains controversial with the general public (Kellert 1985, Andelt 1987).

Predation by red foxes (*Vulpes vulpes*), skunks (genera *Conepatus*, *Mephitis*, and *Spilogale*), raccoons (*Procyon lotor*), and mink (*Mustela vison*) can be a major source of mortality to waterfowl (Sovada et al. 2001, Pearse and Ratti 2004), grouse (subfamily Tetraoninae; Hewitt et al. 2001, Schroeder and Baydack 2001), ring-necked pheasant (*Phasianus colchicus*; Riley and Schulz 2001), quail (subfamily Odontophorinae; Rollins and Carroll 2001), Neotropical migrant songbirds (Heske et al. 2001), and rare or endangered species

such as sea turtles (family Cheloniidae; Ratnaswamy et al. 1997, Engeman et al. 2006), forest mammals (Dexter and Murray 2009), and rare birds (Hartman et al. 1997). Predation may affect nest success, juvenile survival, and adult survival. The **red fox** is possibly the most serious predator of waterfowl because it can kill nesting hens as well as destroy eggs (Sargeant et al. 1984). Nest predation by **raccoons and skunks** also can impact nesting waterfowl, as well as threatened and endangered bird species.

How predators impact other predators is a topic of growing interest (Johnson et al. 1996). Many larger predators directly kill smaller competing carnivores, some of which are endangered species or species of concern; see Johnson et al. (1996) and Creel et al. (2001) for reviews on **interspecific competition** and intra-guild predation. For example, coyotes killing swift foxes (*V. velox*; Sovada et al. 1998, Schauster et al. 2002) and kit foxes (*V. macrotis*; White and Garrott 1999, Cypher et al. 2000) has been well documented, with this level of mortality possibly causing population declines or limiting recruitment (White et al. 2000, Kamler et al. 2003, Karki et al. 2007). Recent reintroductions of wolves into the northern Rocky Mountains has brought about changes in coyote abundance (Berger and Gese 2007) and a subsequent shift in trophic interactions resulting in an increase in pronghorn (*Antilocapra americana*) fawn survival (Berger et al. 2008). **Indirect effects**, such as spatial avoidance or segregation, temporal separation, and resource partitioning, also are influential on the distribution and dynamics of smaller sympatric predators (Creel et al. 2001, Gosselink et al. 2003, Thornton et al. 2004). Understanding the interactions between competing predators will continue to be important, particularly in areas where increased human development will limit available habitat (Creel et al. 2001).

Actually witnessing a predator killing a prey item is rare. Therefore, an accurate assessment of a predation event requires careful observational skills (O'Gara 1978a, Bowns and Wade 1980). O'Gara (1978a), Wade and Bowns (1982), and Acorn and Dorrance (1998) provide a review of examination and identification of predators involved in depredation events. In general, upon arrival at a depredation site, personnel should approach the site carefully, and be sure not to trample tracks, feces, blood, vegetation, or other evidence that may assist in identifying the cause of death and the predator involved (if it is predation). **Signs of predation** and the possible predator involved should be searched for on the prey item and around the kill site. Collection of salivary **DNA** samples from the attack wounds can be used to identify the responsible predatory species, as well as the sex and identity of the individual animal (Blejwas et al. 2006). These sterile samples should be collected prior to handling or skinning the carcass to prevent sample contamination. Extensive **hemorrhaging** usually is characteristic of predation. If predation is suspected, skinning the carcass (particularly around the neck, throat, and head) may provide clues

to the predator involved by examination for subcutaneous hemorrhage, tissue damage, and the size, spacing, and location of tooth marks (O'Gara 1978a, Wade and Bowns 1982). Hemorrhaging occurs only if the skin and tissue damage occurred while the animal was still alive. Animals that die from causes other than predation normally do not show external or subcutaneous bleeding, although bloody fluids may be lost from body openings (O'Gara 1978a, Wade and Bowns 1982). The cause of death is best evaluated if the carcass is examined when fresh. **Tracks and scats** alone are not proof of depredation or of the species responsible, only that a particular predator is in the area. Other signs associated with a depredation event include nervous or alert livestock, injured livestock, or females calling or searching for young (Acorn and Dorrance 1998). Thus, all evidence must be considered to ascertain whether the death was due to a predator and the predatory species responsible. Many predators will scavenge carcasses; hence, scavenging should not be confused with predation. Although not tested for this purpose, scent-matching dogs (Smith et al. 2003) hold promise as a method to detect and identify the predator species at a kill site, and even to identify the individual animal (Kerley and Salkina 2007).

Identification of Species Damage

Badgers

Badgers are opportunistic feeders, preying primarily on mice, prairie dogs, marmots, pocket gophers, ground squirrels, and occasionally on rabbits (especially young; Messick 1987, Lindzey 1994). Badgers destroy nests of ground-nesting birds and occasionally kill small lambs and poultry. Their burrows in a field may slow harvesting or cause damage to machinery, and their digging can damage earthen dams or dikes (Lindzey 1994, VerCauteren et al. 2005a). Badger tracks appear similar to coyote tracks, but badger tracks appear to be pigeon-toed and impressions from the long toenails are apparent under most conditions (Murie 1954). Signs of digging near prey remains may be the best evidence of badger activity. **Damage management techniques** include fencing, frightening devices, traps (foothold), snares and shooting.

Black and Grizzly Bears

Conflicts with bears occur when they prey on livestock, feed on field crops, destroy beehives, or become a nuisance around campgrounds, cabins, landfills, and garbage dumps (Hygnstrom 1994, Jonkel 1994, Baruch-Mordo et al. 2008). Bears usually kill by biting the neck or by slapping the victim, leaving a mauled and mutilated carcass (O'Gara 1978a, VerCauteren et al. 2005a); the neck may be broken (Acorn and Dorrance 1998). Bears will trample the vegetation and often vomit or defecate near the carcass. Large prey items are usually opened ventrally and the heart and liver consumed (Bowns and Wade 1980); the udder of lactating females may be consumed. The intestines often are spread

around the site, and the animal may be partially skinned where the carcass is fed upon (VerCauteren et al. 2005a). Sheep and goats may be consumed almost entirely, with only the rumen, skin, and large bones remaining (Acorn and Dorrance 1998). Bears use their feet while feeding, and do not slide the prey around (O'Gara 1978a). However, if the prey is killed in the open, the carcass may be dragged to a secluded spot before or after initial consumption (Acorn and Dorrance 1998).

Brown bears have a feeding and killing pattern similar to that of black bears (Jonkel 1994), but they usually cover their prey after the initial feeding, whereas black bears rarely cover the prey item (Acorn and Dorrance 1998). Cattle are usually killed by a bite through the back of the neck and large prey often has claw marks on the flanks or hams. The back of an ungulate is often broken in front of the hips where the bear pushes the animal down. Young calves are sometimes bitten through the forehead. Sheep may stampede at the onset of a bear attack and injure or kill themselves by tripping on downed timber.

Urbanization has brought about an increase in human–bear interactions (Baruch-Mordo et al. 2008), particularly in the western United States. Availability of anthropogenic food sources in towns occupying mountainous regions has increased conflicts between bears and humans, with subsequent effects to local bear populations (Beckmann and Lackey 2008). Some of these conflicts were originally believed to be the result of **social learning** (i.e., sows teaching their cubs to raid garbage), but genetic evidence suggests, “the acquisition of food conditioning behavior was not solely a function of social learning or inheritance” (Breck et al. 2008:428).

Black bears can cause significant damage to trees, especially in second-growth forests (Noble and Meslow 1998, Partridge et al. 2001, Nolte and Dykzeul 2002). Damage can be recognized by the large, vertical incisor marks and claw marks on the sapwood and ragged strips of hanging bark, or branches broken to feed on fruit (Hygnstrom 1994). Most bark damage occurs during May to July. Damage to field crops also can be substantial, with corn and oats being preferred crops (Hygnstrom 1994). **Damage management techniques** include supplemental feeding, aversive conditioning, fencing, frightening devices, hazing, repellents, traps (foothold and live traps), foot snares, and hunting with dogs.

Coyotes, Wolves, and Dogs

These canid predators prey on animals ranging in size from big game and livestock to native birds, poultry, and rodents (Andelt and Gipson 1979, Carbyn 1987, Voigt and Berg 1987). **Coyotes** are the most common and most serious predator of livestock in the western United States (Agricultural Statistics Board 2005) and are becoming more of a problem in the eastern United States. Coyotes normally kill livestock with bites to the neck and throat, but may pull the animal down by attacking the side and hindquarters (O'Gara 1978a,

Wade and Bowns 1982, Green et al. 1994, Acorn and Dorrance 1998). The rumen and intestines are not eaten, but often removed and dragged away from the carcass. When canids kill small lambs, their upper canine teeth can penetrate the top of the neck or the skull (Wade and Bowns 1982). Calf predation by coyotes is most common when calves are young. Calves attacked, but not killed, exhibit wounds to the flank, hindquarter, or front shoulder (Wade and Bowns 1982). Deer that are killed are completely dismembered and eaten (VerCauteren et al. 2005a). With increased urbanization, complaints of pets being killed by coyotes have increased and attacks on humans (mainly children) are an increasing concern in urban areas. Agricultural producers using drip irrigation systems report that coyotes chew holes in plastic pipe and disrupt irrigation (Werner et al. 1997). Fruit crops, particularly watermelons (*Citrullus lanatus*), also can be consumed or damaged by coyotes (Green et al. 1994).

Wolves prey mainly on larger ungulates such as deer, caribou, moose, elk, and cattle. Cattle, especially calves, are most vulnerable to wolf predation (Paul and Gipson 1994, Acorn and Dorrance 1998), as are domestic sheep (Gula 2008). Although predation on livestock is usually rare (Fritts et al. 1992, Oakleaf et al. 2003), wolf predation on cattle and sheep has been increasing in the Northern Rocky Mountain states as wolf recovery progresses (Bangs et al. 2006). Wolves usually kill ungulates by attacking the hindquarters or by seizing the flanks (Paul and Gipson 1994). Slash marks made by the canine teeth may be found on the rear legs and flanks (VerCauteren et al. 2005a). When the victim is badly wounded and collapses, wolves will often disembowel the animal (Paul and Gipson 1994). Wolves usually eat the viscera and hindquarters first. Most of the carcass is consumed and large bones may be chewed or cracked open (Acorn and Dorrance 1998). Wolves may carry parts of the carcass to dens or rendezvous sites for the pups to consume.

Domestic dogs can be a serious problem to livestock, especially to sheep pastured near cities and suburbs (Green and Gipson 1994). Dogs may be indiscriminate as to how and where they attack, but often attack the hindquarters, flanks, and head, and rarely kill as effectively as coyotes (Green and Gipson 1994, VerCauteren et al. 2005a). O'Gara (1978a) considered dogs to be "sloppy" killers, often slashing and tearing victims and leaving many cripples (Acorn and Dorrance 1998). If dogs eat sheep or big game, they normally eat the hams and often vomit near the site (O'Gara 1978a). Normally little flesh is consumed (Green and Gipson 1994, Acorn and Dorrance 1998). Dogs generally wound the animal in the neck and front shoulders; the ears often are badly torn (VerCauteren et al. 2005a). Attacking dogs often severely mutilate the prey (Acorn and Dorrance 1998); skinning the animal will often reveal 80% of the body bruised by bites that did not penetrate the skin (O'Gara 1978a).

Coyote and dog tracks are similar, but distinguishable. The larger size of wolf tracks often separates them from

coyotes and dogs. Coyote tracks are more oval in shape and compact than dogs (Green et al. 1994, Acorn and Dorrance 1998). Dog tracks are round with the toes spread apart and toenail marks usually are visible on all toes. Coyote tracks tend to follow a straight line more closely than dogs (Murie 1954, Green et al. 1994). **Damage management techniques** include livestock husbandry practices, livestock protection collars, guard animals (dogs, llamas [*Lama glama*], and donkeys [*Equus asinus*]), electronic training collar, fencing, frightening devices, reproductive interference, M-44s, aerial hunting, calling and shooting, denning, traps (foothold), and snares.

Mountain Lions, Bobcats, and Lynx

Felids that cause damage are primarily mountain lions, bobcats, and lynx (*L. canadensis*). **Mountain lions** are primarily carnivorous and prey on native ungulates (mainly deer and elk), and livestock (particularly horses, sheep, goats, and cattle; Lindzey 1987). They also will eat rodents and other small mammals when available (VerCauteren et al. 2005a). Livestock depredations are often random and unpredictable; it is common for several animals to be killed in a short period of time (Knight 1994a).

Sheep, goats, calves, and deer are typically killed by mountain lions with bites to the top of the neck or head (Knight 1994a, Acorn and Dorrance 1998). Lions also may sever the vertebral column and break the neck of their prey. Mountain lions kill in a similar manner to bobcats, but the tooth punctures will be larger (0.63–0.79 cm) and more round than bobcat punctures (O'Gara 1978a). Strips of skin also will be present at the kill site from the lacerations caused by the lion's claws. Mountain lions usually feed first upon the shoulders of their prey (O'Gara 1978a). The stomach generally is untouched (Acorn and Dorrance 1998). The large leg bones of prey may be crushed and ribs may be broken (VerCauteren et al. 2005a). Often a lion will cover its kill with soil, leaves, grass, and debris (Knight 1994a) and may return to feed for 3–4 nights. They normally uncover the kill at each feeding and move it 10–25 m before covering the carcass again. After the last feeding, the remains may be left uncovered (Shaw 1983).

Mountain lion tracks may be difficult to observe except in snow or sandy or wet soil (Murie 1954). Adult lion tracks are approximately 10 cm across and have a distinguishable 3-lobed heel pad (Knight 1994a). Mountain lions have retractable claws; therefore, no claw marks will be evident. Large dog tracks could be confused with lion tracks. However, dog tracks normally show distinctive claw marks, are less round than mountain lion tracks, and have different heel-pad marks (VerCauteren et al. 2005a).

Bobcats are opportunistic predators, feeding mainly on rabbits, rodents, and birds (Rolley 1987). They will occasionally kill and consume poultry, goats, small dogs, house cats, and rarely, calves (Virchow and Hogeland 1994) and sheep (Neale et al. 1998). Bobcats usually kill their prey by biting

the back of the neck or base of the skull (O’Gara 1978a). Bobcats often may be carried a short distance by an adult deer before completing the kill. Victims usually die of suffocation and shock, or from dislocated neck vertebrae. Hair and strips of hide may be found at the site where the cat first attacked. **Scratches** are usually evident on the shoulders, back, or sides of the prey (Virchow and Hogeland 1994). Bobcats often attack and kill lambs by holding the victim with their claws while biting the neck or head. Skulls of the victim may be fractured, but not crushed like those bitten by coyotes (O’Gara 1978a). The hindquarters of deer or sheep usually are eaten first by bobcats, although the shoulder, neck, or flank also may be consumed first. The rumen is often untouched. Carcasses are usually covered before being left and may be buried under leaves, snow, or soil, or the remains may be carried and cached under shrubs (O’Gara 1978a, Virchow and Hogeland 1994). Bobcats reach out 30–35 cm when covering their kill, whereas mountain lions reach out to 90 cm (Young 1958). Poultry usually are killed by biting the head and neck (Young 1958); the heads usually are eaten. Tooth punctures from a bobcat are similar to those of a coyote, but tend to slash more than those of canids (O’Gara 1978a). The distance between the canine teeth marks also will help distinguish a mountain lion kill from a bobcat kill: 3.8 cm versus 1.9–2.5 cm, respectively (Wade and Bowns 1982). **Lynx** may kill livestock (Odden et al. 2008), but mainly specialize on snowshoe hares (*Lepus americanus*; Quinn and Parker 1987). Bobcat and lynx feces are similar in size and shape (Murie 1954). In areas inhabited by both species, careful examination of the tracks will help identify the species responsible for a depredation event. The lynx has larger feet with much more hair, and the toes tend to spread more than those of bobcats (Murie 1954). Small **Neotropical felids** in the United States, such as the ocelot (*Leopardus pardalis*), margay (*L. wiedii*), and jaguarundi (*Herpailurus yagouaroundi*), pose little threat to livestock, but may occasionally kill a chicken. They mainly consume native birds, small mammals, and reptiles (Tewes and Schmidly 1987). **Damage management techniques** include fencing, frightening devices, traps (foothold), snares, and hunting (by calling and shooting and with dogs).

Foxes

Gray (*Urocyon cinereoargenteus*) and **red foxes** feed primarily on rabbits, hares, small rodents, poultry, birds, fruit, and insects (Voigt 1987). Although poultry is the most commonly killed domestic prey, red foxes (and to a lesser extent gray foxes) may prey on livestock, mainly lambs and kids (Phillips and Schmidt 1994). Predation of poultry by **swift and kit foxes** is almost nonexistent (O’Farrell 1987, Scott-Brown et al. 1987). **Arctic foxes** (*V. lagopus*) may prey on livestock (Garrott and Eberhardt 1987). Foxes usually attack the throat of lambs and kids, but kill some prey by multiple bites to the neck and back (Wade and Bowns 1982, VerCauteren et al.

2005a). Foxes do not have the body or jaw power of larger canids; thus, they are unable to seize and immobilize large prey and multiple bites may be evident (Wade and Bowns 1982). Foxes generally eat the viscera first and may begin feeding through the ribs. Foxes killing fowl usually leave behind only a few drops of blood and feathers and carry the prey from the kill location (Phillips and Schmidt 1994). Eggs usually are opened enough to allow the contents to be licked out and are often left beside the nest (VerCauteren et al. 2005a).

When attempting to identify the predator of a depredated animal, note the canine teeth are smaller and the spacing is narrower in foxes compared to coyotes (Wade and Bowns 1982). Red fox tracks may resemble coyote tracks, but fox tracks are generally smaller than coyote tracks and have a shorter stride (Murie 1954). Gray fox tracks are slightly smaller than those of red foxes. **Damage management techniques** include guard dogs, fencing, frightening devices, M-44s, aerial hunting, traps (foothold), snares, calling and shooting, and hunting dogs.

Opossums

Opossums (*Didelphis marsupialis*) are primarily insectivorous and omnivorous and prefer fish, crustaceans, insects, mushrooms, fruits, vegetables, eggs, and carrion (Seidensticker et al. 1987). Opossums will occasionally raid poultry houses and generally kill one chicken at a time, often mauling the victim. Eggs will be mashed and messy; the shells often are chewed into small pieces and left in the nest. Young poultry or game birds are consumed entirely. Opossums in urban areas may be a nuisance where they get into garbage cans, compost piles, bird feeders, and pet food (Jackson 1994a). **Damage management techniques** include fencing, traps (foothold and live traps), shooting, and hunting dogs.

Raccoons

Raccoons are omnivorous predators, eating mice, birds, snakes, frogs, insects, crawfish, grass, berries, acorns, corn, melons, turtle eggs, and various grain crops (Sanderson 1987). Raccoons are notorious for raiding fields of sweet corn and tearing ears off the plants. In watermelon fields, raccoons will dig into the melon and scoop out the contents with their front paws (Boggess 1994). In urban areas, raccoons readily raid garbage cans and dumps. They cause damage to buildings when gaining access to attics and chimneys. Agricultural fields and gardens near wooded areas may experience damage from raccoons. Raccoons may prey on eggs and young of ground- and cavity-nesting birds, or raid artificial nesting structures (Boggess 1994). Predation by raccoons on nests of sea turtles (Ratnaswamy et al. 1997), ancient murrelets (*Synthliboramphus antiquus*; Hartman et al. 1997), and other threatened and endangered species is a growing concern for conservation efforts.

Raccoons rarely kill small lambs. When they do, they usually grab their prey with their paws and bite the neck

(O’Gara 1978a). Similar to the bites of a fox, bites from a raccoon attack usually encircle the whole neck (O’Gara 1978a). Skinning the carcass will reveal bruises where the prey was grabbed, but not deep scratches as with bobcats. Raccoons often feed on a carcass at the loins or by making a small hole in the side of the carcass and pulling the viscera from the body cavity to consume it (O’Gara 1978a). Raccoons occasionally raid poultry houses and may kill many birds in a night. The heads of adult birds are usually bitten off and left, the breast and crop may be torn and chewed, and the entrails may be consumed (Boggess 1994). Young birds in pens or cages may be killed or injured when the raccoon grabs a bird through the wire mesh and tries to pull it from the cage. Eggs may be removed and eaten away from the nest, or consumed on the spot with only shell fragments remaining.

Raccoons leave a distinctive 5-toed track resembling a small human handprint (Boggess 1994). Tracks usually are paired, and the left hind foot is placed beside the right forefoot. Raccoon and opossum tracks can be difficult to distinguish in soft sand where toe prints are not distinctive. **Damage management techniques** include fencing, traps (foothold and live traps), shooting, and hunting dogs.

Skunks

Skunks are opportunistic omnivorous predators consuming insects (particularly grasshoppers, beetles, and crickets), bird eggs, mice, and occasionally rats and cottontail rabbits (Rosatte 1987, Knight 1994b). Skunks become a nuisance when they dig small (7–10-cm), cone-shaped holes, or turn over patches of earth in lawns, gardens, and golf courses in search of insect grubs (VerCauteren et al. 2005a). They may burrow under porches and buildings. Their odor is a common complaint when they take up residence under human dwellings. Skunks may damage beehives when attempting to eat the bees.

Skunks are major predators of waterfowl nests. Non-lethal techniques to reduce skunk predation on waterfowl nests have had limited success (Greenwood and Sovada 1996, Greenwood et al. 1998). Skunks occasionally kill domestic poultry and eat eggs, but usually will not climb fences to raid poultry houses (Knight 1994b). When skunks kill poultry, they generally kill only 1–2 birds, and often maul them. Eggs usually are opened at one end with the edges crushed inward as the skunk punches its nose into the hole to lick out the contents (Knight 1994b). When in a more advanced stage of incubation, eggs are likely to be chewed in small pieces. Eggs may be removed from the nest, but are rarely moved far (VerCauteren et al. 2005a).

Inhabited dens can be recognized by fresh droppings containing undigested insect parts near the mound or hole (VerCauteren et al. 2005a). Dens usually have a characteristic skunk odor, although the odor may not be strong. Tracks are relatively distinctive with both front and rear feet having

5 toes, with claw marks often visible (Knight 1994b). The heel of the forefeet may not be visible and in some cases, the fifth toe may not be obvious (Knight 1994b). **Damage management techniques** for skunks include fencing, repellents and fumigants, traps (foothold and live traps), and shooting.

Weasels and Mink

Weasels (*Mustela erminea*, *M. frenata*, and *M. nivalis*) feed mainly on insects and small rodents, and occasionally prey on birds, fish, amphibians, reptiles, nests of ground-nesting birds, and berries (Fagerstone 1987). Mink are generalists and feed mainly on small rodents, muskrats, and lagomorphs. Mink also will prey upon fish, birds, and invertebrates (Eagle and Whitman 1987). Weasels and mink have a similar killing pattern in which they bite the prey item through the skull and upper neck. When feeding on muskrats, mink will often make an opening at the back or side of the neck. As the mink consumes the flesh, ribs, and pieces of the adjacent hide, the head and hindquarters are pulled through the same hole and the animal is skinned; weasels demonstrate a similar feeding pattern when consuming small rodents.

Weasels and mink will raid poultry houses at night and kill or injure fowl (Henderson 1994b). They often kill many birds by biting them in the head and often eat only the heads of the victims, but will consume the body as well. Rat predation usually differs from weasel predation in that portions of the chicken are eaten and carcasses are dragged into holes or concealed places (Henderson 1994b). Waterfowl eggs destroyed by weasels tend to be broken at the ends, with openings 15–20 mm in diameter (Teer 1964). Close examination of shell fragments will often disclose finely chewed edges and tiny tooth marks left by a weasel (Rearden 1951).

Weasels den in burrows in the ground, under rocks or brush piles, in barns, or in piles of stored hay (VerCauteren et al. 2005a). The den itself is an enlarged chamber (3.5–5.0 cm) lined with dry grass and the fur of previous kills (Fagerstone 1987). **Mink** may use cavities in roots of trees, rocks, brush piles, logjams, and beaver lodges (Eagle and Whitman 1987). Mink also will use abandoned burrows of other animals as den sites, especially those of muskrats. **Damage management techniques** include fencing and traps (Conibear, foothold, and live traps).

Feral Cats

Feral cats are house cats living in the wild, although even house cats can cause damage by killing native small mammals and songbirds (Soulé et al. 1988, Crooks and Soulé 1999). Feral cats are opportunistic predators that prey on ducks, pheasants, rabbits, quail, rodents, insects, reptiles, amphibians, and fish (Fitzwater 1994). Similar to feral dogs, feral cats are often described as “sloppy” killers, with parts of their prey strewn about when feeding. Cats generally consume the meaty portions of large birds, leaving loose skin with

feathers attached (VerCauteren et al. 2005a). Small birds generally are consumed and only the wings and scattered feathers remain. Cats usually leave tooth marks on every exposed bone of their prey. Nesting birds are vulnerable to cat predation and cats can exact a heavy toll on bird populations (Churcher and Lawton 1987, Jurek 1994, Coleman et al. 1997). Unlike domestic house cats, feral cats often are extremely wary of humans. **Damage management techniques** include fencing, frightening devices (dogs), traps (foothold and live traps), snares, and shooting.

Management Techniques

Protecting livestock and poultry from predators is a complex endeavor, with each case requiring an assessment of the legal, social, economic, biological, and technical aspects, with no one technique solving the problem in all circumstances (Knowlton et al. 1999, Bangs et al. 2006). Successful resolution of conflicts with predators involves an analysis of the efficacy, selectivity, and efficiency of various management scenarios (Knowlton et al. 1999, Gese et al. 2005), with an integration of opportunities to empower the local public to protect their private property (Bangs et al. 2006). **Control techniques** may be considered either **corrective** (after a depredation event) or **preventive** (before the event). Selectivity of the technique is important when attempting to solve the depredation problem (Mitchell et al. 2004). Results from general population reduction are mixed. Sometimes reducing the size of the predator population reduces depredations (e.g., Herfindal et al. 2005), while other times it has no effect on solving the depredation problem (e.g., Conner et al. 1998). Certain techniques (e.g., livestock protection collars, calling and shooting) that **selectively** remove the offending individual (Sacks et al. 1999a, b; Blejwas et al. 2002) are **nonselective** techniques (e.g., traps or snares) that predators learn to avoid (Sacks et al. 1999a), or that may create more wary animals (Mettler and Shivik 2007). Identifying the “problem” animal can be difficult (Linnell et al. 1999). Methods that are more benign in their effects on other species are preferred to those creating greater perturbations (Knowlton et al. 1999). Often, providing livestock producers a variety of tools to manage depredation may improve the likelihood of acceptance of predators (Bangs et al. 2006). Increased predation on livestock may be exasperated when native prey species decline in abundance, thereby reducing their **buffering effects** (Knowlton et al. 1999, Stoddart et al. 2001, Sacks and Neale 2007).

A diverse array of techniques (nonlethal and lethal) has been used to prevent or deter depredations on livestock and poultry (Green et al. 1994, Knowlton et al. 1999, Gese et al. 2005). Regrettably, many of these techniques do not often carry over to protecting wildlife resources. However, Seidler (2009) recently documented that sterilization of coyotes increased pronghorn fawn survival. Some techniques developed for protection of domestic commodities (e.g., fencing, lethal removal) may reduce depredations on natural re-

sources (Ratnaswamy et al. 1997, Garrettson and Rohwer 2001), but are generally limited to small-scale applications. Most nonlethal procedures are within the operational purview of the agricultural producer. Livestock producers spent close to \$200 million on **nonlethal techniques** in 2005, with **guard animals, exclusion fencing, and frequent checking of stock** the most common methods employed (Agricultural Statistics Board 2006). Although there are reports of success with some methods, failures are common; few such methods have been subjected to critical evaluation or testing, and none have proven a panacea (Knowlton et al. 1999).

Livestock Husbandry Practices

Various livestock management practices have been suggested as a means of reducing depredation losses (Robel et al. 1981, Wagner 1988, Acorn and Dorrance 1998). Some of the most common **practices include** (1) confining or concentrating flocks during periods of vulnerability (e.g., at night or during lambing), (2) using herders, (3) shed-lambing, (4) removing livestock carrion from pastures, (5) synchronizing birthing, and (6) keeping young animals in areas with little cover and in proximity to human activity (Knowlton et al. 1999). These procedures generally require additional resources and effort, and frequently only delay onset of predation, or may have undesirable side effects (Knowlton et al. 1999). For these methods to be effective, producers must develop strategies for their own situations. Producers also must realize that economic advantages of modifying their husbandry practices may be difficult to demonstrate (Knowlton et al. 1999), but can assist in herd management and production. Surveys indicate that producers used fencing (52%), night penning (33%), and guard dogs (32%) in their sheep management operations (Agricultural Statistics Board 2005).

Guard Dogs

Use of **guard dogs** to deter coyotes from livestock has been used traditionally by many sheep producers, particularly in fenced pastures (Acorn and Dorrance 1998). In several western states, about 32% of producers surveyed used guard dogs to protect their flocks (Agricultural Statistics Board 2000). In Colorado, Andelt (1992) reported that sheep producers estimated their guard dogs saved an average of \$3,216 worth of sheep annually and reduced their need for other control techniques. **Dog breeds** most commonly used as livestock guardians include Great Pyrenees, Komondor, Akbash, Anatolian, and Maremma (Fig. 34.18). Although there does not appear to be one breed that is most effective, livestock producers rated Akbash as more effective at deterring predation because it was more aggressive, active, intelligent, and faster (Andelt 1999). The Great Pyrenees was the most common guard dog breed in Alberta, Canada (Acorn and Dorrance 1998). Studies investigating efficacy of guard dogs have shown the dogs to be effective in some situations and ineffective in others (Linhart et al. 1979, Coppinger et al. 1983, Green et al. 1984, Green and Woodruff 1987, Conner

Fig. 34.18. Various dog breeds can be used to defend domestic livestock from predators. Photo by U.S. Fish and Wildlife Service.

1995, Andelt and Hopper 2000). This disparity may be due to the inherent difficulty guard dogs have in effectively protecting large flocks that are dispersed over rough terrain and/or in areas where thick cover conceals approaching predators. Training and close supervision of the dogs are important for success with this technique (Acorn and Dorrance 1998). Some poorly trained or minimally supervised guard dogs have killed sheep and lambs, harassed or killed wildlife, and threatened people that intrude upon their territory. However, not all guard dog failures or undesired behaviors stem from poor training or supervision. There is considerable behavioral diversity within a litter of guard dog pups; some turn into valuable and effective guard animals, while others do not, despite similar training and effort. Use of guard dogs precludes use of other control devices (e.g., traps, snares, M-44s) and techniques (e.g., calling and shooting; Knowlton et al. 1999). Dogs can be killed or injured by poisons, snares, and traps used for predator control (Acorn and Dorrance 1998).

Guard Llamas

Use of **llamas** for protecting livestock from predators takes advantage of the llama's evolution with predators and their aggressiveness toward predators (Fig. 34.19). Use of llamas as guard animals is growing in popularity, with about 22% of western producers surveyed using them (Agricultural Statistics Board 2000). Studies have found use of llamas to be a practical and effective technique to deter predators, mainly coyotes and dogs, from depredating livestock (Franklin and Powell 1994, Meadows and Knowlton 2000). Llamas can be kept in fenced pastures with sheep or goats, do not require any special feeding program, are relatively easy to handle, and live longer than guard dogs (Knowlton et al. 1999). Although guard animals may not deter coyotes from inhabiting the immediate area near livestock, they may change predators' behavior and activity patterns when in those areas (Knowlton et al. 1999). Traits that may be useful in selecting a guard llama include dominance, alertness, and body weight (Cavalcanti and Knowlton 1998).

Guard Donkeys

Donkeys also have been used as livestock guardians (Green 1989, Acorn and Dorrance 1998), with about 6% of produc-

ers in the western United States using donkeys as a management tool (Agricultural Statistics Board 2000). The protective behavior of donkeys apparently stems from their dislike of dogs. A donkey will bray, bare its teeth, chase, and try to kick and bite coyotes and dogs (Acorn and Dorrance 1998). Recommendations on using guard donkeys include using only a jenny (female) or gelded jack (male; intact jacks are too aggressive toward livestock), and placing one donkey per flock or group while keeping other donkeys or horses away to prevent the guard donkey from bonding with any animal except those to be protected. Furthermore, donkeys should be introduced to the livestock about 4–6 weeks prior to the onset of anticipated predation events to properly bond with the group (Acorn and Dorrance 1998). Donkeys are most effective in small, fenced pastures.

Supplemental Feeding

Supplemental feeding, to divert a predator from a vulnerable commodity, has received some attention. Many predators will readily consume food provisioned by humans. Greenwood et al. (1998) found that although skunks and other predators responded to supplemental feeding, depredations on waterfowl nests remained unchanged. They concluded that food provisioning had limited value for managing depredations on waterfowl nests in the Prairie Pothole region of North America because the predator community was large and complex. In the Pacific Northwest, black bears damage coniferous trees by feeding on sapwood during spring (Noble and Meslow 1998, Partridge et al. 2001). Collins (1999) reported that damage to trees by black bears was highest in areas where bears did not receive supplemental feeding (i.e., pellet feeders). Supplemental feeding of bears reduced damage to the trees (Ziegeltrum 2004), with apparently no long-lasting effect on bear condition or productivity (Partridge et al. 2001). One also must consider how the animal community may respond to supplemental feeding. Godbois et al. (2004) observed that supplemental feeding of northern bobwhite (*Colinus virginianus*) resulted in a spatial

Fig. 34.19. Llamas are often used to defend domestic sheep from predators. Photo by U.S. Fish and Wildlife Service.

response of bobcats; radiocollared bobcats were found 10 times closer to the supplemental food than expected.

Fencing and Barriers

Livestock, poultry, crops, and waterfowl and sea turtle nests may be protected from predators with a properly constructed and located barrier. However, West et al. (2007) documented that red foxes routinely penetrated fences designed to protect waterfowl nests, and they questioned many fence designs that had been previously recommended. About 52% of livestock producers surveyed stated that they used fencing to reduce predator losses to sheep and lambs (Agricultural Statistics Board 2005). **Barriers** may take the form of flagging or fladry (Musiani et al. 2003, Shivik et al. 2003), an enclosure, electric fence, nest screen, or even a moat (e.g., deCalesta and Cropsey 1978, Linhart et al. 1982, Shelton 1984, Nass and Theade 1988, Melvin et al. 1992, Lokemoen and Woodward 1993, Ratnaswamy et al. 1997). **Standard fencing** will not keep most predators from entering gardens or poultry ranges because they learn to jump over or dig under such fences. Many large predators may be deterred or excluded by adding an **electrified** single-wire strand charged by a commercial fence charger along a wire mesh fence. The electrified wire should be placed 20 cm outside of the main fence line and 20 cm above the ground (VerCauteren et al. 2005a). A fence 1.5 m high with 9–12 alternating ground and charged wires spaced 10–15 cm apart is an effective barrier against coyotes (Gates et al. 1978, Acorn and Dorrance 1998). A high-tensile **woven-wire fence** that is more versatile, longer lasting, and can be tightened more than conventional wire mesh, also can be used (Acorn and Dorrance 1998).

Skunks may be deterred from entering a poultry area with a 0.9-m-high wire mesh fence extending 0.6 m above-ground and 0.3 m below the surface; a 15-cm length of the portion belowground should be bent outward at right angles and buried 15 cm deep (VerCauteren et al. 2005a). **Mink and weasels** may be excluded from barns or coops by covering all openings larger than 2.5 cm with metal or hardware cloth. **Asiatic black bears** (*U. thibetanus*) in Japan were deterred from entering crop fields and apiaries with an electric fence (Huygens and Hayashi 1999). Installation costs usually preclude use of fences for protecting livestock in large pastures or under range conditions. For wildlife resources, fencing may be best suited to protecting waterfowl nests or high-value commodities in small areas (e.g., sea turtle nests; Ratnaswamy et al. 1997). If electric fencing is used, the behavior of the wildlife resource being protected also should be considered (Trottier et al. 1994) and modifications to the design may assist in protection efforts without deleterious effects on the species being protected (Pietz and Krapu 1994).

Frightening Devices

Lights, distress calls, loud noises, scarecrows, plastic streamers, propane cannons, aluminum pie pans, and lanterns have

been used to **frighten predators** (Acorn and Dorrance 1998). Most testing has focused on devices that periodically emit bursts of light or sound to deter coyotes from sheep in fenced pastures and open-range situations (Linhart 1984; Linhart et al. 1984, 1992), but the benefits are short-lived (Bomford and O'Brien 1990, Koehler et al. 1990, Darrow and Shivik 2009). All of these devices can provide temporary relief from damage or in deterring predators, but habituation and learning by predators is common (Acorn and Dorrance 1998, Shivik 2006). Changing the location of devices, the pattern of the disruptive-stimuli (Shivik 2006), or combining several techniques can prolong the frightening effect (Linhart et al. 1992). Linhart (1984) reported that a combination of **warbling-type sirens and strobe lights** reduced coyote predation on lambs by 44%. These battery-operated devices were activated in the evening by a photocell set on a schedule of 10-second bursts at 7–13-minute intervals. Pfeifer and Goos (1982) found use of **propane exploders** delayed or temporarily prevented lamb losses to coyotes. Similarly, VerCauteren et al. (2003c) reported no kills during the lambing period when flocks were bedded near predator-activated frightening devices. Darrow and Shivik (2009) suggested that **light** may be the most important component of a frightening device. A new device, the **Nuisance Bear Controller**, proved effective at deterring black bears from raiding bird feeders, was relatively inexpensive, portable, and could be used to deter bears from concentrated food sources (Breck et al. 2006).

A recent development used to deter wolf predation is the **Radio Activated Guard (RAG) box** (Shivik and Martin 2001, Breck et al. 2002) and the **Movement Activated Guard (MAG) device** (Shivik et al. 2003). The RAG is activated only when a radiocollared wolf is in the vicinity, preventing habituation of the animal to the lights and siren. The RAG has application only in areas with radioed animals, but can deter endangered predators from causing problems to livestock producers (Breck et al. 2002). The MAG device is activated by a passive infrared detector and sets off lights and sound to scare away predators from the area (Shivik et al. 2003). Use of frightening devices is not widespread, with only 6% of producers using frightening devices (Agricultural Statistics Board 2000). The use of sirens and strobe lights at night near people is generally not acceptable (Knowlton et al. 1999).

Repellents and Aversive Conditioning

Presently, no commercial repellents deter predation (Knowlton et al. 1999). A variety of **gustatory, olfactory, and irritating** compounds have been tested, with a few (e.g., thia-bendazole, pulegone, cinnamaldehyde, allyl sulfide) reducing food consumption among predators (Hoover and Conover 1998, 2000; Ternent and Garshelis 1999). Although quinine hydrochloride and capsaicin may discourage coyotes from chewing on irrigation hoses (Werner et al. 1997), there is little information demonstrating that these repellents deter predation (Lehner 1987, Burns and Mason 1997). Polson (1983)

used thiabendazole to condition black bears to avoid beehives. Ternent and Garshelis (1999) reported that black bears could be discouraged from consuming meals-ready-to-eat (MREs) on a military reservation by treating the MREs with thiabendazole. Skunks may be repelled from areas with ammonia-soaked cloths or mothballs (Knight 1994b).

Conditioned taste aversion, using lithium chloride, to reduce coyote predation on sheep had received much attention >20 years ago. Study results were mixed, with some reporting success (Gustavson et al. 1974, 1982; Ellins and Martin 1981; Forthman-Quick et al. 1985a, b), while others were either unable to replicate those findings or found lithium chloride to be ineffective in the field (Conover et al. 1977; Burns 1980, 1983; Bourne and Dorrance 1982; Burns and Connolly 1985). Although lithium chloride reduces prey consumption, it does not deter the act of predation. Ten years after field trials using lithium chloride (Gustavson et al. 1982, Jelinski et al. 1983), a survey of the same sheep producers revealed only one producer still used it (Conover and Kessler 1994). Evidence suggests that conditioned taste aversions are either ineffective or unreliable for deterring predation (Knowlton et al. 1999), but may limit food consumption (Polson 1983, Ternent and Garshelis 1999). Predation on sea turtle nests by raccoons was unaffected using conditioned taste aversion (Ratnaswamy et al. 1997).

Aversive conditioning may be effective in “teaching” brown bears to fear and avoid humans (Jonkel 1994). For valuable endangered species, the expense may be necessary, considering the alternative for problem bears is usually destruction of the animal (Jonkel 1994). In many national parks, lethal techniques are considered the last resort when dealing with problem carnivores. Hazing of these animals is implemented in an attempt to discourage these animals from returning to a campground, landfill, or residential area. **Hazing** often involves park personnel yelling, firing cracker shells or rubber slugs, or chasing the animals with trained dogs, thereby pursuing the animal until it has left the area (Yosemite National Park 2003). Breck et al. (2007) reported on an automated system developed to alert park personnel whenever a radiocollared bear entered a particular area in Yosemite National Park, allowing personnel to respond promptly before the situation progressed. Leigh and Chamberlain (2008) reported that of 11 black bears exposed to aversive conditioning involving rubber buckshot and dogs, 10 (91%) returned to nuisance behavior within 5 months, and concluded these techniques had limited short-term effectiveness.

Electronic Training Collar

A device receiving attention as a nonlethal method to deter coyote and wolf predation on livestock is an electronic training (shock) collar used for training domestic dogs (Andelt et al. 1999, Shivik and Martin 2001, Shivik et al. 2003, Schultz et al. 2005). Using captive coyotes, Andelt et al. (1999) reported the training sequence with the electronic collar stopped all attempted attacks on lambs, decreased the prob-

ability of an attempted attack, eliminated successive chases, and even caused avoidance of lambs. Hawley et al. (2009) tested the use of electronic collars on wolves and found wolves did shift farther away from bait stations after being shocked, but conditioning was not clearly demonstrated once shocking ceased. All investigators caution that application may be limited under field conditions because the predator must be captured and the training collar attached, but do suggest that changing the behavior of the predator during the attack phase of a predatory sequence holds promise as a nonlethal technique (Andelt et al. 1999, Shivik and Martin 2001).

Reproductive Interference

An interest in influencing the reproductive rate of canids with **chemical sterilants** dating to the 1960s assumed that reduced reproduction would reduce population levels and that fewer predators would result in fewer depredations (Balser 1964, Knowlton et al. 1999). Trials with diethylstilbesterol indicated that reproduction among coyotes could be curtailed (Balser 1964, Linhart et al. 1968), but timing was critical and the approach was impractical without an effective delivery system (Knowlton et al. 1999). Currently there is renewed interest in reproductive inhibition using immunocontraceptive agents (DeLiberto et al. 1998, Levy et al. 2004, Fagerstone et al. 2008), both as a means of reducing predator populations (Ramsey 2007) or changing predatory behavior (Till and Knowlton 1983, Bromley and Gese 2001a). Conner et al. (2008), using a spatially explicit, individual-based model, indicated that sterilization of coyotes appeared to be the management strategy that had the largest and most lasting impact on coyote population dynamics. **Surgical sterilization** (tubal ligation and vasectomy) of coyotes was effective in reducing predation rates on domestic lambs by changing predatory behavior and did not affect social behavior and territory maintenance (Bromley and Gese 2001a, b). **Vasectomy** of male wolves has been proposed as a method of population control (Haight and Mech 1997). However, currently there are no substances available for fertility control in predators that are species-specific; specificity might be achieved with appropriately designed delivery systems. In Australia, immunocontraception was investigated for fertility control and population reduction of nonnative red foxes (Strive et al. 2007).

Relocation of Problem Animals

Management programs using **relocation** of problem animals has had limited success for grizzly bears (Brannon 1987), but less so with wolves killing livestock (Bangs et al. 1995, Cluff and Murray 1995). Wolves that learn to kill livestock often return to the capture site, or begin killing livestock in the new area and have to be removed from the population (Bangs et al. 1995). Although relocation efforts are expensive, they are considered worthwhile and necessary when dealing with endangered predatory species.

Financial Incentives

Resistance by the livestock community to recovery of wolves in the Northern Rocky Mountains was tempered by **compensation** for livestock losses. Compensation programs for livestock deaths from some predatory species exist in the United States and Canada (Fritts 1982, Gunson 1983, Fritts et al. 1992). Problems identified with compensation programs are that producers believe they do not receive fair market value, that compensation is only for verified losses (does not include missing animals), and that payment for losses does not encourage producers to correct poor management practices or attempt nonlethal techniques (Fritts et al. 1992). Bulte and Rondeau (2005) cautioned that compensation programs could actually cause adverse effects to wildlife by increasing agricultural expansion and habitat conversion, decreasing efforts to prevent damage, and intensifying agricultural production. A careful assessment of local ecological and economic conditions should be performed before implementing a compensation program, and incentives may best be realized if tied to conservation outcomes (Bulte and Rondeau 2005). A recent incentive has been the production of "predator friendly" products in which consumers pay more for goods (e.g., wool, meat) that come from ranches that do not kill predators.

Livestock Protection Collar

The **livestock protection collar** (LPC) is a collar with an attached rubber pouch or bladder filled with Compound 1080. The device is placed around the neck of lambs and kid goats (Acorn and Dorrance 1998). **Compound 1080** is an acute toxicant formerly used as a predicide and rodenticide. Most predicide uses were banned in 1972 because of non-target hazards, and rodenticide uses were banned in 1990 (Fagerstone and Schafer 1998). The LPC is designed to kill coyotes when they puncture the bladders during an attack on a lamb or kid. The major advantage of LPCs is that they selectively remove the problem animal and frequently kill individual predators that have evaded other control techniques (Connolly 1980, Connolly and Burns 1990, Blejwas et al. 2002). The LPC comes in 2 sizes (large and small), with the larger LPC working effectively on larger lambs (Burns et al. 1996). The major disadvantages of LPCs are initial purchase costs and labor required for application and maintenance (collars must be adjusted as animals grow), incidental puncturing of the collar (by thorns, wire, or other snags), anticipating which lambs or kids are most likely to be attacked, and keeping accurate records of the amount of predicide used in each LPC (Wade 1985, Acorn and Dorrance 1998, Knowlton et al. 1999).

M-44

The **M-44** is a mechanical device that ejects sodium cyanide into the mouth of an animal after it pulls on the device (Connolly 1988, Acorn and Dorrance 1998). The unit consists of

a case holder wrapped with cloth, fur, wool, or steel wool; a plastic capsule or case that holds the cyanide; and a 7-cm ejector unit (VerCauteren et al. 2005a). The M-44 case is loaded with sodium cyanide and an additive to reduce caking. A spring-loaded plunger ejects the cyanide. When assembled, the components are encased in a tube driven into the ground. The cocked ejector with the case in the holder is screwed on top, placed into the tube, and baited with fetid meat, a lure, or tallow. When an animal is attracted to the bait and tries to pick up the baited case holder with its teeth, the cyanide is ejected into its mouth. Canids, skunks, raccoons, bears, and opossums sometimes are attracted to the bait used on M-44s; however, species specificity can be enhanced by proper site and lure selection (Acorn and Dorrance 1998). A study on coyotes in California found the M-44 was not a selective technique in targeting or removing the breeding animals involved in sheep depredations (Sacks et al. 1999a). The M-44 is registered and authorized by different agencies depending upon the country of use (e.g., Pest Control Products Act of Canada, Environmental Protection Agency) for control of coyotes, foxes, and feral dogs, and has numerous restrictions.

Aerial Hunting

Aerial hunting is commonly used for reducing predator numbers (e.g., Wagner and Conover 1999). Various fixed- and rotary-wing aircraft have been used in control programs for wolves, coyotes, bobcats, and foxes (Wade 1976). Hunting is most effective with snow cover because the target animals can be more readily spotted and tracked. When the specific animal is found, the pilot approaches at approximately 20 m of altitude, preferably into the wind. The ground speed of the aircraft is about 60–85 km/hour, but the air-speed should never approach the stall speed of the aircraft. A 12-gauge semiautomatic shotgun is the most common weapon used, with number 4 buckshot, BB, and number 2 shot preferred.

Several modifications have been made to fixed-wing airplanes to increase safety and effectiveness, including a larger propeller and drooped wingtips to provide added power, lift, stability, and maneuverability (VerCauteren et al. 2005a). Larger balloon-type tires have been added to provide clearance for the longer propeller and to better use primitive runways for landings. Rotary-wing aircraft (helicopters) also are used in predator control. The helicopter, with its ability to hover, can be more effective in rough, brushy terrain. Visibility and tracking ability are improved in models with a Plexiglas bubble cockpit.

Fixed-wing aircraft and helicopters can be used cooperatively. The helicopter is used for tracking and dispatching the animal, while the fixed-wing aircraft flies above the helicopter and maintains surveillance. This combination works in areas of thick vegetation or in areas where animals are hunted heavily with helicopters. Aerial hunting can be more

efficient if a ground crew works with the aircraft (Wade 1976). The ground crew induces coyotes to howl by using a horn, siren, voice, or recorded howl. When animals respond, the aircraft is directed to the area by 2-way radio communication. Early morning and late afternoon tend to be the most productive times for aerial hunting. Federal law requires each state where aerial hunting is allowed to issue aerial hunting permits. Some states also require low-level flying waivers.

Denning

Increased depredations of livestock (mainly sheep) and poultry during spring and summer by coyotes and foxes usually indicate that a pair of coyotes or foxes has a litter of pups nearby. During spring and summer, adults will increase their predation rates in order to provision pups (Till and Knowlton 1983). In a study in Wyoming, sheep losses to coyotes were greatly reduced after removal of only the pups, and was similar to reduction in predation rate when both pups and adults were removed (Till and Knowlton 1983). **Denning (direct removal)** of pups in the den, by digging or use of a chemical smoke cartridge, is often used to destroy the pups (Acorn and Dorrance 1998). An alternative to denning is surgical sterilization of adult breeding coyotes, which worked as effectively as denning, with a long term (several-yr) efficacy, but without the requirement of finding the den (Bromley and Gese 2001a, b).

Dens are usually located by tracking or observing the adults, or by use of simulated howling to get the pups to respond. Den hunting is often based on the assumption that adults that kill livestock will return to the den via the most direct route possible. An active den is evidenced by hairs around the entrance, fresh tracks, and (if the pups are large enough to have emerged from the den), matted and worn vegetation around the entrance and small scats. Dens also may have prey remains lying about the den area.

Den hunting is difficult and time-consuming, particularly on hard ground and in heavy cover (Acorn and Dorrance 1998). Some people use a dog to aid in locating the den. A call imitating a frightened or injured pup sometimes will bring adult coyotes near a den site, allowing the den to be located. Caution should be taken while digging out dens because of the possibility of cave-ins and ectoparasites. These hazards can be eliminated if a gas cartridge is used to kill the pups in the den. At times, an aircraft is used to locate coyote and fox dens. From the air, signs of an active den include cleaned-out holes and trampled vegetation.

Traps

Live traps (Fig. 34.20) of variable construction are available from several companies in various sizes and configurations to capture small, medium, and even large predators such as bears. Problem bears can be caught in a live trap made from steel culverts equipped with a trapdoor and trigger device,

Fig. 34.20. Live traps can be utilized to capture some predator species. Photo by U.S. Fish and Wildlife Service.

and mounted on a trailer that allows personnel to easily relocate the bear (VerCauteren et al. 2005a). Generally, coyotes, foxes, and bobcats are difficult to live-trap because of their cautious nature and reluctance to enter confined areas. However, a growing international concern for animal welfare is causing increased emphasis on more humane capture devices (Harris et al. 2006, Munoz-Igualada et al. 2008).

Canned dog or cat foods are effective **baits** to entice raccoons, opossums, skunks, and cats into live traps. Traps for skunks can be covered with a canvas or heavy cloth and provided with a flap for the door. When a skunk is captured, the trapper can approach the trap on the covered side and carefully drop the flap over the door, allowing the skunk to be transported to the release site. To release it, the trapper should stand beside the trap and ease the flap and door open; the trap may need to be propped open to allow the animal to leave when it is ready.

Foothold or steel traps are manufactured in various sizes. Modification of traps (e.g., padded jaws) and attachment of a trap **tranquilizer device** can greatly diminish injuries to the animal (Sahr and Knowlton 2000). **Tension devices** also should be considered to minimize captures of nontarget species (Phillips and Gruver 1996). Use of trap monitors (Benevides et al. 2008, Darrow and Shivik 2008) can be beneficial for traps or other capture devices set in areas with difficult access, or if trapping in areas occupied by endangered species that require prompt removal from the trap. Selectively removing (via trap) the offending animal causing the depredations can be difficult (Sacks et al. 1999a); however, sometimes just attempting to trap the offending animal and increasing the level of human activity in the area might deter future depredations (Harper et al. 2008). The following **trap sizes** are recommended for various species: numbers 0 and 1, for weasels and ground squirrels; numbers 1 and 1.5, for skunks, opossums, mink, feral cats, and muskrats; numbers 2 and 3, for foxes, raccoons, small feral dogs, nutria, marmots, and mountain beavers; numbers 3 and 4, for bobcats, coyotes, large feral dogs, badgers, and beavers; numbers 4 and 4.5, for wolves; and numbers 4.5 and 114, for mountain lions.

Success in trapping depends on placing the trap along travel ways, such as along dirt roads and trails. A trap usually is set in the ground by digging a shallow trench the size of the trap and deep enough to allow the stake (or drag) and chain to be placed in the bottom of the hole and covered with soil. The trap is set firmly on top of the buried chain and should be about 11 mm below the soil surface. A piece of canvas, cloth, mesh screen, or a plastic sandwich bag is placed over the pan to prevent soil from getting beneath the pan and preventing its depression. The trap is then covered with soil and other material natural to the area near the trap. The trap can be set without bait in a trail (i.e., a “**blind**” or **trail set**). Traps also may be set off the trail and baited with a lure, bait, or natural substance, such as scat or urine (a **dirt-hole set**). The trap is set in the same manner as the blind set, but instead of placing the scent on the ground, the lure is placed in a small hole (about 15 cm deep) dug behind the trap. **Lure selectivity** for the target species is important. The location of a set also influences its selectivity. When placed beside a carcass, a trap can catch nontarget animals such as vultures, eagles, badgers, and other nontarget predators. Many states no longer allow trapping near a carcass. Weather also can impact operation of traps, with frozen or wet ground preventing a trap from springing. Foothold traps must be checked often to minimize time captured animals are restrained. Most states have regulations on types of traps, baits, sets, and trap visitation schedules. Some states no longer allow use of foothold traps; state and local regulations should be consulted prior to conducting any trapping activity.

Calling and Shooting

Calling and shooting can be a selective means to control coyotes, bobcats, and foxes. Calling and shooting, with or without help of lure dogs, can be a means of removing offending coyotes that kill livestock, particularly during denning and pup-rearing seasons (Coolahan 1990, Sacks et al. 1999a). Several commercial calls and recorded calls are available from various manufacturers or outlets. The call is blown to imitate the sound of a rabbit in distress. This sound either arouses the predator’s curiosity or indicates an easy meal. However, some predators become wise to calling. Conversely, the call may be an effective method to remove a trap-wise animal. Calls imitating a pup in distress also can attract the adults. Generally, 3 factors should be kept in mind to successfully call in a predator: (1) ensure the caller is downwind from the area being called to prevent the predator from detecting the caller’s scent before the animal comes into shooting range; (2) within limits imposed by terrain and vegetation, acquire a full view of the area so the predator will be unable to approach unseen; and (3) avoid being seen by wearing camouflage clothing and hiding in vegetation (Acorn and Dorrance 1998). The most effective times to call predators are early morning and late afternoon. The hunter

can gain an added advantage by locating an animal before beginning to call by inducing howls. Calling at night and using a spotlight (where legal) also can be effective.

Hunting Dogs

Two types of dogs can be used for lethal predator control. Dogs that hunt by **sight** (i.e., greyhounds), can be kept in a box or cage until the predator is seen, then released to catch and kill the animal. This type of dog is effective only in relatively open terrain. The other type of dog is the **trail hound** (Fig. 34.21), which follows an animal by its scent. Trail hounds hunt on bare ground; however, snow or heavy dew makes trailing easier. Hot, dry weather makes trailing difficult; therefore, early morning is the most effective time to hunt with trail hounds. Bluetick, black and tan, Walker, and red-bone hounds, in packs of 2–5 dogs, are typically used. Trained trail hounds are used to catch and “tree” raccoons, opossums, bobcats, bears, and mountain lions. Often these dogs are able to track a depredating predator from a kill, making this method highly selective. State and local regulations should be consulted prior to hunting with dogs.

Snares

Snares are made of varying lengths and sizes of wire or cable looped through a locking device that allows the snare to tighten. There are generally 2 types of snares: body and foot. As described by Dolbeer et al. (1994b), the body snare is used primarily on coyotes and foxes. This snare is set where an animal crawls under a fence, at a den entrance, or in some other narrow passageway. The snare is situated so that the animal must put its head through the noose as it passes through the restricted area. When the snare is felt around the neck, the animal normally will thrust forward and tighten the noose.

Fig. 34.21. Trained hounds can be used to chase and tree some depredating predators, particularly mountain lions or black bears. Photo by U.S. Fish and Wildlife Service.

The **spring-activated** foot snare has been used to capture large predators (Logan et al. 1999). As described by Dolbeer et al. (1994b) when the animal steps on the trigger the spring is released, propelling the noose around the foot. The animal instinctively recoils, tightening the snare cable around the foot. The foot snare can be used in a bear pen or cubby set. A **bear pen** is just large enough to accommodate the bait, which is usually the remains of an animal killed earlier by the predator. The pen can be built of brush or poles and has an open end where the snare is set. The pen and guide sticks force the bear to step into the snare while trying to reach the bait. Bears and mountain lions also can be caught with a foot snare in a trail set (Logan et al. 1999). The snare should be set in a narrow trail known to be traveled by the animal. Deer and livestock can be prevented from interfering with the snare by placement of a pole or branch across the trail, directly over the set about 0.9 m above the ground.

Selectivity of the foot snare may be improved by placing, under the trigger, sticks that break only under the weight of heavier animals (VerCauteren et al. 2005a). Open-cell foam pads can be placed under trigger pans to prevent unintentional triggering of snares by small mammals (Logan et al. 1999). Foot snares have advantages over large bear traps in that they are lighter, easier to carry, and less dangerous to humans and nontarget animals.

SUMMARY

Wildlife-damage management can loosely be defined as resolving human–wildlife conflicts. Often, competition for limited resources between wildlife and society results in wildlife damage. Managers continually seek means to alleviate damage when wildlife threaten human health and safety (e.g., deer–vehicle collisions, zoonotic disease transmission), domesticated animals are damaged by wildlife (e.g., wolves preying on beef cattle), or resources are damaged (e.g., elk eating forage that was to be consumed by beef cattle).

Our world is continually changing, thus creating new challenges and compounding current challenges (i.e., urban sprawl, subdividing large landholdings, expanding populations of invasive species, climate change, and emerging infectious diseases) relating to the relationship between society and wildlife. As cities encroach into adjacent agricultural and undeveloped landscapes, highly adaptable species such

as Canada geese and white-tailed deer thrive in these new environments. These altered environments typically provide refugia (with minimal or no hunting pressure) to wildlife, which allows relatively unrestricted population growth, furthering potential for human–wildlife conflict. Increasing urban wildlife populations create unique management situations due to the attitudes and perceptions of urban stakeholders.

In this chapter, we introduced ways to assess wildlife damage, explored a diverse array of birds, ungulates, rodents and other small mammals, and carnivores and other mammalian predators commonly associated with damage, and we presented numerous management options that may be applied to reduce wildlife damage. Human–wildlife conflicts are growing and situations are becoming more varied; thus, techniques for managing these conflicts must be adaptable to be effective. Hence, we provided detailed information on a wide variety of proven tools and variations therein. The importance of approaching a management problem with an open mind must be emphasized, because each problem will likely deviate slightly from previous problems.

This chapter provides a starting point for laying out the framework (i.e., 4-part structure) for developing a wildlife-damage management program. Programs should be developed in steps, beginning with a definition of the problem and study of ecology of the problem species to understand why damage is occurring. This understanding should then be used to select and initiate appropriate management techniques, followed by an evaluation of the prescribed effort to assess efficacy and adapt the program if necessary. Further, an integrated approach utilizing several complimentary techniques is usually the best approach to reach a desired goal.

There appears to be a growing disconnect between society and wildlife management through lethal means, thus increasing the need for effective nonlethal tools. Yet incidents such as wildlife-related collisions with aircraft or vehicles will continue to be threats to human health and safety, due to potentially unmanaged wildlife populations. Furthermore, wildlife management professionals with expertise in public relations and formulating management plans will be fundamental in alleviating damage and ensuring management tools remain available for the future. It continues to be important that professionals in this field be well-versed in the human dimension aspects of human–wildlife conflicts.

Ecology and Management of Small Populations

L. SCOTT MILLS,
J. MICHAEL SCOTT,
KATHERINE M. STRICKLER,
AND STANLEY A. TEMPLE

INTRODUCTION

HUMAN-CAUSED CHANGES to natural landscapes are **fragmenting wildlife habitats** and causing many species to decline, often **creating small, isolated populations**. Management concerns for small populations are frequently unlike those for large or thriving populations. When the small population of concern is a **threatened or endangered species**, management is a high-profile process, occurring in a regulatory environment and typically involving intensive management practices (Temple 1978b, Clark et al. 1994, Scott et al. 1994). In many cases, issues faced by managers of small populations are intensified versions of tasks important for managing any wildlife population: regulating rates of birth, dispersal, and mortality; maintaining habitat quantity and quality; and managing disease, predators, competitors, and other **extrinsic factors**. These issues often become critically important in management of small populations, with limited time and few second chances for management to succeed. In addition, managers must cope with a number of questions more specific to small populations, such as avoiding genetic problems, doing viability analyses, and stimulating population growth.

In this chapter, we address a number of issues of special interest in **management of small populations**. First, we summarize **biological and legal criteria** for identifying small populations, and review the range of population sizes that are considered “**small**.” We then discuss factors that affect whether small populations will persist or become extinct. Finally, we provide management guidelines for small populations, including a detailed description of viability assessment in general, and population viability analysis in particular, as practical, powerful tools for planning the management of small populations.

WHAT IS A SMALL POPULATION?

There are few precise definitions of a “**small population**.” The reluctance to assign specific criteria is no doubt because so many variables are involved when considering population size across a wide range of species and conditions.

The Oxford English Dictionary (Simpson and Weiner 1989, XV:767) **defines “small” as**: “of limited size; of comparatively restricted dimensions; not large in comparison with other things, esp. of the same kind.” This definition highlights the comparative nature of any criteria; except in extreme cases (what Scott et al. [2001] called **vanishingly small populations**), small size is a relative concept. Whether or

not a population is considered small is dependent on a series of comparisons with populations of conspecifics, similar species, historical population sizes, and even arbitrary management standards. For an **exploited species** such as the canvasback (*Aythya valisineria*), conservation plans may call for corrective management to be implemented when population sizes decrease to the tens of thousands. In contrast, conservation efforts for **threatened species** may be delayed until the population falls below 100 or is putatively extinct (e.g., 'ō'ū [*Psittirostra psittacea*]). Thus, an attempt to define a universal criterion for small based on numbers may be useful as a heuristic exercise, but should not be interpreted too strictly (Box 35.1).

The definition of a small population also may be influenced by a species' life-history characteristics. In general, **extinction probability** increases as population size decreases, an idea deeply rooted in wildlife biology and ecology (e.g., Leopold 1933, MacArthur and Wilson 1967). In some (but not all) cases, **restricted geographic range or local endemism** can serve as proxies for small population size (Channell and Lomolino 2000, Purvis et al. 2000). Populations with higher

variance in population growth rate relative to mean population growth rate will have to be larger to avoid extinctions (Lande 1993; Fagan et al. 1999, 2001). **Species attributes** such as litter or clutch size, age at first reproduction, and intervals between births may be useful for predicting population growth rate or variation in growth rate and, therefore, vulnerability of a population (Purvis et al. 2000, Fagan et al. 2001).

By contrast, the use of secondary surrogates such as home range size, group size, or body size as general indicators of **extinction vulnerability** has been largely unsuccessful because correlations are weak and inconsistent (e.g., large-bodied animals tend to show lower variation in numbers, but also lower population growth rates; Lawton 1995). Some animals may be more vulnerable because of their sensitivity to **anthropogenic threats**, limited dispersal capability, narrow habitat requirements, and the extent to which a species is harvested or persecuted by humans, rather than because of body size or home range size per se. Vulnerability also may derive, in part, from particular **behavioral attributes** (Reed 1999); for example, species might be more vulnerable

BOX 35.1. THE "50–500 RULE"

As a historical footnote while considering the meaning of a small population, it is worth reviewing the famous "50–500 rule." This rule of thumb emerged from a meeting on the application of conservation genetics to wild species (Franklin 1980, Soulé 1980, Frankel and Soulé 1981), and over the next decade was accepted into the Puerto Rican parrot (*Amazona vittata*) recovery plan (U.S. Fish and Wildlife Service 1987) and a number of other management plans and biological opinions (e.g., U.S. Fish and Wildlife Service 1998). In essence, the rule provides a minimum genetic effective size for short-term and long-term protection, respectively.

An effective size of 50 was proposed as a minimum to protect against short-term loss of fitness due to inbreeding, based on empirical observations of the decrease in fitness-related traits with incremental inbreeding in a variety of animal species. Several caveats implicit in the original rule were lost as management was applied (Soulé 1987, Soulé and Mills 1992). For example, 50 is the *genetic effective size* (N_e), which is only about 20–33% that of the total population size (Frankham et al. 2002); thus, a N_e of 50 would translate to 150–250 or so actual animals. Second, the rule was proposed as a short-term guideline for captive breeding and similar "holding operations," not for long-term survival of wild populations, which would have many other factors affecting their persistence. Third, this was a rule based on genetic factors, not incorporating other factors that would increase the minimum necessary size for persistence. Based on these considerations, it is untenable to argue that an actual population size of 50 is sufficient as a rule to support any wildlife population into the foreseeable future.

The 500 number was proposed as the minimum size necessary to ensure long-term maintenance of genetic variation, thereby preserving evolutionary options for future adaptation. In more formal terms, the number was the estimated minimum genetic effective size where the loss of additive genetic variation of a quantitative character due to genetic drift would be balanced by new variation due to mutations. This number has received serious scrutiny by population geneticists, with arguments being made for minimum population sizes ranging up to 5,000 or more (Frankham et al. 2002). This debate will likely continue (Allendorf and Ryman 2002), but there is little doubt that the *actual* (as opposed to genetic effective) population size necessary to maintain evolutionary potential for the long term should be thousands of individuals and not hundreds.

if they show Allee effects (reduced survival or reproduction at small numbers), naiveté toward predators (e.g., dodo [*Raphus cucullatus*]), or aggregated dispersion (e.g., passenger pigeon [*Ectopistes migratorius*]). The final utility of these ecological and life-history characteristics as **predictors of extinction** depends on the specific context of the environment and the species in question (Tracy and George 1992, Belovsky et al. 1999, Channell and Lomolino 2000). For example, vulnerabilities of primates and carnivores were underestimated by a model based on species characteristics in cases where the species had lost habitat, been commercially overexploited, or where problems had been created by **exotic species** (Purvis et al. 2000).

One way of summarizing these complex factors is to survey many species and ask how large populations must be in order to be considered likely to persist. Two recent **meta-analyses** of thousands of studies for hundreds of species conclude that the median population size for expected high likelihood of persistence (>80%) for ≥20–100 years was about 1,400–4,000 individuals (Brook et al. 2006, Traill et al. 2007). Although these would not be robust “**magic numbers**” for precise conservation targets, they provide rough rules-of-thumb for when a population might be considered too “small” for persistence.

Finally, any consideration of “small” should not be limited to **persistence criteria**, but also should include **ecological function** of the species, and long-term ability to **adapt and evolve**. Both of these numbers will likely be much larger than the size necessary to support a population in the short term. We know of no generalizations for the population size of a species required for it to carry out its ecological role, but note by example that population size for a strongly interacting species to carry out its ecological function (e.g., prairie dogs [*Cynomys* sp.] or elk [*Cervus canadensis*] as habitat modifiers, wolves [*Canis lupus*] as top-down predators, or small mammals as prey) will certainly be much larger than the size needed for persistence per se. For evolutionary potential, one proposal would scale a threshold according to the population size necessary to retain 95% of the heterozygosity of the population for 100 years (Allendorf and Ryman 2002). What this size will be depends on mating system and other characteristics affecting the generation time and **genetic effective population size** (see Chapter 22, Volume 1); Traill et al. (2010) suggest that number to be roughly 5,000 adult individuals or more.

Guidelines for “Small” from Categorization Systems

Guidelines to what is considered “small” have been established by agencies. For example, the **International Union for the Conservation of Nature** (IUCN, or World Conservation Union) has developed a categorical system for assigning risk based in part on small population size (“Rule-of-Thumb” approach discussed later in chapter). Species with small, stable populations are considered “**critically endan-**

gered” if their populations fall below 50 mature individuals, “**endangered**” if their populations have <250 mature individuals, and “**vulnerable**” if they consist of ≤1,000 mature individuals. Small, declining populations have higher threshold values for each category (Table 35.1; also see “Rules-of-Thumb” in section on “Other Approaches to Assess Viability”).

In the United States, a comprehensive system of assessing the conservation status and extinction risk for species has been developed by the **Natural Heritage Network and The Nature Conservancy** (Master et al. 2000). The heritage ranking system is based on the perceived vulnerability of a species to extinction, taking into consideration both **intrinsic risks and external threats**. A species is considered “**critically imperiled**” if fewer than 1,000 individuals exist across its range; at the other end of the spectrum are “**apparently secure**” species with ≥10,000 individuals (Table 35.2). Although these categories are not based on scientific criteria, they provide insights into what may be considered a “**small population**” for management purposes.

Finally, a measure of a “small population” might be extracted from listings under the **Endangered Species Act** (ESA). Between 1985 and 1991, the median population size

Table 35.1. International Union for Conservation of Nature (IUCN) Red List criteria that are relevant to defining small populations

Red list category	Very small population	Small population and declining
Critically endangered	<50 mature individuals	<250 mature individuals, population declining
Endangered	<250 mature individuals	<2,500 mature individuals, population declining
Vulnerable	<1,000 mature individuals	<10,000 mature individuals, population declining

From IUCN (2001).

Table 35.2. Natural Heritage Program conservation status rank definitions

Rank	Definition
1	Critically imperiled. Typically ≤5 occurrences or ≤1,000 individuals.
2	Imperiled. Typically 6–20 occurrences or 1,000–3,000 individuals.
3	Vulnerable. Rare; typically 21–100 occurrences or 3,000–10,000 individuals.
4	Apparently secure. Uncommon, but not rare; some cause for long-term concern; usually >100 occurrences and >10,000 individuals.
5	Secure. Common; widespread and abundant.

From Master et al. (2000).

for threatened and endangered species at time of listing was 1,075 individuals for vertebrates, 999 for invertebrates, and 120 for plants (Wilcove et al. 1993).

Naturally Small versus Declining Populations

Not all small populations have declined. In fact, a longstanding generalization in community ecology (tracing back at least to Preston [1948]) holds that many, perhaps most, species in a community are relatively rare. Indeed, **naturally small populations** often persist on true islands, or island-like continental environments (Walter [1990] provided an example with the Socorro Island hawk [*Buteo jamaicensis socorroensis*]). Other wildlife species that typically occur in naturally small populations include top carnivores such as wolverines (*Gulo gulo*), large animals such as mountain sheep (*Ovis canadensis*), and species restricted to small areas of habitat (e.g., big-eared kangaroo rat [*Dipodomys venustus elephatinus*]). These populations may share some risk factors with declining populations, but more likely have distinctive life-history features that allow them to persist (Angermeier 1995, Fagan et al. 2001). **Management** of naturally small populations may focus primarily on maintaining the status quo: supporting natural disturbance regimes, avoiding habitat loss or degradation, and preventing the introduction of competitors, predators, parasites, or diseases. Also, naturally “small” populations are only locally small, but are connected to a greater **metapopulation**; in these cases, connectivity also should be retained.

In contrast to naturally small populations are species that were once common or widely distributed, but are now restricted to small, isolated populations following a reduction in population size. A **population’s decline** may be due to deterministic drivers such as habitat fragmentation or loss, introduced species, disease, overharvest, or a combination of factors, but the result is a population that is usually at **increased risk of extinction** due to both **deterministic and stochastic factors** (Clark et al. 1990, Reed et al. 2002, Mills 2007). Native birds of the Hawaiian Islands and Guam (Scott et al. 1986, Savidge 1987) are examples of situations where entire avifaunas have been placed at risk because of a combination of factors. Additional management activities may be required, because small populations are more vulnerable to extinction (see below).

LEGAL MANDATES FOR MANAGEMENT OF SMALL POPULATIONS

In the United States, there are **53 federal statutes** providing for conservation of species through restrictions on take and commerce, conservation of wildlife habitat, conservation of endangered species, conservation of both species and habitat, and control of “problem wildlife” (Box 35.2). Detailed descriptions of these statutes and treaties can be found in Goble and Freyfogle (2002a, b). These statutes, while provid-

ing the legal framework for protecting species, deal with issues of population size only vaguely; none incorporate the phrase “small population size” or define when population size reaches the point at which management is mandated. In contrast, the **Marine Mammal Act** (Section 2:130) explicitly addresses the population size necessary to maintain ecosystem integrity, and states that “population stocks should not be permitted to diminish beyond the point at which they cease to be significant functioning elements of the ecosystem of which they are a part and, consistent with this major objective, they should not be permitted to diminish below their **optimum sustainable populations**.” Further, to reduce the chance that stocks will be overharvested, the concept of uncertainty has been incorporated into the day-to-day implementation of the Marine Mammal Act (Taylor et al. 2000). Next, we describe in more detail the 3 statutes of greatest relevance for conservation of small wildlife populations in North America.

Endangered Species Act

Foremost in the United States among federal wildlife statutes that specifically address the management needs of “small populations” is the **Endangered Species Act** of 1973 with its subsequent amendments (Goble and Freyfogle 2002b). The Act provides for the protection and recovery of **species** (defined as species, subspecies, and distinct population segments for vertebrates, and as species and subspecies for plants and invertebrates). The Act’s objective was to conserve “to the extent practicable the various species of fish and wildlife and plants facing extinction throughout all or a significant part of their range” (U.S. Fish and Wildlife Service [USFWS] 1973:1). **No numerical criteria** for either population size or trends are specified in the ESA as a threshold for listing a species as endangered or threatened. The number of individuals at the time of listing varies by orders of magnitude even within a class of organisms (Wilcove et al. 1993). For example, the Inyo California towhee (*Pipilo crissalis eremophilus*) was listed as threatened when it reached a population size of 175 individuals, whereas the coastal California gnatcatcher (*Poliophtila californica californica*) still numbered in the thousands when it was listed as endangered. Similarly, there are **no demographic criteria** for down-listing or delisting species beyond a directive for “objective, measurable criteria which, when met, would result in a determination . . . that the species should be removed from the list” of threatened and endangered species (Goble and Freyfogle 2002a:354).

Species at Risk Act

The recently passed **Species at Risk Act** (SARA) of Canada (S.C. 2002, c.29) provides for the protection of rare wildlife, which includes species, subspecies, variety, or geographically or genetically distinct populations. The **criteria for listing or delisting** a species in Canada are more similar to IUCN criteria and more specific than the ESA. In 1988, the Council

BOX 35.2. FEDERAL STATUTES RELATED TO THE MANAGEMENT OF WILDLIFE

1. Conserving Species through Restrictions on Take and Commerce
 - a. Lacey Act, 1900, 1981
 - b. Migratory Bird Treaty Act, 1918
 - c. Tariff Act of 1930
 - d. Bald and Golden Eagle Protection Act, 1940, 1962
 - e. Act Prohibiting the Use of Aircraft and Motor Vehicles to Hunt Feral Horses and Burros, 1959
 - f. Horses and Burros, 1959
 - g. Airborne Hunting Act, 1971
 - h. Wild Free-Roaming Horses and Burros Act, 1971
 - i. Marine Mammal Protection Act, 1972
 - j. Magnuson–Stevens Fisheries Conservation and Management Act, 1976
 - k. Neotropical Migratory Bird Conservation Act, 1999
 - l. Wild Exotic Bird Conservation Act, 1992
 - m. African Elephant Conservation Act, 1988
 - n. Asian Elephant Conservation Act, 1998
 - o. Rhinoceros and Tiger Conservation Act, 1998
 - p. Great Ape Conservation Act, 2000
2. Conserving Wildlife Habitat
 - a. Federal Wildlife Refuges
 - b. Migratory Bird Conservation Act, 1929
 - c. Migratory Bird Stamp Act, 1934
 - d. Wetlands Loan Act, 1961
 - e. Refuge Revenue Sharing Act, 1935, 1964
 - f. Refuge Trespass Act, 1948
 - g. Refuge Recreation Act, 1962
 - h. Refuge Administration Act, 1966
 - i. National Marine Sanctuaries Act, 1992
 - j. National Wildlife Refuge System Improvement Act, 1997
3. Funding State Acquisition of Habitat
 - a. Federal Aid in Wildlife Restoration Act, 1937 (The Pittman–Robertson Act)
 - b. Federal Aid in Fish Restoration Act, 1950 (Dingell–Johnson Act)
 - c. Land and Water Conservation Fund Act, 1964
 - d. Fish & Wildlife Conservation Act, 1980
4. Consideration of the Effect of Federal Actions on Wildlife Habitat
 - a. Fish and Wildlife Coordination Act, 1934, 1946, 1958
 - b. National Environmental Policy Act, 1969
5. Planning and Coordination
 - a. The Anadromous Fish Act, 1965
 - b. Sikes Act Extension, 1974
6. Conserving Endangered Species
 - a. Endangered Species Act, 1973
7. Conservation of Both Species and Habitat—Federal Lands
 - a. National Park Service
 - i. Antiquities Act, 1906
 - ii. National Park Service Organic Act, 1916 and General Authorities Act, 1970
 - b. U.S. Forest Service
 - i. National Forest Service Organic Act, 1897
 - ii. Multiple-Use Sustained-Yield Act, 1960
 - iii. National Forest Management Act, 1976
 - c. Bureau of Land Management
 - i. Federal Land Policy and Management Act, 1976
 - ii. Public Rangelands Improvement Act, 1978
 - d. Military Lands
 - i. Sikes Act, 1960, 1997
 - e. Preservation Land Systems
 - i. Wilderness Act, 1964
 - ii. Wild and Scenic Rivers Act, 1968
 - f. Federal Waters
 - i. Rivers and Harbors Act, 1899
 - ii. Federal Power Act, 1920
 - iii. Federal Water Pollution Control Act, 1972
8. Conservation of Both Species and Habitat—Private Lands
 - a. Wetlands
 - i. Federal Water Pollution Control Act, 1972
 - ii. “Swampbuster” Provisions, 1985, 1990, 1996
 - iii. Coastal Barrier Resources Act, 1982
 - b. Uplands
 - i. Conservation Reserve Program, 1985
 - ii. Environmental Easement Program, 1990
 - iii. Forest Legacy Program, 1990
9. Problem Wildlife
 - a. Lacey Act, 1900
 - b. Animal Damage Control, 1931
 - c. Nonindigenous Aquatic Nuisance Prevention and Control Act, 1990

of Canadian Wildlife Ministers signed an agreement establishing the **Recovery of Nationally Endangered Wildlife** (RENEW) program (Scudder 1999). The objectives of RENEW are to prevent the extinction of species, prevent additional species from becoming threatened or endangered, reintroduce extirpated species, establish recovery plans to remove species from the threatened and endangered list, and prepare recovery plans for all threatened and endangered species (Canadian Wildlife Service 2001).

CITES

The Endangered Species Act of 1973 also included provisions for increased **protection of endangered and threatened species worldwide** (Bean 1983). As of 2 October 2009, 30% of listed species were outside the United States (USFWS 2009). The ESA implemented the **Convention on International Trade in Endangered Species of Wild Flora and Fauna** (CITES) in the United States and provided a program to encourage foreign governments to establish programs for conservation of species (Bean 1983). Species listed under CITES cannot be transported between countries without special permit. The **criteria for listing** are only vaguely defined and the decision to list a species depends largely on consensus of the parties. Mexico also is signatory to CITES.

The **United States/Mexico Joint Committee on Wildlife Conservation** was established in 1974 to help address the question of vulnerable species. This agreement provides the basis for cooperation on conservation efforts for species occurring in both nations, such as sharing survey information and cooperation on recovery efforts for species. However, it is vague about defining a small population.

FACTORS AFFECTING PERSISTENCE IN SMALL POPULATIONS

Deterministic Factors

In managing a small and declining population, the most important factors to consider are what caused the population to become small, and how to reverse the decline. Whether the cause of decline was habitat loss, overharvest, exotic species, change in disturbance regime, or some combination of these or other causes, the perturbations that led to the population becoming small are of paramount importance (Caughley and Gunn 1996) and greatly influence the possibility of recovery (Abbitt et al. 2000, Miller et al. 2002). These factors are “**deterministic**,” indicating the outcome for the population can be expected to follow in a relatively predictable way. Thus, deterministic factors that affect population growth in known ways are distinguished from “**stochastic**” or random factors that also affect small populations.

Stochastic Factors

Unfortunately, when a population becomes small it becomes particularly susceptible to a host of other threats that

interact with and exacerbate problems caused by deterministic factors. Thus, for small populations, even if the deterministic problems were reversed so the population achieved a positive average population growth, the population could still be driven toward extinction. Factors are called “**stochastic**” because they have a large element of randomness in how they affect any particular population.

Two important points emerge from an understanding of stochastic factors: (1) with all else equal, small populations are more likely to become extinct than large ones; and (2) with all else equal, populations with large variation in vital rates are more likely to become extinct than those with small variation. There are 3 main types of stochasticity affecting **population persistence** (Shaffer 1987): demographic, environmental, and genetic. The operation and effect of stochastic factors on populations are less intuitive than deterministic factors; therefore, we explain how they affect small populations (see Mills 2007 for more details).

Demographic Stochasticity

Demographic stochasticity arises from inevitable deviations around mean birth and death rates because these rates are probabilistic. For small populations, demographic stochasticity causes variation in population growth even in a constant environment, with no change in mean birth or death rates. One of the easiest ways to understand demographic stochasticity and its special effects on small populations is by example. If you toss a fair coin, the expected probability of heads is a constant 50%. But if you toss the coin only 3 times, you cannot possibly get 50% heads: you can only get 0%, 33%, 67%, or 100% heads, by chance! Even if you tossed it 4 times, you would not be too surprised to get something other than 50:50. However, if you tossed the coin 100 times you would expect the percentage of heads to be much closer to 50%, and if you tossed it 1,000 times you would be highly confident of converging on 50%, the expected probability of heads.

Consider how this analogy would apply to **sex ratios**, which are typically expected to be close to 50:50 at birth if there are many births occurring in the population. If, however, there are few births because of small population size, stochasticity could easily result in a marked deviation from the expected 50:50 ratio; this stochastic change could impair the population's ability to recover. Similarly, survival and birth rates in a small population could deviate widely from the expected mean by chance alone. Thus, demographic stochasticity **can affect sex ratio, reproduction, and/or survival**, causing each to be more or less than the mean expectation. Therefore, even if the environment is relatively constant and birth and death rates are such that average population growth should be positive, demographic stochasticity in a small population could still cause a decline toward extinction. An often-cited example of the effects of demographic stochasticity in sex ratio is the extinction of the dusky seaside sparrow (*Ammospiza maritime nigrescens*)

when all of the last 6 survivors happened to be males (James 1980, Avise and Nelson 1989, Post and Greenlaw 1994).

Just as a coin toss converges on 50:50 with many tosses, demographic stochasticity is minimized when abundance exceeds about 100 individuals (Morris and Doak 2002), so only relatively small populations are highly likely to decline from this factor alone. In some cases, **individual variation** is characterized as stochastic to ease analytical tractability when really there are **deterministic drivers**, perhaps due to maternal provisioning, genetic makeup, territory quality, or other factors. The extent to which this occurs can affect the influence of demographic stochasticity (McCarthy et al. 1994, Fox and Kendall 2002, Kendall and Fox 2002).

Environmental Stochasticity

In contrast to demographic stochasticity, **environmental stochasticity** produces random changes in mean vital rates for all individuals. Environmental stochasticity results from factors that are **extrinsic to the population**. Although environmental factors can be either physical or biotic, they occur in unpredictable patterns. The most obvious form of environmental stochasticity is climate, including normal vagaries of temperature and other weather-related phenomena, such as severe storms. Regardless of the underlying (and usually unknown) mechanism, mean vital rates for all animals in the population and, therefore, population growth rate, vary over time and space in unpredictable ways. Unlike demographic stochasticity, environmental stochasticity does not disappear in large populations. For example, a change in population growth rate from a 2% increase to a 2% decrease/year translates into changes in population size whether there are 50 or 500 animals in the population.

An underappreciated result of environmental stochasticity is that it can make the most likely (stochastic) growth rate for a population be greater or less than the average growth rate without stochasticity (Doak et al. 2005, Morris et al. 2008). Consider a simple case of a population whose **annual population growth rate** is equally likely to be $\lambda = 1.6$ or $\lambda = 0.6$ in any given year ($\lambda = 1.0$ is stable). The arithmetic mean of the growth rate is $1.1 [= (1.6 + 0.6)/2]$, indicating an increasing population, but the stochastic growth rate is $0.98 (\lambda = \sqrt{1.6 \times 0.6})$, meaning the most likely trajectory for this fluctuating population is to decline. This phenomenon could lead a manager to believe a population is likely to increase, based on the mean population growth derived from count data or matrix models, when actually it is most likely to decrease in a variable environment (Fig. 35.1). Although this simple example of population growth without age structure shows stochasticity decreasing population growth, negative correlations among vital rates could actually cause variation to increase population growth (Doak et al. 2005).

A practical point to remember about environmental stochasticity as estimated from field data is that it has an **associated sampling error**. In essence, sampling variation adds noise to the estimate of environmental variation. Thus, total variance should be partitioned into true process variance (**spatial and temporal variation**) distinct from the “noise” of sampling variance. The use of total variance for environmental stochasticity, instead of true process variance, will make nature seem more “variable” than it actually is. The artificially inflated variance will both reduce confidence in the actual trend, and will lead to biased-high predictions of extinction in population viability analysis (Ludwig 1999).

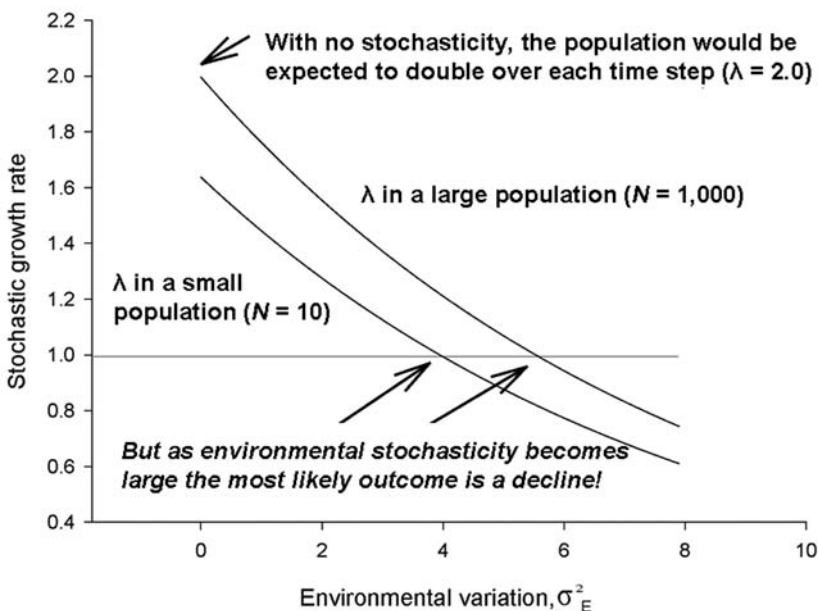

Fig. 35.1. An example of environmental stochasticity (with no covariation among vital rates or over time) decreasing the expected population growth rate relative to the mean rate. The upper curve shows the reduction in a large population ($N = 1,000$). The lower curve shows the further decrease in a small population ($N = 10$) due to demographic stochasticity. Modified from Mills (2007).

Methods for partitioning total variance into the component process versus sampling variation are discussed in Thompson et al. (1998) and White (2000b).

Finally, we note that populations can be exposed to stochastic events that are extreme beyond the tails of expected environmental stochasticity. These events are called “**catastrophes**” or “**bonanzas**,” and can have profound effect on persistence of small populations (Shaffer 1987, Morris and Doak 2002). For example, a 1963 hurricane decimated the last Laysan teal (*Anas laysanensis*) population; volcanic eruptions in Japan almost destroyed the last colony of the short-tailed albatross (*Phoebastria albatrus*); and a severe winter coupled with overbrowsing killed all but 50 of the 6,000 reindeer (*Rangifer tarandus*) on St. Matthew Island (Simberloff 1988).

Genetic Stochasticity

The third stochastic factor refers to **random loss of alleles** (alternative forms of a gene), and the subsequent effects on population dynamics in small populations. **Genetic stochasticity** arises from **genetic drift**, the process whereby random inheritance of alleles in a small, randomly mating population leads to the “drifting” of the frequency of alternative alleles toward either 1.0 or 0.0, and an accompanying increase in homozygosity. Vertebrates carry enough **deleterious alleles** (“lethal equivalents per individual”) to kill each individual about 3 times over (reviewed by Keller 1998), but in large populations natural selection holds them at low frequency, and their recessive nature means their effects are masked by a nonharmful allele. However, genetic drift can lead to reduced survival or reproduction via inbreeding depression when these deleterious alleles become expressed as **homozygotes**.

Loss of **heterozygosity** and expression of inbreeding depression due to genetic drift in small wildlife populations are well-established processes that can affect both captive and wild populations (Mills and Tallmon 1999). Like any other process (predation, disease, weather events, etc.), the effects of **inbreeding depression** on population dynamics will range from nonexistent to strong, for any particular population. Reviews indicate that a majority of small wildlife populations may exhibit inbreeding depression, and reductions in fitness can be substantial (Crnokrak and Roff 1999, Keller and Waller 2002).

If genetic drift and inbreeding depression decreases viability of a small population, the good news is that these effects can, in principle, be reversed by **genetic rescue** (Tallmon et al. 2004) through immigration of individuals from outside the population. Genetic rescue leads to a “breaking” of inbreeding depression and an increase in population growth by more than the demographic contribution of the immigrants; therefore, it can be an effective management action (Chapter 36, This Volume). In an excellent example, a population of bighorn sheep (*O. canadensis*) founded by 12 indi-

viduals and isolated for 10–12 generations, showed inbreeding depression followed by 23–257% increase in fitness-related traits following experimental restoration of immigration (Hogg et al. 2006). If genetic rescue is accompanied by considerations to also restore historical levels of diversity to maintain evolutionary potential efforts and prevent genetic swamping, then the small population will be the recipient of **genetic restoration** (Hedrick 2005).

Genetic restoration raises the important point that loss of genetic variation in small populations also depletes the raw material of evolution underlying a population’s capacity to adapt to changes in climate, habitat, competitors, disease, etc. If it is lost in small populations, the ability to survive future changes can be compromised even if the population subsequently recovers to its former size (Soulé 1980, Frankham et al. 2002). As an example, Botta’s pocket gopher (*Thomomys bottae*) populations that have low genetic variation are actually able to accept reciprocal skin grafts from individuals within their population; populations with high variation reject the grafts (Sanjayan et al. 1996). This extreme consequence of loss of variation, resulting in an individual not being able to distinguish self from nonself, implies that ability to recognize and destroy intruder viruses, microbes, and other diseases will be compromised.

PREDICTING THE RISKS OF SMALL POPULATION SIZE

The Extinction Vortex

We have stressed that both deterministic and stochastic factors affect the likelihood of a small population declining, or becoming extinct. The interaction of all of these factors is portrayed by the **extinction vortex** (Fig. 35.2). This captures the idea that primary drivers of concern for declining and/or small populations are deterministic **human-caused perturbations**. How the perturbation affects a particular population depends on its **structure** (life-history characteristics, age structure, behavioral interactions, distribution, physiological status, etc.), and on the **environment** (habitat, weather, competition, predators, food abundance, etc.). These perturbations can decrease **vital rates** (reproduction and survival), thereby decreasing both population growth rate and population size. Each turn of the feedback cycle increases extinction probability because decreased population size and growth rate lead to increased effects of inbreeding depression and stochastic events, further decreasing population size and growth. The extinction vortex emphasizes the need to consider the relative importance of these different factors and how they interact in a particular case (Gilpin and Soulé 1986, Lande 1988, Soulé and Mills 1992, Mills and Smouse 1994).

Greater prairie-chickens (*Tympanuchus cupido*) in Illinois provide an example of the **extinction vortex in action** (Bouzat et al. 1998a, b; Soulé and Mills 1998; Westemeier et al. 1998; Bouzat et al. 2009). As native grasslands have been in-

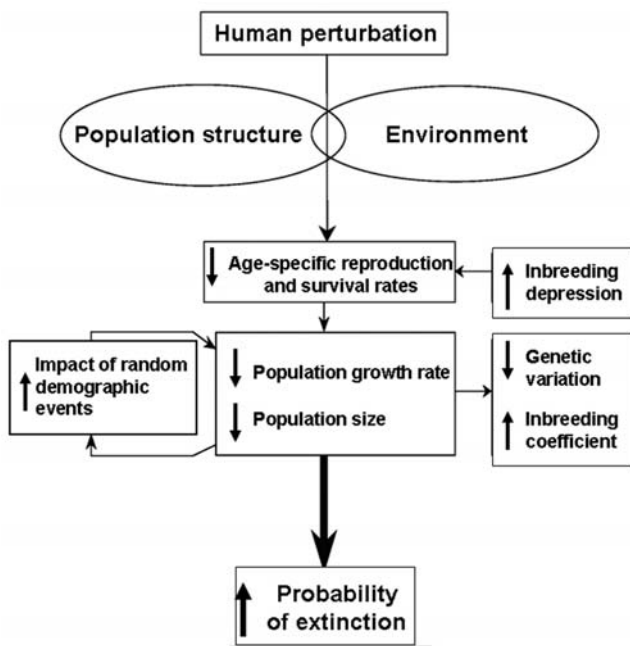

Fig. 35.2. A simplified representation of the extinction vortex. Adapted from Soulé and Mills (1998).

creasingly fragmented, the Illinois population of the greater prairie-chicken **became small and isolated** from other populations, declining from about 2,000 individuals in the early 1960s to 50 birds by the early 1990s. Although habitat loss and alteration, and associated increases in predators, clearly caused the decline, stochastic factors became relevant at small population size. In particular, **genetic variation** for Illinois prairie-chickens **declined** relative to both historical samples collected from that population and to populations in neighboring states, which had remained relatively large and widespread. **Translocations** of prairie-chickens from neighboring states from 1992 to 1996 appeared to lead to successful **genetic restoration**, as genetic diversity was restored to historic levels, **inbreeding coefficients decreased** (at least to some extent), and significant **increases in both fertility and hatchability** rates indicated that inbreeding depression was ameliorated. Nevertheless, in a somber note that underscores the difficulty in breaking out of the extinction vortex, the transient increases in population size following translocation have stalled, probably due to limitations in habitat availability and habitat quality. In short, this example demonstrates that **management actions** can be taken to redirect population growth away from the extinction vortex, but these will ultimately be successful only with continued vigilance in providing adequate habitat and addressing deterministic causes of declines (Maehr and Lacy 2002, Bouzat et al. 2009).

The Process of Viability Assessment

Wildlife viability assessment (Box 35.3) formalizes evaluation of the processes of the extinction vortex. It places intu-

ition, field data, and theory into an operational framework to allow assessment of the factors that caused decline and that may cause further decline in the future. It is a framework for incorporating multiple, interacting processes; therefore, it can reveal nonintuitive and nonobvious outcomes that can help in management decisions. The intellectual roots of assessing viability of wildlife populations date to at least the 1930s (Reed et al. 1998b). Leopold (1933:47) noted the importance for wildlife managers to recognize “the **minimum number** of individuals which may successfully exist as a detached population.”

A subset of viability assessment procedures includes **Population Viability Analysis (PVA)**. As the quantitative arm of the body of approaches to assessing viability, PVA can be defined as “the application of data and models to estimate probabilities that a population will persist for specified times into the future (and to provide insights into factors that constitute the biggest threats)” (Mills 2007:254).

We believe PVA embraces the concept of a “**Minimum Viable Population (MVP)**” and makes this concept somewhat obsolete. MVP is problematic for both philosophic and scientific reasons. Philosophically, it strikes us as risky to manage for the “minimum” number of individuals that could persist on this planet. Scientifically, the problem is that we cannot specify a specific “**minimum number**” of individuals that will insure long-term viability, because of all the uncertainties involved in the persistence of a small population.

Several reviews of practical applications of PVA are available (e.g., Sjögren-Gulve and Ebenhard 2000, Young and Clarke 2000, Beissinger and McCullough 2002, Morris and Doak 2002, Reed et al. 2002). We highlight these applications for management of small populations, focusing both on the quantitative framework of PVA, as well as on other methods that constitute the assessment of viability.

Three Characteristics of Population Viability Analysis

Quantitative viability assessment using PVA has 3 central concepts: persistence threshold, time, and likelihood. **Persistence** is usually in the sense of “not extinct,” implying that a population remains above zero individuals (or one mating pair). This is an important threshold, but there are often thresholds other than zero that are useful to track for biological or management reasons. These “**quasi-extinction**” thresholds might include, for example, biological thresholds below which Allee effects occur or where strongly interacting species become unable to perform critical ecosystem functions (Conner 1988, Soulé et al. 2003). Quasi-extinction thresholds also may include management thresholds such as the triggering number to bring a wild population into captivity, or the abundance below which a threatened species would be reclassified as endangered (Ginzburg et al. 1990, Burgman et al. 1993, Scott et al. 1995). Therefore, when we refer to “**extinction**” we include both true extinction and quasi-extinction thresholds.

BOX 35.3. COMPONENTS OF A POPULATION VIABILITY RISK-MANAGEMENT PROCESS

1. *Describe the species.* Identify and screen for species at risk.
2. *Describe pertinent regulations and laws.* Define the range of acceptable conditions that meet policy regulations or law. Identify responsible agencies and institutions and coordinate their planning activities.
3. *Describe species' conditions and ecology.* Describe the species' environmental relationships and reasons for viability concern or population decline.
4. *Develop planning alternatives.* Develop a range of planning or management strategies. Describe risk attitudes of publics and responsible agencies and institutions. Describe perceived and expected utilities of planning alternatives. Identify factors and value ranges in decision criteria to be used to select among the alternatives.
5. *Evaluate viability effects of the alternatives.* Conduct a viability risk analysis. Analyze how the alternatives affect population size, distribution, and persistence, resource tradeoffs, and social concerns.
6. *Array the alternatives according to anticipated effects.* Assess the benefits to population viability, indirect costs, opportunity costs, and foregone options for each alternative. Identify and array the range of acceptable alternatives that meet decision criteria.
7. *Select an alternative.* Apply decision criteria to results and select a course of action.
8. *Implement the alternative.* Institutionalize management guidelines of the selected alternative. Develop budgets and track implementation.
9. *Monitor results.* Compile and interpret monitoring information; revisit steps 1–8 as suggested by monitoring information and changing conditions.

From Marcot and Murphy (1996).

A second important component of our PVA definition is **time** (Frankel and Soulé 1981). As with any other prediction (e.g., weather, stock market), the assumptions used in PVA will be less and less reliable further into the future. Scott et al. (1995) proposed that when PVA is used in endangered species recovery plans it should incorporate **short-term projections** that are evaluated over time against a long-term goal (see also Goodman 2002). The **long-term** viability assessment should include goals that are biologically based. The short-term projections should explicitly incorporate political–legal–social constraints; monitoring and the iterative application of short-term PVAs can be used to evaluate how well long-term goals are being achieved. Thus, public review (and political trade-offs) can be incorporated in choosing short-term management strategies, but ultimate success is judged against the yardstick of the long-term, biologically based goal.

The final component of the definition of PVA is “**likelihood**.” Obviously, a higher probability of persistence over a given time will require a larger initial population size. Likelihoods are captured in quantitative PVAs with “**quasi-extinction curves**” (Burgman et al. 1993, Groom and Pascual 1998, Akçakaya 2000). There are many ways likelihoods can be portrayed; they are usually presented as the probability of reaching a quasi-extinction threshold over a range of time, or the probability of reaching different population sizes at some point over a fixed time, or the risk of decline

by a given amount. Consideration of these PVA components (viability threshold, persistence time, and likelihood of persistence) argue for PVA being conducted as an examination of alternatives, with a range of data and products, instead of performing just one PVA for a species with “X” data for “Y” probability of persistence over “Z” years.

Many key aspects of PVA have a strong biological basis, but the selection of goals requires the addition of a **social component**. Issues such as “For how long do we want to evaluate persistence?” and “How secure should that persistence be?” require social, cultural, economic, and political considerations (Shaffer 1987; Tear et al. 1995, 2005; Ludwig and Walters 2002; Svancara et al. 2005).

APPROACHES TO ASSESS VIABILITY

We describe several approaches to assessing viability (Mills 2007). The first 3 methods are quantitative approaches of PVA. The second 2 are alternate methods for assessing viability when data are sparser.

Population Viability Analysis Methods Time Series

If a series of abundance estimates over time is available for a small population, those data can be used to estimate the probability of reaching quasi-extinction thresholds. The mathematical approaches can become complicated as they attempt

to accommodate real-world biological and sampling issues such as density dependence, the ability to sample only one stage of a population (e.g., egg counts, breeding adults), sampling variation, and missing data. Morris and Doak (2002) provide a readable overview of this considerable literature.

Underlying all approaches is the idea that a time series of abundance estimates can be characterized by an average trend and variance in that trend (see Humbert et al. [2009] for the best way to estimate these for exponential growth); if past trends and variability are assumed to be reflective of the future, one can calculate the probability that the population might reach some quasi-extinction threshold in the future. The math captures the nonintuitive, but important, fact discussed earlier that variance in population growth rate means that even populations that tend to increase, on average, may be most likely to decrease to extinction. From a practical viewpoint, this implies that effects of management on variability in population growth can be as important as effects on the growth rate itself (Burgman et al. 1993).

As an alternative to estimating trend and variance, “**risk-based viable population monitoring**” uses a simple exponential growth model to directly estimate risk of decline over time, updating the risk assessment with each new abundance estimate, providing an efficient means of warning of future declines and demonstrating status (Staples et al. 2005). Software is available (http://www.cnr.uidaho.edu/population_ecology) to implement this methodology, building off an exponential growth model that incorporates both process and sample variance (Humbert et al. 2009).

Demographically Explicit Models

This class of PVA models uses estimates of vital rates, including **age- (or stage-) specific survival and reproduction rates**, their variances and covariances, and other information such as age structure and sex ratio of the population, density dependence, and effects of inbreeding depression. Although this method requires difficult-to-obtain information, it has the advantage of assembling biological information in a way that suggests specific actions that might reduce the chance of extinction (Beissinger and Westphal 1998, Mills 2007). For example, for an Amazonian forest frog (*Anomaloglossus stephensi*) declining on Amazonian forest fragments, adult male survival was not reduced by fragmentation, but mean clutch size was reduced by 17%. Biological meaning for these changes came from a demographically explicit model, which showed that a reduction in clutch size of this magnitude would be sufficient to cause the observed magnitude of population declines in fragments (Funk and Mills 2003).

Because of the multiple interacting factors in a demographically explicit PVA, **computer simulations** are typically used. Demographic stochasticity in survival is usually applied in 1 of 2 ways. The first approach draws the number of survivors in a cohort from a **binomial distribution** with

the specified mean survival rate for that time step and number of individuals in the cohort. The second way that demographic stochasticity is incorporated is to pick, for each individual, a random number from a **uniform distribution**; if the chosen number is greater than the mean survival rate of that time step, the individual dies; if it is less, the animal lives.

Mean survival (and reproduction) rates change in each time step due to environmental stochasticity. Operation of environmental stochasticity is mimicked in a PVA by choosing mean vital rates for each time step from a distribution of random numbers with a specified mean and variance (the variance is the process variance, separated from sampling variance). An alternate approach may randomly pick one of several vital rates measured in the field (or even entire matrices of vital rates from field data; Akçakaya 2000). When **modeling environmental stochasticity**, it also is important to specify correlation among vital rates and through time for particular rates because it affects both variance in population growth and probability of extinction (Ferson and Burgman 1995, Groom and Pascual 1998). If necessary, PVAs can include catastrophes (the extreme events outside the normal range of environmental stochasticity) by specifying the magnitude and average timing for their occurrence.

Genetic stochasticity, or the consequences of inbreeding due to genetic drift in a small population, is incorporated into demographically explicit PVAs by decreasing vital rates at different levels of inbreeding. It is difficult to measure both inbreeding level and fitness for most wildlife species (Oyler-McCance and Leberg 2005). Thus, in many PVAs, a range of values from other species are used to bracket possible effects; measurements of inbreeding depression have recently emerged for many wildlife populations (Crnokrak and Roff 1999, Keller and Waller 2002). The shape of the curve relating inbreeding to fitness is complex and includes the extent to which cost of inbreeding is or is not “**purged**” over time (Mills and Smouse 1994, Ballou 1997, Lacy 1997, Frankham et al. 2002). The range of inbreeding costs expected for any species, as well as uncertainty in the shape of the curve relating inbreeding to fitness, implies that incorporating genetic stochasticity is the same as with any other uncertain parameter in PVA (for example, dispersal rates, density dependence, breeding structure, etc.). The user should include a range of plausible possibilities, including “worst-case” and “best-case” scenarios.

Density dependence can and should be incorporated into demographically explicit PVAs if field data are sufficient. Unfortunately, density dependence is one of the hardest parameters to estimate in field populations; yet, subtle differences in how it is included in PVA models can drastically affect predictions (Mills et al. 1996). Burgman et al. (1993:163) argue, “It is probably silly to pretend there exists a perfect density-dependence curve in a scattergram of data and tortuously thread some guess at its form.” They present

an alternate strategy using field data to describe density dependence in a “density vague” manner. The **uncertainty** of parameterizing density dependence, and its effect on PVA projections, has led to the recommendation that PVA models should include at least one set of runs without density dependence, to provide a baseline understanding of extinction risks (Ginzburg et al. 1990, Mills et al. 1996). The real existence of density dependence will affect the interpretation of the products of the model for a particular management scenario (Boyce 1992, Groom and Pascual 1998).

The framework for incorporating factors into a demographically explicit PVA varies widely. In some cases, it is possible to use “canned” PVA programs. Two of the most popular are the **matrix-based RAMAS** (Ferson and Akçakaya 1990, Akçakaya 2002) and the **individual-based VORTEX** (Lacy 2000). Examples of species with published PVAs using these 2 programs include Chinese Hainan eld’s deer (*Cervus eldi hainanus* or *C. e. siamensis*; Song 1996), Hawaiian stilt (*Himantopus mexicanus knudseni*; Reed et al. 1998a), Florida manatee (*Trichechus manatus latirostris*; Marmontel et al. 1997), and Florida scrub jay (*Aphelocoma coerulescens*; Root 1998). In other cases, particular aspects of proposed management options or of the animal’s life history lead to development of PVA programs that are more species-specific, such as for African wild dogs (*Lycaon pictus*; Vucetich and Creel 1999), cheetah (*Acinonyx jubatus*; Kelly and Durant 2000), greater sage-grouse (*Centrocercus urophasianus*; Johnson and Braun 1999), and red-cockaded woodpeckers (*Picoides borealis*; Daniels et al. 2000).

Demographically explicit PVAs also allow the user to perform a **sensitivity analysis** to evaluate which life-history components and/or management actions will have the largest effect on population recovery (Fig. 35.3). Sensitivity analysis in the broad sense (reviewed by Mills and Lindberg 2002)

includes a variety of approaches, including direct perturbation of vital rates in a model, analytical sensitivity and elasticity calculations, and simulation-based approaches such as life-stage simulation analysis (Wisdom et al. 2000). Regardless of the approach, sensitivity analysis can guide both research and management. For example, field research into causes of global amphibian declines would be more efficient if coupled with sensitivity analysis to indicate which changes in certain vital rates would most affect population growth rate (Biek et al. 2002). Citta and Mills (1999) showed that sensitivity analysis could be used to explore how to decrease pest population growth by examining options for controlling brown-headed cowbirds (*Molothrus ater*) that would cause cowbird populations to decline. Similarly, sensitivity analysis can be used to explicitly incorporate human demographic, economic, and social systems with PVA of wildlife species (Lacy and Miller 2002).

The main obstacle to using demographically explicit PVA approaches is that they require substantial data. If data are not available, managers should resist the temptation to guess and, instead, should focus on collecting the relevant information or choose a different approach. However, where the match between model needs and data availability are reasonable, a useful approach is to “embrace uncertainty” about processes or parameters by acknowledging the uncertainty explicitly, and considering scenarios across a range of plausible values.

PVA with Multiple Populations

Any PVA approach for a single population can be scaled up from single population analysis to consider multiple populations across the landscape. With sufficient data, multiple-population PVA models can be spatially explicit, incorporating exact spatial locations of populations or individuals or

Fig. 35.3. An example of sensitivity analysis using Life-Stage Simulation Analysis (LSA) for greater prairie-chickens. Different potential management actions vary in how successful they would be in modifying the population growth rate. From Wisdom et al. (2000).

other features (Reed et al. 2002). Two additional concepts that enter into PVA evaluation of multiple small populations are the extent of **connectivity and correlation** in dynamics among the populations. Connectivity is important because it can lead to gene flow, which affects genetic structure (Mills and Allendorf 1996). It also can facilitate **colonization or recolonization** of unoccupied patches (Singer et al. 2000) and decrease local extinction probability via a “rescue effect” (Brown and Kodric-Brown 1977). Connectivity can, at times, have negative ramifications for small populations across a landscape, as when diseases are transmitted (Cunningham 1996) or maladaptive learned traits are transferred socially (Laland and Williams 1998). **Connectivity** involves complex behavioral processes such as dispersal (Reed et al. 2002), which have traditionally been difficult to measure accurately. However, measurement of connectivity for wildlife populations is becoming easier with development of field and analytical tools based on telemetry, mark–recapture analysis, and genetic sampling (Mills et al. 2003).

The other important component of multiple population models is the extent of correlation in dynamics of different populations. If there is **decoupling** of environmental stochasticity among small populations, it becomes much less likely that a single bad year or series of years would cause all populations to be lost (Harrison and Quinn 1989). For example, consider 3 populations of 50 animals each. If all 3 populations had probabilities of extinction of 0.2/year, but their probabilities were independent (because of decoupling of environmental stochasticity), the probability of total extinction for all 3 populations in a given year would be $(0.2^3) = 0.008$. In contrast, if the fates of the populations were completely coupled (for example, the populations were adjacent to each other), the probability of total extinction would be 0.2/year, the same as for 1 population.

The extent of **correlation, or coupling**, in environmental stochasticity can be largely affected by distance among populations, because similar climatic events or other perturbations (invasions by exotics, deaths caused by predators or disease, etc.) are more likely to occur simultaneously to populations that are close together. Movement of individuals (connectivity) also facilitates correlations among population. For example, Canada lynx (*Lynx canadensis*) populations across western North America are connected by dispersal, which may facilitate the relatively synchronous dynamics of lynx populations at the continent-wide scale (Schwartz et al. 2002).

In addition to application of time-series or demographically explicit models across more than one population, data for species with multiple populations facilitates another type of PVA. These are broadly called “**patch occupancy models**,” or “**incidence function models**” (Hanski and Ovaskainen 2000, Hanski 2002). They are conceptually similar to logistic regression modeling of colonization and extinction events (e.g., Sjögren-Gulve and Ray 1996, Sjögren-Gulve and Han-

ski 2000). Focusing on the widely used incidence function models, the key data are patch occupancies (whether or not a patch is occupied). The other parameters are **distance** between patches (metrics of connectivity other than distance can be used if available) and **size** of the patches (“size” can be scaled to account for habitat quality, but population size is ignored, and patches are assumed to be distinct). An important assumption of incidence function models is no increasing or decreasing trend in patch occupancy, for example due to recent severe habitat loss (Moilanen 1999, 2000). **Incidence function models** are best suited for short-term predictions of consequences of management scenarios rather than predicting long-term extinction risk. They are most appropriately used for relatively common species with rapid turnover of local populations in fragmented landscapes (Hanski 2002). If populations are relatively large or long-lived, so that local (within-population) dynamics are important, then other approaches are more appropriate (e.g., Lindenmayer et al. 1995).

Other Approaches to Assess Viability

From a biological perspective, the worst-case scenario is conducting an assessment of viability when time is short and data are scarce to nonexistent. Yet, this is normal for wildlife biologists around the world when adequate data for time-series, demographically explicit, or multiple population models are lacking. For example, in 1993, the President of the United States appointed a Forest Ecosystem Management Assessment Team (FEMAT) to evaluate the effects of large-scale timber-harvest options on wildlife species in western Washington, Oregon, and northern California (Forest Ecosystem Management Assessment Team 1993, Meslow et al. 1994, Thomas 1994). More than 1,000 plant and animal species were to be included in the assessment, including many species that were (and are) little known. The team had 3 months to complete the job. Difficult, if not impossible, tasks such as this are given to biologists far too often, and the problem is exacerbated on the global scale where data are often even sparser.

In the case of the 1,000 species assessed as part of FEMAT, the best that could be done was to implement a subjective “**expert panel**” approach to assess viability. This method had evolved from earlier use in analyses in the Pacific Northwest of the United States (e.g., Thomas et al. 1993), and continued to evolve after the FEMAT process (Marcot et al. 1997).

Unfortunately, whenever expert opinion or other subjective approaches are the only options for assessing viability, the results will be somewhat suspect. Humans are inherently bad at guessing risks (even when they are informed guesses), in part because we are led astray by factors such as how visible or controllable the risk appears, or the consequences of the risks (Burgman et al. 1993). Thus, we overestimate many low-level risks (e.g., death by tornado) and

underestimate high-level risks (e.g., death by heart disease). Second, and perhaps more importantly, the subjective decision-making process is based on the experience of the “expert” making the decision; “severe risk” will mean different things to different people. It is difficult to make transparent or testable the logic, mechanisms, predictor variables, sources of uncertainty, or other processes that go into the outcome of an expert judgment. Expert opinion assessments of viability will remain an uncomfortable and insufficient last resort.

In closing the discussion of methods for assessing viability, it is important to consider less data-intensive methods that are not part of PVA per se, but which can be used to assess viability when detailed population data are not available. Two approaches are described.

Rules-of-Thumb

Rule-of-thumb approaches assign qualitative ranks of risk using specified, operational criteria (reviewed by O’Grady [2002]). Common rule-of-thumb approaches include those developed by The Nature Conservancy (Master 1991, Master et al. 2000, Samson 2002) and the World Conservation Union (IUCN) Red List Categorization System (Mace 1995, IUCN 2001, Mace et al. 2008).

As an example of a rule-of-thumb approach, we focus on the IUCN Red List Categorization System (Mace and Lande 1991; Mace 1994, 1995; Gärdenfors 2000; IUCN 2001), which forms the basis for “Red Lists” that assess the conservation status of >18,000 plant and animal species worldwide.

Specifically, the IUCN approach (see Table 35.1) assigns species to 1 of 9 categories. To be placed in 1 of the 3 **categories at risk of extinction** (i.e., critically endangered, endangered, and vulnerable), at least one operational rule-of-thumb criterion must apply. These **criteria include** (1) rapid population decline, (2) small geographic range and decline, (3) small population size and decline, (4) very small or restricted population size, and (5) unfavorable quantitative analysis (Mace et al. 2008; Fig. 35.4). The fifth criterion for assigning species (quantitative analysis) includes a direct quantitative estimate of extinction probability within specified timeframes using a PVA. However, data limitations mean that, in practice, the IUCN system usually consists of criteria 1 through 5 (Mace and Lande 1991, Gärdenfors 2000). Sophisticated methods for making uncertainty explicit in the risk assessment procedure have been proposed for IUCN categorization (Todd and Burgman 1998, Akçakaya et al. 2000, Taylor et al. 2002), and software is available to standardize the process (Akçakaya and Root 2007).

A key philosophy behind the IUCN approach underscores an important general point about small population management; a distinction is made between assessing the severity of threat and setting conservation priorities (Mace 1994, 1995; Gärdenfors et al. 2001). Categories of threat established by the rules-of-thumb are just one piece of information used to set conservation priorities. At least as impor-

tant are additional criteria, which might include likelihood of success in restoring the species, number of other threatened species occupying the same habitat, taxonomic uniqueness, availability of funds, and the legal and political framework for conserving a particular species.

There are obvious **limitations** to any rule-of-thumb approach. For example, a single set of rules will not fit all species and situations (O’Grady 2002). Despite the limitations, biologists must turn to these methods at times, because they may be the best available. Mace and Hudson (1999:244) reported that

Although the IUCN system may be efficient at picking up different species facing diverse threats, it is not designed to be an accurate tool for measuring extinction risk, for projecting population status, or for designing population management plans. Its role is to highlight species exhibiting one of several symptoms of pending extinction and to classify species according to the relative severity of the apparent threat. The **Red List** is a useful conservation tool only when listing leads to measures to assess the causes of threat and to develop, where necessary, appropriate management responses and species recovery plans. In short, the IUCN red list criteria are designed to be robust and precautionary across a wide range of circumstances, to operate when data are scarce, and to pinpoint species in need of attention.

In contrast to the IUCN guidelines, the **Endangered Species Act** of the United States does not offer specific rules-of-thumb criteria for identifying species at risk of extinction. The ESA **uses qualitative assessments** to classify species as **endangered** (“in danger of extinction throughout all or a significant portion of its range”; USFWS 1973:2) or **threatened** (“likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range”; USFWS 1973:4). Classification, or listing, is based “solely on the basis of the best scientific and commercial data available . . . after conducting a review of the status of the species” (USFWS 1973:5). In the absence of robust criteria for listing and recovery, **listing determinations and recovery goals** have often been inconsistently applied (Scott et al. 1995, Tear et al. 1995).

Approaches Based on Habitat and Other Information

At times, more information is available about species–habitat relationships than demographic variables for a **species of concern**. Although we believe that the relevant population data should be collected for a proper viability assessment, there are cases where habitat information alone can contribute useful information (Boyce 1992). Recently, researchers in federal land-management agencies in the United States have developed a **Bayesian Belief Network** approach that

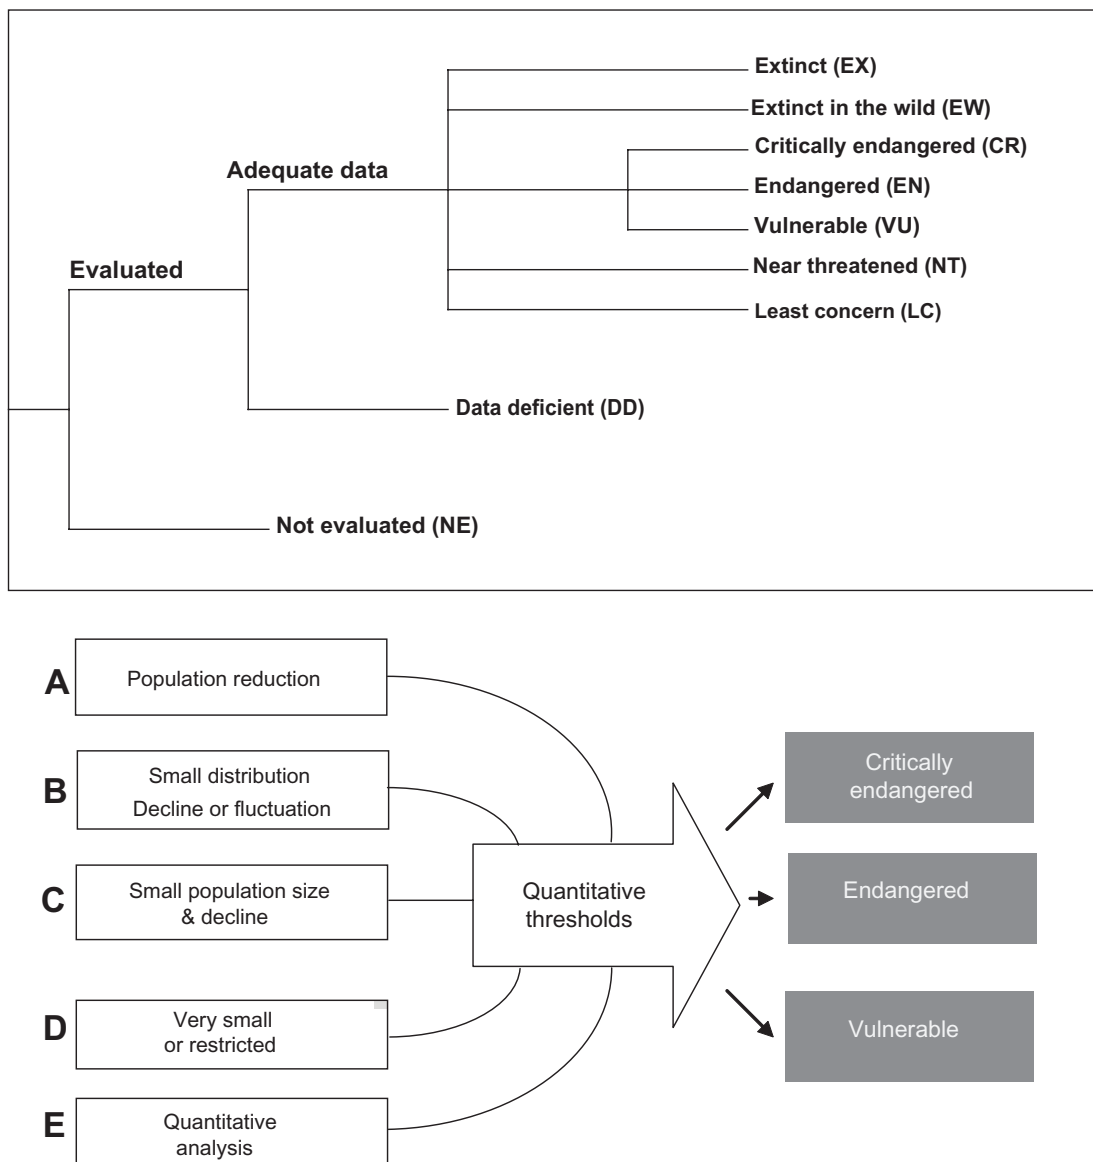

Fig. 35.4. The International Union for the Conservation of Nature (IUCN) population assessment procedures. From Gärdenfors et al. (2001), IUCN (2001).

combines vegetation associations with other information for region-wide or species-wide assessments (Lee 2000, Marcot et al. 2001, Raphael et al. 2001). Information in the Bayesian Belief Network includes associations with habitat and other variables, as well as expert opinion and ancillary models (including true PVA models). When expert opinion is included, it is incorporated so it can be easily scrutinized. Using a Bayesian statistical framework, input variable values are combined with conditional probability tables to estimate the probability of a response relevant to population status. Risks associated with alternative courses of actions can be explored. As an example of this approach, 28 species have recently

been assessed as part of land planning for the 58-million-ha Interior Columbia River Basin (for example, Wisdom et al. [2002] for assessment of greater sage-grouse and Rowland et al. [2003] for wolverine).

Marcot et al. (2001:29–30) described the **utility and limitations** of these approaches, noting that they do not substitute for the more rigorous and quantitative PVA approaches. Rather, these approaches are most useful when empirical data on demography and genetics are unavailable, but a decision-making process is inevitable. In these cases “the experts must provide their best professional evaluation or step aside and let activities proceed.”

PRACTICAL THOUGHTS ABOUT WILDLIFE RISK ASSESSMENT

The largest benefit to assessing viability for a small population is that it forces us to be explicit about the threats to a population. It places assumptions on the table where they can be discussed. For example, if one person believes that genetic isolation is the largest threat for a particular species, they may argue that connectivity enhances viability; alternatively, someone else concerned about disease risk for that species might argue that connectivity decreases viability. The assumptions are explicit.

From published works and our own experience, we offer 3 important messages regarding **assessing viability** as part of the management of small populations. First, be aware of the **quality of data** available and match those data with the most appropriate approach. Currently there is interest in the effects of data quality and sampling error on model performance. **Sampling error** will tend to make nature seem more “variable,” which tends to bias upward the predicted probability of extinction. The extent to which sampling error compromises PVA has been discussed intensely (Ludwig 1999, Fieberg and Ellner 2000, Meir and Fagan 2000, Holmes 2001, Sæther and Engen 2002). In any case, wildlife biologists should heed suggestions on how parameters of viability models can be estimated so that sampling error can be quantified (White 2000b, White et al. 2002). Second, viability assessment is more useful as a **comparative tool** for ranking management options than it is for making precise predictions of viability. Although there can be heartening matches between PVA predictions and actual population trajectories (Brook et al. 2000), instances where this is true are likely limited (Lindenmayer et al. 2000, Coulson et al. 2001).

Using PVA to evaluate relative merits of different management options allows it to be incorporated into the decision-making process that guides management action and policy (Maguire 1991, Noon and McKelvey 1996, Dreschsler and Burgman 2004). For example, consider a case of how PVA was used to improve the decision-making process (Fig. 35.5). Management of the Australian marsupial, **Leadbeater's possum** (*Gymnobelideus leadbeateri*), is one of the most contentious forestry issues in Australia. The primary threat to this species is its requirement for nest sites in trees >150 years old. Early this century, fires burned >60% of the forest within the range of the species, and clearcut logging has more recently occurred over 75% of its known distribution. The species now occupies an area 60 km \times 50 km in the central highlands of the state of Victoria in southeastern Australia. Current management is to avoid cutting in certain areas (including old-growth patches) while clearcutting continues in other areas; areas that burn in the future may be salvage-logged.

Possingham et al. (2002) examined the viability of Leadbeater's possum subject to current and potential future management options (see Fig. 35.5). Under current management, possums would be expected to persist for the next 150 years (only 38% chance of extinction), but not into the future (100% chance of extinction). If old-growth forest was not salvage-logged, trees damaged (but alive) after a fire would not be removed; this would increase possum viability so that extinction probability would decrease to 33% and 58% over the next 150 years and expected long term, respectively. If there were further limitations to **salvage logging**, so that it was prohibited both in old growth and in other areas that could grow into old growth, extinction probability drops even more. Two popular suggestions for further aiding this species are to increase the rotation time and to make more reserves, so these possibilities were considered next. Although increasing rotation time decreases extinction probabilities, it requires an almost complete halt of logging for the next 150 years, hardly a politically realistic possibility! In contrast, setting aside **reserves** improves viability even more, but reduces logging little; for example, setting aside just 6 (50-ha) reserves (5% of the forest block) decreases extinction probability to 18% over the long term, but reduces logging by only 5% at most. With identification of additional permanent reserves as a viable approach, a number of scenarios were considered, trading size and number of reserves. The authors **assessed the sensitivity of conclusions** by modeling a range of possibilities for processes about which they were uncertain. The recommendations emerging from this work are currently being implemented (Possingham et al. 2002).

Clearly, PVA needs to be explicitly and seamlessly incorporated into a small-population modeling and decision-making process, analogous to the **adaptive management framework** used to marry field data, biological process, sociopolitical goals, and management strategies for harvested species. Incorporating PVA as part of such an adaptive management framework for small populations has been termed **Population Viability Management** (PVM; Bakker and Doak 2009). As an example for endangered island fox (*Urocyon littoralis*) on the Channel Islands (Bakker and Doak 2009), the first step is to set recovery criteria in terms of quasi-extinction risk in a public forum, accounting for the inevitably complex sociopolitical and biological considerations. Next, readily monitored population attributes are chosen (adult population size and adult mortality in this case), and PVA is used to link these attributes to quasi-extinction thresholds, clarifying that uncertainty in the monitoring data will delay the delisting of a recovering population (Fig. 35.6). Finally, PVM incorporates management actions that will affect the population attributes; for example, determining how decreasing predation on fox by controlling golden eagles (*Aquila chrysaetos*) would achieve delisting, given the practi-

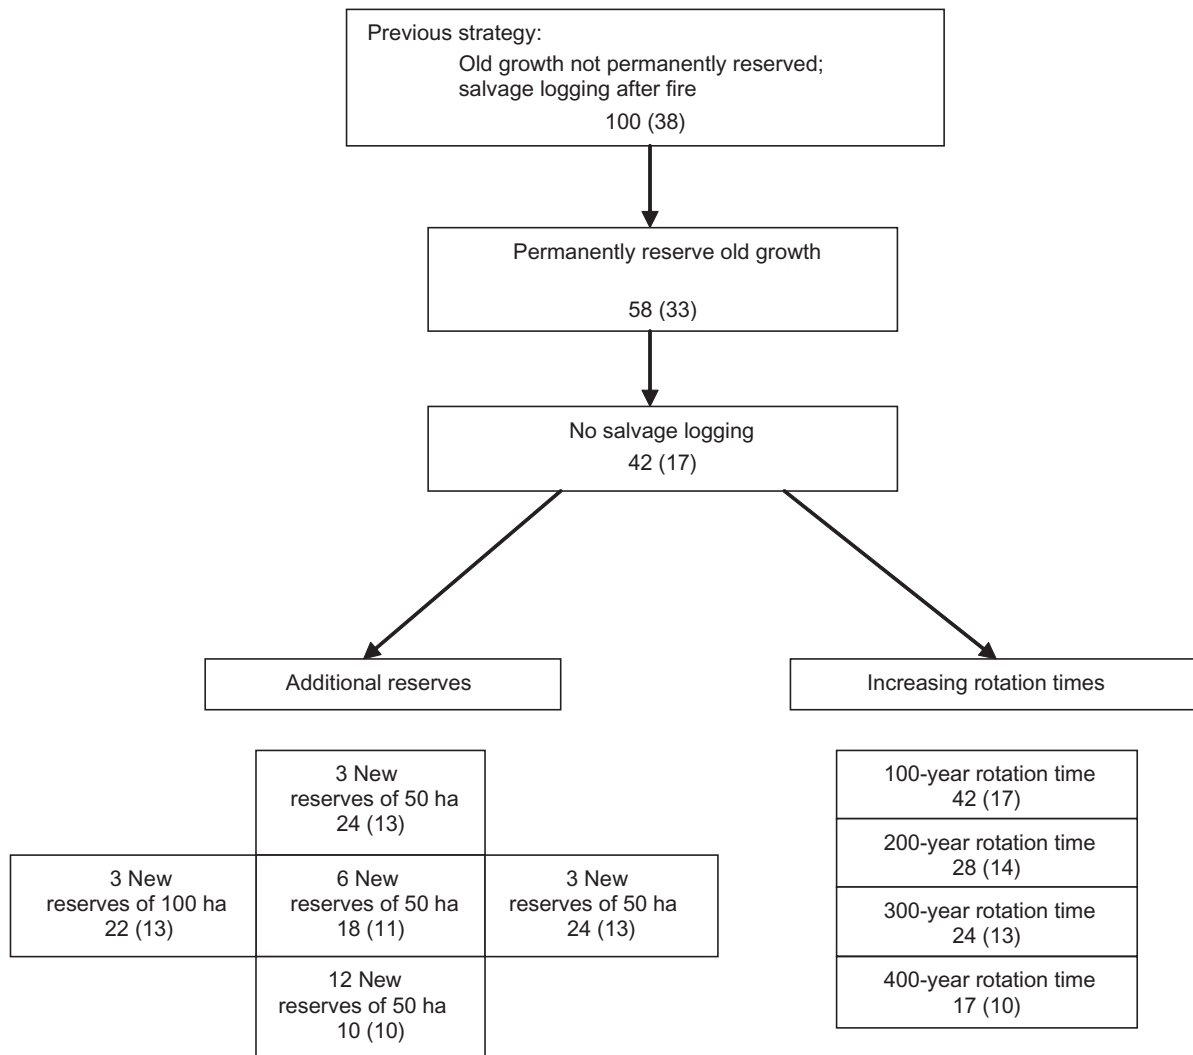

Fig. 35.5. Population viability analysis for decision analysis, made in the case of Leadbeater's possum. For each option, the number gives the probability of extinction over the next 150 years (in parentheses) and over a typical 150-year period in the future when the forest has reached equilibrium with the management actions (think of this as the period 500–650 yr from now, assuming constant conditions). From Possingham et al. (2002).

cal constraints of monitoring. As with the possum example, we see that PVM provides a platform for integrated adaptive decision-making. This would allow increasing knowledge and changing management outcomes to be accounted for in data-based decisions.

A third message for assessing viability is to **consider a range of possibilities** for every step of a PVA for which there is doubt about a process, functional relationship, or measured parameter. The worst PVAs are those that take one set of data and provide one estimate of extinction probabilities, while the best are those that consider a variety of biological and management information to produce a range of predictions (Taylor 1995, Ellner et al. 2002). Ideally, a PVA would be performed with multiple methods (Mills et al. 1996, Gärdenfors 2000, Kindvall 2000). **Sensitivity analysis** in the

broad sense, evaluating how information affects products, is an essential part of PVA (Reed et al. 1998b, Mills and Lindberg 2002). Also, Bayesian approaches directly incorporate parameter uncertainty into analysis (Taylor et al. 1996, 2002; Goodman 2002; Wade 2002).

Burgman and Possingham (2000:104) recalled the comment that “**All models are wrong, but some are useful**” (from Box 1979) to emphasize their point

The only correct model is an entire reconstruction of the actual system—whereupon it ceases to be a model. The utility of a PVA is determined by several things, including the care taken to include all ecological intuition faithfully, the care taken to represent all views (hypotheses) as structural alternatives, the detail and transparency of state-

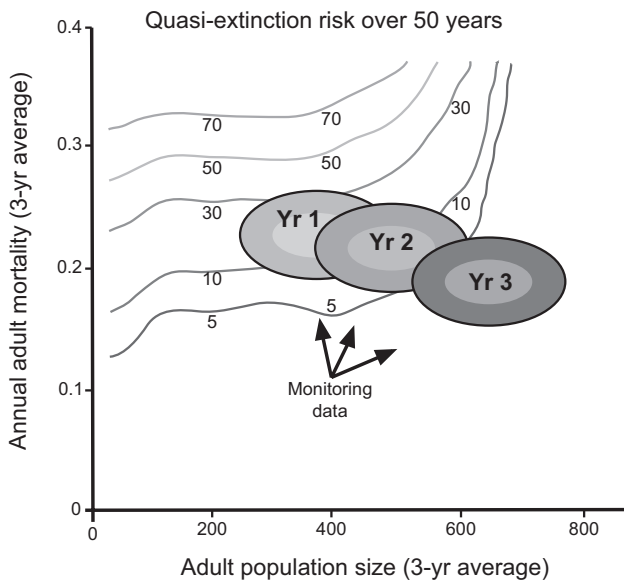

Fig. 35.6. An example of Population Viability Management (PVM) as an adaptive management strategy for endangered island foxes on Santa Cruz Island. The consensus recovery criteria was a 5% risk of quasi-extinction over 50 years (dark blue isocline in figure), with uncertainty in monitoring data controlled for by requiring that 80% confidence regions fall below the risk isocline. Different management actions that affect vital rates (e.g., predator control, captive breeding) can be compared via PVM, recognizing that less precise monitoring data (outer region of monitoring data ovals) could delay meeting the delisting criterion (because less of the confidence region would fall below the risk isocline). From Bakker and Doak (2009).

ments about assumptions, and the role of the model within the decision-making framework. One of the most important steps in establishing the credibility of a PVA is to communicate the uncertainties embedded in the model and its assumptions.

MANAGEMENT OF SMALL POPULATIONS

The results of a viability assessment or sensitivity analysis can provide managers with specific insights into how to most effectively increase size of a small population and reduce risk of extinction. A variety of techniques can be used; some are identical to those used with abundant species, but many others are especially adapted to the needs of populations with small numbers of individuals.

Effective management of small populations must address both **ultimate and proximate causes** of population declines. The ultimate cause of a species' decline is usually some change in the environment resulting from human activities. These changes might be novel events the species has not experienced (e.g., introduction of synthetic toxic chemicals, like DDT, into a species' food chain) or somewhat normal events that suddenly occur in **temporal or spatial patterns**

that are unprecedented (e.g., disturbing a forest through logging more frequently and on a different spatial scale than would occur under natural disturbance regimes, thus eliminating old-growth conditions). Regardless of the ultimate cause, the population fails to cope, resulting in proximate causes of decline such as reduced survival and reproduction, or both. Species are often faced with multiple threats whose effects are poorly documented; therefore, it is often difficult to distinguish between proximate and ultimate threats (Gurevitch and Padilla 2004).

The distinction between ultimate and proximate causes of species declines can lead to a dichotomy in management approaches (Temple 1978b). Clearly, management must correct the **ultimate causes** of decline by addressing the specific environmental changes that threaten the small population. **These causes include** such widespread problems as habitat loss or deterioration, effects of exotic organisms, toxic chemicals, and mortality directly related to human activities. Frequently, ultimate problems are difficult to remedy; typically, a long time is required for corrective measures to improve a species' environment. Time is a factor working against the persistence of most small populations.

To hasten recovery of a perilously small population, managers often must address **proximate factors** in a manner that is somewhat unrelated to the ultimate cause of a population's decline. Typically, the approach is to increase **survival and reproductive rates** by whatever means possible to stimulate population growth (ideally, building on the efficiencies made possible by sensitivity analysis; see next section). Ultimate problems are then addressed somewhat independently of these activities, which is similar to the treatment of a critically ill patient in a hospital's emergency room: treat the life-threatening symptoms and then remedy underlying problems (Zimmerman 1975).

Two birds, **osprey** (*Pandion haliaetus*) and **peregrine falcon** (*Falco peregrinus*), illustrate the benefits of addressing proximate problems (Spitzer 1978, Cade et al. 1988). Both species were threatened by the ultimate problem of contamination of their food chains with **chlorinated hydrocarbons**, especially dichlorodiphenyltrichloroethane (DDT). In each situation, populations declined precipitously after reproduction was impaired when eggs with DDT-thinned shells failed to hatch. Although measures were taken during the late 1960s and early 1970s to address the ultimate problem, by curtailing use of the offending toxic chemicals, both species continued to decline and remained at risk because of the persistence of the chemicals already in the environment.

To offset the proximate problem of inadequate recruitment, managers successfully augmented reproduction in wild ospreys and **released captive-reared individuals** into wild populations of peregrine falcons. Reproduction of ospreys was enhanced by reducing nest-site limitations through **erecting artificial nest platforms** in areas that lacked natural nesting sites (Postupalsky 1978), and by replacing thin-

shelled eggs with thick-shelled eggs (Spitzer 1978). Captive breeding and subsequent reintroduction of peregrine falcons provided an important boost to recruitment to populations that were producing too few young (Cade et al. 1988), which was critical to achieving positive population growth (Kauffman et al. 2003). In both situations, regional populations were doomed to eventual extinction unless attention to proximate causes improved the status of the species while ultimate problems were being addressed. In the post-DDT era, both ospreys and peregrine falcons recovered impressively after chlorinated hydrocarbon pesticides eventually were purged from the food chain (Spitzer et al. 1983, Cade et al. 1988).

The **efficacy of specific management actions** affecting particular vital rates can be assessed using sensitivity analysis. Next, we describe the critical links necessary to efficiently connect management actions to specific vital rate changes and increases in population size of small populations.

Improving Birth and Death Rates

The fundamental truth most relevant to managing small populations is that management actions are not all equal in influencing birth and death rates, and all birth and death rates are not equal in how they influence population growth (Mills 2007). The key, then, is to identify which management actions, through their effects on vital rates, will be most efficient at achieving an increase in numbers for small populations.

The good news is that an impressive toolbox of analytical approaches exists to quantify how individual birth and death rates alter population growth (see “Demographically Explicit Models” section above). Some vital rates have particularly large proportionate or absolute influence on population growth even though they vary relatively little, while others affect population growth because they can be changed drastically in nature or under management (Mills et al. 1999).

In some cases, enough work has been done to generalize across taxa which vital rates are most “important” for increasing population growth. For example, in ungulates and indeed across many long-lived species, **adult survival** tends to have the highest proportionate effect on population growth, but **calf survival** tends to vary so much that it is often the vital rate that most drives variation in population growth (Gaillard et al. 1998, Raithel et al. 2007). For endangered Sierra Nevada bighorn sheep (*O. canadensis sierrae*), life-stage simulation analyses indicated that, indeed, adult survival had the highest proportional effect on population growth; however, different populations differed in which vital rate had been disturbed the most, so that the most “important” vital rate, and most effective management strategy (e.g., predator control or augmentation), was population-specific (Johnson et al. 2010). A critical information need is to determine how different management actions affect vital rates in small population, thus connecting the dots

between management actions, vital rates, and population growth rate.

With demographic models guiding the process of identifying **proximate vital rates** that will most efficiently change population growth rate, the manager will be poised to implement management to improve those rates. Methods exist to increase both reproduction and survival. In birds, **natality** (e.g., litter size or clutch size) can be increased by stimulating additional egg laying bouts via removal of eggs from the nest. **Egg viability** can be ensured by artificially incubating the extra eggs or placing them in nests of foster parents (Cade 1978). A few species present the opportunity to increase frequency of reproduction. Animals that have long periods of **parental care** of offspring are inhibited from reproducing while caring for dependent young. Shortening the time to independence can reduce the intervals between breeding. For example, California condors (*Gymnogyps californianus*) can be induced to breed annually, in contrast to the normal biennial rate, thus effectively doubling fecundity (Snyder and Hamber 1985).

In some populations, only a proportion of the reproductively competent individuals have the **opportunity to breed**. **Shortages of specific resources** essential for breeding typically are responsible for limiting the number of breeders in a population. If these limitations to breeding can be removed, previously excluded individuals can breed. **Nesting sites** frequently limit the number of breeders and provision of artificial nesting sites such as nest boxes, cavities, and burrows can result in improved fecundity (Snyder 1978).

Reproductive failures normally reduce recruitment below the potential rate suggested by a species’ natality. Losses of young before recruitment into the population can be substantial. Preventing those losses effectively increases recruitment. Many techniques have been used, including the quality of breeding sites, reducing risks (e.g., predation) to young animals, or implementing “**head starting**” approaches that give young animals improved prospects for survival to breeding age (Temple 1978b).

Survival also may be increased as a means of stimulating population growth. **Reducing effects** of predators, pathogens, competitors, and accidents can be effective (Jackson 1978). These manipulations may reduce losses below normally expected levels and enhance survival in a population, even if poor survival is not an important factor in the population’s decline. For example, protecting an endangered species from human exploitation can improve survival, even if overexploitation is not an identified cause of endangerment. **Improving the quality of a species’ habitat** also can improve survival; however, habitat improvement is rarely a short-term solution.

Population Augmentation

Translocations can be used for augmenting small populations to increase population size, enhance genetic diversity, diversify age or gender composition, or create new popula-

tions through reintroduction to a previously occupied area. Examples include amphibians (Arano et al. 1995, Marsh and Trenham 2001, Rathbun and Schneider 2001; but see Seigel and Dodd 2002 and Trenham and Marsh 2002), adders (*Vipera berus*; Madsen et al. 1996, 1999), greater prairie-chickens (Soulé and Mills 1998), red-cockaded woodpeckers (Allen et al. 1993, Haig et al. 1993, Carrie et al. 1999), Laysan ducks (Reynolds et al. 2008), New Zealand robins (*Petroica australis*; Armstrong and Ewen 2002), sea otters (*Enhydra lutris*; Bodkin et al. 1999), cougars (*Puma concolor*; Ruth et al. 1998), black bears (*Ursus americanus*; Eastridge and Clark 2001), and woodland caribou (*Rangifer tarandus caribou*; Compton et al. 1995). In spite of some high-profile successes, Griffith et al. (1989) and Wolf et al. (1996) found that only about two-thirds of translocations in the United States, Canada, Australia, and New Zealand were considered successful, with success rates varying among taxonomic groups. Drake and Temple (Chapter 36, This Volume) provide a thorough discussion of guidelines, issues, and techniques related to animal translocation.

Habitat Protection

When populations are small because of the **ultimate problem of habitat loss or fragmentation**, protection or restoration of habitat is a necessary step in preventing further declines and increasing population size. Recovery of populations to sizes that are robust to stochastic factors will not occur unless larger habitat patches are available to support a viable population size. A PVA can provide managers with an estimate of the habitat requirements (quantitatively and qualitatively) for a viable population and goals for habitat protection and restoration. For example, spatially explicit PVA models examined how proposed habitat management actions in a U.S. Forest Service District would affect Bachman's sparrows (*Aimophila aestivalis*), a species endemic to pine woodlands of the southeastern United States (Liu et al. 1995).

We live in an increasingly fragmented world; therefore, nearly all **protected areas** (e.g., National Wildlife Refuges, National Parks, wilderness areas, private nature reserves, wildlife management areas) are small and increasingly embedded in substrates that prevent distant movements of many of the species for which protected areas were established. Newmark (1987, 1995) found that in western North American parks, extinctions have exceeded colonizations since park establishment and that rate of extinction was inversely related to park area.

DellaSala et al. (2001) found 97% of all protected areas in North America to be 10,000 ha in size, with 76% of all reserves 200 ha. By themselves, these areas are **too small to support viable populations** of even small animals, and far short of the area needed to support larger carnivores or ungulates (Schonewald-Cox 1983). When reserve sizes were compared to the minimum area requirements of terrestrial mammals in eastern North America (Gurd et al. 2001), only 14 of 2,355 existing reserves (0.6%) were sufficiently large to

meet the lower confidence limit of the area required to prevent loss of terrestrial mammal species. This analysis may be optimistic for species conservation, because use of the upper confidence limit rather than the lower would mandate even larger reserves for maintaining viable populations of mammals.

Collectively, these findings of the inadequacy of protected areas mean, first, that management of the **matrix surrounding protected areas** is essential; and second, that even after important habitat areas are identified for protection, it is frequently necessary to plan for ecological restoration (a long-term process) to create habitat in areas not presently suitable for the species (Howell 1988). In addition to occurring in only a fraction of the species' **historical range**, many small declining populations occur at the extremes of former range in habitats that may be suboptimal. The whooping crane (*Grus americana*) provides an example (Lewis 1986), as do many of the upland forest birds of Hawaii (Scott et al. 1986, Channell and Lomolino 2000). **Habitat restoration** may be essential to allow a small population to expand its size to the point that it can be considered no longer in danger of extirpation.

Monitoring

Establishing **monitoring programs** for small populations presents special challenges for the manager. At the most fundamental level, the range of a rare species and its specific habitat requirements may not be known. **Surveys**, thus, may be conducted in unused or unsuitable habitat, unnecessarily increasing the cost of monitoring efforts. Also, observers may be unfamiliar with identification of a rare species and, after failing to find it, conclude incorrectly the population has been extirpated (Scott et al. 1986, Diamond 1987, Reed 1996), or underestimate the effort needed to detect individuals and delineate the limits of small populations (Scott et al. 2008). Finally, small populations will inherently have statistical limitations of insufficient power to detect trends.

Ideally, a monitoring program should address these issues by incorporating as much information as possible about the species' putative range and its habitat associations within that range. It should include a **species-specific program** to train observers in survey techniques and accurate identification of the species of interest, including exposure to the full range of variation (e.g., plumage, pelage, vocalizations, or sign) for the species (Kepler and Scott 1981, Scott et al. 1986). To infer the presence or absence of the species, an important component of the monitoring program will be estimation of the probability of detecting the species at a particular point (Reed 1996, MacKenzie et al. 2002). **Detection** is dependent on a variety of factors (Kepler and Scott 1981, Scott et al. 1986, Reed 1996) including density of individuals, sampling effort, species behavioral characteristics, observer bias, weather conditions, time of day, season, and ambient noise (e.g., wind, water, or anthropogenic noise). **Noninvasive genetic sampling** (Box 35.4) has particular promise (although

Box 35.4. THE NATIONAL LYNX SURVEY AND ETHICS IN COLLECTING DATA ON SMALL POPULATIONS

For many small populations, the first step in monitoring requires an inventory to identify where the species exists. In the lower 48 United States, the Canada lynx became a species of special concern to land managers in the late 1990s, and was listed in March 2000 as a federally threatened species. However, it was not known precisely where the species occurred in its range in the continental United States. The National Lynx Survey was conceived to bring the properties of consistency, standardization, and reliability to the process of identifying current range for lynx, thereby providing a basis for subsequent monitoring.

The National Lynx Survey sampled lynx distribution at an unprecedented scale: 16 states across the northern United States. Collection of samples required the efforts of hundreds of field personnel. The sampling device for this elusive and low-density species was noninvasive, based on 10 × 10-cm carpet pads smothered in a beaver castoreum and catnip oil scent lure, with nails sticking out. Lynx (and other species) willingly rub against it and leave hairs behind (McDaniel et al. 2000), which can be analyzed for species identification using DNA markers (Mills et al. 2000a). At each sampling site, 125 rub-pads were placed in a systematic grid: 25 transects, 3.2 km apart, with each transect consisting of 5 rub-pads, 100 m apart. Pads were checked after 2 weeks. The survey was conducted for 3 years, with an additional pilot year.

Before the survey was initiated, the principal investigators at the University of Montana and at the Rocky Mountain Research Station, U.S. Forest Service, developed reliable DNA-based tests to distinguish lynx from other species based on the degraded and low-quantity samples obtained from single hairs (Mills et al. 2000a). Importantly for identification of species of political concern, exhaustive tests to validate the species-identification protocol were conducted prior to initiating the survey (Mills et al. 2000a, Mills 2002). These validation tests were included in a detailed protocol sent to all field workers, which also included comprehensive written instructions for all aspects of gathering, labeling, and submitting samples.

After 3 years of sampling, the survey can be considered a success (McKelvey et al. 2002). More than 21,000 pads were placed, and approximately 4,000 samples were processed. About 80% of the hair samples (including single hairs or fragments of hairs) were identified to species. Many other species were detected even though the sampling method was designed to target lynx.

Despite its success in verifying and establishing lynx presence on a nationwide scale, the implementation of the National Lynx Survey identified a challenge broadly relevant to sampling small populations at large scales: the need for field personnel to maintain integrity of all data collected. Despite the detailed written protocol sent to all field-data collectors, a handful of field personnel ignored the protocol and labeled hair from petting zoos and wall mounts as if they were field-collected samples; by sending in these mislabeled samples without informing the principal investigators, they threatened the integrity of the data stream in the nationwide study. A nationwide political and media furor erupted (Mills 2002, Thomas and Pletscher 2002). Fortunately, firewalls were in place in terms of field and lab protocols to protect the scientific integrity of the study to contribute to land management decision-making. Not only were the analyses of the noninvasively collected hair samples fully validated, but also the study design ensured that hair collection in the survey was only the first step in evaluating lynx presence. Follow-up snowtracking and trapping efforts were built into the study to separate actual lynx populations from transient individuals, fur-farm escapees, or mislabeled samples (McKelvey et al. 2002).

Noninvasive DNA sampling opens up the potential for large-scale sampling of distribution and abundance of wide-ranging and small populations. However, the integrity of the samples collected must remain paramount.

not without pitfalls) for both identifying distribution and monitoring abundance of hard-to-sample and rare populations (Mills et al. 2000a, b; Oyler-McCance and Leberg 2005).

Even when monitoring abundance in an area where a small population is known to exist, low densities can lead to a low capture or detection probability, which increases sample variance and decreases the likelihood of detecting real declines. The **problem of low power** in monitoring is rele-

vant to all wildlife biology studies (Steidl et al. 1997, Gibbs 2000). It takes on amplified importance in small populations, where failure to detect a decline (Type II error) can lead to extinction (Taylor and Gerrodette 1993, Reed and Blaustein 1997). The concern over inherently low power to reject the null hypothesis of “no decline” for small populations has led to consideration of how to reverse the “burden of proof” for detecting a decline in abundance (Mapstone 1995).

The problem of **high sampling variance** inherent for estimates of abundance in small populations leads to other risks where management plans are based on abundance estimates (e.g., setting recovery goals, harvest levels, or listing under the ESA). An approach to avoiding this problem has been implemented by the National Marine Fisheries Service. In guidelines developed under the Marine Mammal Protection Act, stock assessments are based, in part, on an estimate of minimum population size (U.S. Department of Commerce 1995). The estimated **minimum population size** (N_{\min}) is defined as the lower 60% confidence limit of a distribution resulting from a point estimate of abundance and its coefficient of variation. This method increases the probability that population size is equal to or greater than the estimate, accounting for the uncertainty of sampled small populations (Taylor et al. 2000).

The challenges of monitoring trends in abundance, especially for small populations, have led to the development of alternative monitoring frameworks that sidestep abundance and instead rely on **presence-absence, or occupancy** (MacKenzie et al. 2006). In effect, these methods target detection of changes in occupancy measured as the proportion of sampling units where the species is present, correcting for detectability. Although less information is collected at each site than in traditional abundance-based trend monitoring, more sites can be sampled for presence-absence. Indeed, the trade-off of larger scale sampling makes occupancy monitoring an optimal strategy in many cases, especially with cryptic or low-density species and limited funding (Joseph et al. 2006). For example, Witczuk et al. (2008) found that presence-absence sampling was the preferred method for monitoring trends over time of endemic Olympic marmots (*Marmota olympus*) in Olympic National Park.

Finally, we underscore that managers should not deal with the frustrations of monitoring small populations by taking shortcuts in design or study implementation. In particular, **indirect indices of abundance** (e.g., tracks, burrow counts, animal counts uncorrected for detectability) should be implemented only reluctantly and with great care.

Conservation-Reliant Species

In many cases, implementation of well-designed management actions will stabilize or increase the size of a small population to the point that it is expected to persist without further intervention. These successes, whereby population objectives are maintained, are consistent with **societal goals** (e.g., recovery, recreationally viable, ecologically functional). For other species, it is increasingly clear that continued, sometimes intensive management will be required to sustain viable populations. When a species' decline is caused by factors that can be controlled, but not eliminated, it is considered **conservation-reliant** (Scott et al. 2005) and will need continuous intervention to keep risk factors at bay. Conservation reliance is often found when declines are due to ultimate factors that are so widespread or slow to remedy (e.g.,

habitat loss, competition from invasive species) that treatment of proximate factors such as recruitment or dispersal will be necessary until the ultimate causes of decline can be corrected.

Scott et al. (2005) identified varying degrees of conservation reliance, from species that are entirely dependent on human intervention to those that are able to maintain viable populations once primary threats have been removed. For example, while both the **Aleutian cackling goose** (*Branta hutchinsii leucopareia*, formerly known as the Aleutian Canada goose *B. canadensis leucopareia*) and the Hawaiian stilt were **threatened by nonnative predators** and responded well to **predator removal programs**, their needs for ongoing predator control differ. Aleutian cackling geese nested on small islands and declined due to predation by introduced Arctic foxes (*Vulpes lagopus*). The size of the islands, size of the predator, and **intensive predator-control effort** made it possible to eliminate foxes from the goose's breeding islands, and population size increased to a point that far exceeded recovery goals; **the species was delisted** with no further predator control actions required. **Hawaiian stilts** also declined to small population sizes due to **nonnative predators** (e.g., black rats [*Rattus rattus*], feral cats [*Felis catus*], Indian mongoose [*Herpestes javanicus*]), and **extensive predator-removal efforts** within protected areas have been effective in increasing survival and reproduction of stilts. Because the stilt's predators are found throughout the island of Oahu, however, it has not been possible to eliminate them, and predator control **actions will be required for the foreseeable future** even if numbers of individuals and populations consistent with recovery goals are exceeded.

In reality, most small populations may well require **ongoing conservation actions** to maintain viability even after populations have increased (Scott et al. 2005). Managers will need to identify the conservation measures that not only will most aid recovery, but also must be continued indefinitely to prevent future declines. Here, PVA and sensitivity analysis, in particular, can help. **Sensitivity analysis** can be used to pinpoint management actions that are most likely to contribute to population persistence and compare estimated levels of success for each action, and can help evaluate the need for continuous management. For conservation-reliant species, the population's potential for long-term recovery will rely on the certainty that ongoing management intervention will continue (Scott et al. 2005).

SPECIAL CONSIDERATIONS FOR MANAGING ENDANGERED SPECIES

Permit Requirements for Endangered Species Programs

When a species is listed as endangered or threatened in the United States, **permits are required** to undertake all types of "hands-on" management or any activity, including research, which may disturb the species. Permits can be granted for

scientific research or management activities that enhance the welfare of the species.

Applications for permits to manipulate a listed species must be submitted to the U.S. Fish and Wildlife Service or the National Marine Fisheries Service. Once a permit application has been received and accepted as providing the necessary information, a notice is published in the *Federal Register* to allow for public review and comment on the application. Once the review is completed, a permit is issued if the activity is not likely to jeopardize the continued existence of the species.

Scientific permits generally are issued for research and management that will benefit the recovery effort for the species, or for research related to the assessment of threats to the species. In general, permits are not likely to be granted for research that can be accomplished on closely related or surrogate species.

Public Scrutiny of Endangered Species Management

All wildlife management activities are **subject to public review**. However, endangered species conservation and management programs can be especially contentious. Endangered species managers must be prepared for the biological, social, economic, and political controversies that seem inevitably to surround most activities (e.g., Liverman 1990, Clark et al. 1994; see Box 35.4).

Although the **recovery process** prescribed by the Endangered Species Act specifically **avoids issues that are not biologically based**, endangered species managers frequently are asked to defend their biological proposals in arenas where the challenges are nonbiological (Tilt 1989). Designations of **critical habitat** and the attendant need to protect or restore specific areas for the benefit of endangered species often have social and economic effects that precipitate acrimonious debates (e.g., conflicts between northern spotted owl [*Strix occidentalis caurina*] recovery programs and the logging industry in the Pacific Northwest; Doak 1989, Thomas et al. 1990).

Climate Change

The 3 ways (Running and Mills 2009) in which all wildlife populations will **respond to climate change is to move** (e.g., shift geographic range), **adapt** (deal with stressors through plasticity or natural selection), **and/or decline** (e.g., unsuccessful adaptation or movement). To the extent that small wildlife populations exhibit traits such as limited dispersal, high habitat and behavioral specificity, short generation

times, and low genetic variability, they will be more prone to decline in the face of novel climate-induced stress; by contrast, the species most likely to prosper through moving and adapting are large populations of generalist invasive and subsidized species (Running and Mills 2009). The ultimate cause of species' declines attributed to climate change is largely out of managers' hands; therefore, it will be critical to enhance a population's capacity to move and adapt. **Potential management actions** include those discussed in this chapter, such as monitoring and improvement of birth and death rates, perhaps with increased importance of population augmentation to offset the effects of limited dispersal and genetic diversity (see also Mills 2007, Scott et al. 2008, Griffin et al. 2009).

SUMMARY

This chapter addresses a range of considerations and tools for managing small populations. It should be clear there is no cookbook approach. The recovery of small populations will be most effective when field data and quantitative tools such as population viability analysis are explicitly incorporated into adaptive management strategies. Because of uncertainties that can affect the persistence and recovery of a small population, managers must be prepared for unexpected problems and adjust their management plans accordingly. Each species and situation presents a unique set of challenges for the manager; the same species may present different management issues in different time periods and different ecological settings. Thus, a modeling framework can be exceptionally helpful to choose among potential management scenarios, and to account for uncertainty in what is known about the species, and what the management will accomplish. Population Viability Analysis is a well-grounded framework for considering dynamics of small and declining wildlife populations. We know that vital rates (e.g., reproduction and survival) are not "created equal" in their effect on population growth or persistence, and that different management alternatives are not equal in the extent that population characteristics can be changed. Thus, sensitivity analyses in the broad sense are a vital component to decide which specific management actions are most likely to aid a small or declining population. As a precautionary and general rule, however, management of small populations should begin early rather than late because, with diminishing population size, a population's vulnerability to extinction increases as management options become more and more constrained.

Captive Propagation and Translocation

INTRODUCTION

CAPTIVE PROPAGATION entails breeding and rearing animals in captivity and can be a useful, and sometimes essential, tool when managing for the recovery of rare and endangered species (Cohn 1988, Rahbek 1993). Along with **translocation** (removing individuals from a source population and releasing them in a different location), these approaches can provide managers with stock that can be used to either introduce or reintroduce a population into suitable habitat and to augment wild populations that have not maintained intrinsic viability. **Introductions** involve releasing animals (from either captivity or the wild) in areas where they have not previously existed, usually because previous habitat is no longer available, but new habitat is considered suitable. **Reintroduction** involves releasing animals in places where they previously existed. To limit confusion throughout this chapter, we use “translocation” in the general sense, unless noted otherwise, and follow the International Union for Conservation of Nature and Natural Resources’ (IUCN) definition of translocation as any movement of animals from one area to another. The IUCN (1998) recognized 3 types of translocation: (1) introduction, (2) reintroduction, and (3) **restocking** (movement of animals to supplement an existing population).

Like most management tools, these strategies have a specific role to play in wildlife conservation and may be crucial in **recovery efforts** for certain species under particular circumstances (Adams and Witkowski 2007). However, because such programs often involve **critically endangered, charismatic species**, they are usually highly visible and attract considerable attention, leading the public to mistakenly believe that these are the routine approaches used by managers to recover threatened species. In this chapter we explain why, when, where, and how captive propagation and translocations can be most effective as components of conservation efforts.

Conservation strategies that involve removing animals from their natural habitat are known as **ex situ** strategies, in contrast to **in situ** strategies that attempt to recover threatened species entirely within their natural habitat (see Chapter 35, This Volume). **Captive propagation** is the most widely recognized ex situ conservation strategy for wildlife species, and it involves removing individuals from the wild, caring for them in captivity, and propagating them in order to produce enough individuals to maintain a self-sustaining captive population and, in most instances, provide additional individuals that can be returned to the wild. In a few special circumstances (i.e., black-footed ferret [*Mustela nigripes*]), long-term maintenance of a species’

population in captivity may become a necessary conservation strategy. Captive propagation of threatened species shares some features with **game farming**, where the objective is to produce animals that can be released for sport hunting, but the goals and challenges are very different.

Translocation is another strategy for obtaining individuals that can be used for introduction, reintroduction, and augmentation of populations in natural habitats. In this instance, the source population is a wild population rather than a captive population. Source populations that are capable of producing a surplus of individuals, beyond what is required to maintain the source population, can be removed in a sustainable manner to obtain stock for translocation. The translocated individuals can either establish a new population or augment an existing population.

Whether the source of individuals is a captive population or a wild population, a common goal is to return the individuals to the wild, where they can become part of a self-sustaining wild population that eventually becomes capable of growing to a point at which it is no longer dependent on continued augmentations. Introducing individuals into new areas, reintroducing them into formerly occupied areas, and translocating them from one population to another are approaches that demand special techniques to maximize the likelihood that these individuals will survive and reproduce, thus founding or rescuing a wild population.

The process of captive breeding and translocating animals to sustain a species' free-ranging population can be a costly, labor-intensive, logistically difficult, long-term endeavor, often with low success rates (Beck et al. 1994, Snyder et al. 1996, Mathews et al. 2005, Germano and Bishop 2008). Before embarking on such a mission, it is critically important to ask questions that can improve program success and avoid wasting financial and human resources. Kleiman et al. (1994) provided factors for consideration prior to implementing a captive breeding and translocation program. Another good source to review beforehand is the IUCN Guidelines for Re-Introductions (IUCN 1998). **Factors for consideration** include the following (Kleiman et al. 1994):

- Does a wild population need to increase the number of individuals or its genetic diversity?
- Is there a taxonomically appropriate, genetically healthy, and available captive or wild source of animals from which translocations can occur?
- Will the translocation endanger or jeopardize the natural population(s) via genetic swamping, disease, resource competition, or other issue?
- Have the original causes for the species' decline (i.e., habitat destruction, overexploitation) been resolved or eliminated?
- Is there an adequate amount of ecologically suitable habitat to house a current population and allow for population growth into the future?

- Will the human population that lives in close proximity to the translocated wildlife population support the efforts, and/or experience any negative effects from increasing the wildlife population?
- Do the necessary state and federal wildlife agencies, as well as relevant conservation organizations, support the translocation effort in terms of (if applicable) financial and personnel commitments, granting of necessary permits, and institutional policy?
- Is there a clear, scientific protocol for release and monitoring of individuals into the wild, and are methods either previously demonstrated to be effective or can new methods or techniques be developed and evaluated?
- Can clear, quantifiable benchmarks be established to objectively and scientifically evaluate the success of the translocation effort?

How to prioritize which questions to ask and answer first will largely depend on the specific situation. It may or may not be imperative to have answers to all of your questions prior to embarking on a captive breeding and translocation program. But, the fact remains that these programs are expensive and may shift resources away from habitat acquisition and/or field research conducted to better understand species' ecology (Loftin 2000). Critics may challenge the management of a species via captive propagation and translocation on grounds of cost-effectiveness and ultimate success (or lack thereof), ethical concerns about manipulating free-ranging, wild populations (i.e., genetic modification), and animal welfare issues surrounding holding animals in captivity and releasing them into an unfamiliar environment (Loftin 2000, Teixeira et al. 2007). Captive breeding and translocation is warranted in certain instances (Snyder et al. 1996), but it is important to ensure that it is warranted and has the best chance to succeed. Thoughtful consideration of questions like those above will determine whether drastic measures like translocation are required, and if so, will greatly improve chances for success in sustaining a population via artificial means.

WHEN IS CAPTIVE PROPAGATION APPROPRIATE?

Captive propagation has broad potential applicability because many wildlife species can be propagated in captivity. Does that mean that this approach should be routinely used as part of recovery efforts? Some have argued that this management tool should always be at least considered, but many suggest that it is most appropriate in only certain situations (Hutchins and Wemmer 1991, Conway 1995). Critics argue that captive propagation is an expensive, high-risk distraction from in situ conservation efforts (Snyder et al. 1996). It can give a false sense of security that a threatened species is secure. In the worst case, they argue that a captive population can be used to justify allowing a species' natural habitat

to be lost or degraded. Nonetheless, it seems clear that when used appropriately, captive propagation can play a key role in some recovery efforts (IUCN 1987).

The most obvious situation is when a species seems doomed in the wild and in situ management appears incapable of preventing an imminent extinction. Captive breeding presents a final option for rescuing such species. An example of such a situation is the Mauritius kestrel (*Falco punctatus*) recovery effort (Cade and Jones 1993). When the kestrel population dropped to 4 individuals with little hope of recovery through in situ management, the decision was made to undertake a last-ditch captive breeding program. These situations usually generate some controversy, and the kestrel decision was certainly debated hotly. The decision ultimately proved to be the key to the kestrel's recovery, because captive breeding for the species has been highly successful in steadily increasing the size of the population.

Another situation is the case of "orphan species" that no longer have suitable habitat in the wild. Habitat destruction, invasive species, environmental contamination and other factors may render a species' habitat unsuitable or unavailable for an extended period until habitat restoration, eradication of invasive species, or decontamination can occur. Often so much time is required for corrective actions to take effect that the only option for the species is an extended period in captivity. An example of such a situation is the Guam rail (*Gallirallus owstoni*), an endangered bird found only on the island of Guam. Its habitat was completely overrun by introduced brown tree snakes (*Boiga irregularis*) that preyed on the rails, causing a rapid population decline toward extinction (Marshall 1985). With no known technique for eradicating the invasive snakes and making the rails' habitat suitable again, the decision was made to bring the remaining 21 individuals into captivity (Derrickson 1987). A successful captive-breeding program increased the population and eventually provided stock for reintroduction in habitat cleared of snakes on Guam and introduction on the nearby snake-free island of Rota (Haig et al. 1990).

When circumstances lead managers to conclude that chances of a successful recovery depend on the types of genetic and demographic manipulations that are feasible in captivity, but not in the wild, captive propagation is appealing. If a population has declined to such a small size that genetic and demographic issues seem almost certain to hamper the ultimate recovery effort (see Chapter 35, This Volume), captivity provides management options not generally feasible in situ. For example, the endangered black-footed ferret was reduced to 18 individuals after canine distemper decimated a managed wild population (Box 36.1). The prospects of genetic and demographic obstacles to recovery led to the remaining individuals being taken into captivity, where a well-executed management plan ensured the retained genetic diversity of this small population was maximized. Without using a planned breeding system in captivity, the

long-term genetic outlook for the ferret population would have been poor (Biggins et al. 1998).

Captive propagation may be useful when there is a need for stock for introductions or reintroductions that can't be met by translocating individuals from source populations in the wild. Often for threatened species, there simply are no source populations sufficiently productive to allow withdrawals without jeopardizing the source population itself. In these situations, captive populations can produce the required individuals without the need to risk harming remnant wild populations. An example of this situation is the peregrine falcon (*Falco peregrinus*) recovery effort in eastern North America (Cade et al. 1988). After a ban on dichlorodiphenyltrichloroethane (DDT) was imposed, the environment in eastern North America again became suitable for falcons, but by that time the population east of the Rocky Mountains had been extirpated. Although other North American falcon populations were recovering from DDT-induced declines, they remained incapable of providing enough individuals for a massive reintroduction effort in the vacant eastern range. A successful captive-propagation effort provided the stock needed for the large-scale reintroduction effort, which succeeded in establishing a flourishing eastern population that was eventually removed from the endangered species list.

A **captive population** can sometimes be used as a temporary safeguard against the stochastic demise of a perilously small wild population that has limited potential for increasing in the short term. Such a reserve captive population must be self-sustaining to fulfill its role as a back-up to the wild population; it cannot achieve its purpose if it is reliant on augmentation from the wild population. Speke's gazelle (*Gazella spekei*) has been declining in the wild for many years, but a well-managed captive population exists as a safeguard against failure of in situ management (Templeton and Read 1983).

Captive populations can be a longer term solution for species that simply have little or no potential to regain a self-sustaining status in the wild in spite of in situ conservation efforts. Some threatened wildlife species have existed for indefinitely long periods of time only in captivity before conditions in the wild eventually allowed for their reintroduction. After becoming extinct in the wild in the 1960s, Przewalski's horse (*Equus przewalskii*) survived for >30 years only in captivity, where the entire population was descended from 9 horses that had been in captivity since 1945. These 9 horses were mainly descended from individuals in captivity since 1900. A reintroduction project eventually returned captive-reared horses to the wild in Mongolia (Boyd and Houpt 1994).

Finally, many threatened species are maintained in captivity without making any direct contributions to a recovery effort. Instead, these captive populations indirectly contribute as part of educational efforts to sensitize the public to the plight of threatened species. Most captive polar bears (*Ursus maritimus*), for example, fall into this category.

Box 36.1. A BRIEF HISTORY OF THE BLACK-FOOTED FERRET RECOVERY PROGRAM

The black-footed ferret is a federally endangered mammal that has an obligate dependence on prairie dogs (*Cynomys* spp.) as prey and on prairie dog burrows for shelter (Miller et al. 1994). The ferret originally ranged across the Great Plains from southern Alberta and Saskatchewan, Canada to Oklahoma and the southwestern United States (Whitaker 1998). Prairie dogs were often viewed as a pest and were eradicated from 98% of their original range as a result of government programs (Miller et al. 1994, Whitaker 1998). Diseases may have also contributed to the decline of prairie dog communities (Biggins et al. 1998). The black-footed ferret is currently the rarest mammal in North America because of the drastic decline in prairie dogs and habitat fragmentation (Miller et al. 1994).

The first captive propagation effort in the early 1970s to recover black-footed ferrets failed. This was coupled with the loss of the free-ranging breeding population inhabiting South Dakota (Biggins et al. 1998). It was thought that black-footed ferrets were extinct in the wild until a population of ferrets was identified near Meeteetse, Wyoming in 1981 (Biggins et al. 1998). The Meeteetse population sustained itself until 1985, when canine distemper and plague (*Yersinia pestis*) affected the ferret population, and plague caused a die-off of white-tailed prairie dogs (*C. ludovicianus*) upon which the ferrets depended (Biggins et al. 1998). The few remaining wild ferrets were taken into captivity, and have grown in number from 18 in 1987 to 349 by 1992; the population is spread among 7 captive-breeding facilities (Miller et al. 1994).

Researchers conducted 2 years' worth of experiments with captive-rearing techniques for black-footed ferrets using a surrogate species, the Siberian ferret (*Mustela ermine*; Miller et al. 1994). Examples of the research conducted included comparing different captive environments and release methods on survival skills, and assessing radiotelemetry monitoring methods (Miller et al. 1994). Other prerelease training for ferrets included predator avoidance and locating and killing prey (Miller et al. 1994). It was determined from the experiments that ferrets raised with minimal prerelease conditioning in 200-m² mock prairie dog colonies (called arenas) exhibited traits similar to wild-reared ferrets (Miller et al. 1994).

The first release of 49 black-footed ferrets occurred in September and October 1991 in southeastern Wyoming (Miller et al. 1994). The ferrets were soft-released using on-site elevated release cages where they received supplemental food (Miller et al. 1994). About 50% of the 37 fer-

Captive propagation was critical to preventing the extinction of the black-footed ferret. Photo by Jessie Cohen, Smithsonian's National Zoo.

rets that were monitored by radiotelemetry abandoned the release area soon after release (Miller et al. 1994). It was determined that 4 ferrets survived the first winter and 2 females produced litters (Miller et al. 1994).

A second reintroduction of 90 black-footed ferrets occurred in autumn, 1992 in the same area of Wyoming (Miller et al. 1994). Seventeen ferrets were soft-released in outdoor arenas measuring approximately 35 m² with access to prairie dog burrows and live prairie dogs, whereas the other 73 ferrets were soft-released using elevated cages (Miller et al. 1994). After 1 month, the postrelease survival of the arena-released ferrets seemed superior to cage-released ferrets (Miller et al. 1994).

Black-footed ferret recovery has achieved mixed results. The current recovery plan objective for delisting is for 1,500 breeding adults occupying ≥ 10 populations scattered over the species' historical range (Lockhart 2007). Since 1987, >6,000 ferrets have been born in captive-rearing facilities and >2,400 have been released at multiple sites in 7 western states, and 1 site in Mexico (Lockhart 2007). The captive breeding facilities have demonstrated their ability to produce surplus ferrets for translocation, and release and monitoring techniques appear to be successful. However, the ferret remains one of the most endangered mammals, with the plague posing possibly the greatest obstacle to ferret recovery (Lockhart 2007). Additional obstacles yet to overcome include private landowner perceptions about, and subsequent persecution of, prairie dogs, political support for ferret recovery, and the establishment of preserves or National Wildlife Refuges for the protection and recovery of black-footed ferrets (Lockhart 2007).

WHEN IS TRANSLOCATION FROM WILD SOURCE POPULATIONS APPROPRIATE?

When **source populations** in the wild are capable of providing sufficient individuals, they may have some advantages over captive populations as a source of stock for introduction and reintroduction efforts. Typically, translocations are less expensive and labor-intensive than captive propagation. They involve far less intervention into the lives of the animals involved. Translocated individuals may adjust to their new habitat more quickly than captive-reared individuals because they are already accustomed to living without assistance from managers.

Critics of translocations point out that these efforts would usually be unnecessary if habitat conservation efforts had been pursued, and they worry about movement of genes and pathogens that may inflict unforeseen harm on recipient populations. There also are concerns that stress on the translocated individuals may compromise their fitness; these stresses can include capture, handling, transport, release, interactions with individuals in the recipient population, and new environmental conditions.

A **key assumption** of most translocations is that the source population is capable of enduring sustained removals of individuals without having its own viability compromised. In essence, the source population is being managed for a sustained yield of individuals for translocation, and all the basic principles involved in sustained-yield harvesting apply (see Chapter 33, This Volume). This assumption may be easily met if a species is threatened or extirpated in one part of its range while doing well elsewhere, but it can be problematic when all of a species' populations have been affected by environmental problems that reduce fitness, as is often the case with threatened species. In such situations, translocations may be less appropriate than captive propagation.

Carefully selected individuals from a source population of endangered Laysan ducks (*Anas laysanensis*) near a limited carrying capacity on Laysan Island were translocated to Midway Atoll National Wildlife Refuge and have succeeded in establishing a new population that is reproducing and growing on its own (Moulton and Marshall 1996). The removals for this introduction resulted in no harmful effects on the source population. Inter-island translocations have been successful components of endangered-species recovery efforts for several island-endemic species. Often these translocations have involved moving individuals from islands infested with harmful invasive species to islands that have been cleared of the invasives. In Western Australia, >80 translocations have taken place with >20 species (15 mammal species, 3 bird species, and a few reptile species). Several of the translocations have resulted in introduced and reintroduced populations that have thrived to the point where species have been taken off endangered lists (Possingham et al. 2004).

Another appropriate use of **translocation** involves the transfer of individuals from a source population to another population in order to **improve the genetic health** of recipient populations that have suffered genetic deterioration due to issues associated with isolation and small population size. **Gene flow** can be enhanced through translocations that maintain genetic diversity and offset the negative consequences of inbreeding depression in small, isolated populations (see Chapter 35, This Volume). Individuals from isolated populations of endangered orangutans (*Pongo pygmaeus* and *P. abelii*) in Borneo and Sumatra have been translocated between locations in order to reestablish gene flow and maintain genetic diversity that might otherwise be lost in small, isolated populations (Payne and Pudente 2008).

In a few instances, **translocations** of a threatened population have been used to **rescue individuals** from imminent demise in a habitat that is certain to be destroyed by human activities (e.g., flooding after a dam construction, draining of a wetland, etc.). In these circumstances there is no issue of harming the source population, which would otherwise be destroyed. Endangered desert tortoises (*Gopherus agassizii*) have been relocated out of the way of military activities (U.S. Fish and Wildlife Service 2008a). Other endangered species, including black rhinos (*Diceros bicornis*), Malayan tigers (*Tapirus indicus*), and Bengal tigers (*Panthera tigris tigris*), have been relocated away from development and poaching threats (Brooks et al. 1997, Karanth 2003, Linklater and Swaisgood 2008).

Translocations clearly have utility in a world where habitat conditions can change in ways that put species at risk, and it seems inevitable that they will be used to help a growing number of threatened species. Current concerns about the consequences of global climate change, for example, have stimulated much discussion of the need for potential interventions such as "**assisted migration**," "**assisted colonization**," and "**managed translocation**" (McLachlan et al. 2007). These terms all refer to strategies for translocating organisms to locations with more favorable climates when their abilities to disperse naturally are judged to be either inadequate or impaired. These strategies are currently being debated because there is a possibility they could have serious unforeseen effects on the translocated organisms and the recipient environments (Ricciardi and Simberloff 2009).

SOME USEFUL ANALYSES TO CONSIDER BEFORE PROCEEDING WITH EX SITU CONSERVATION

All ex situ conservation efforts should ideally be preceded by careful analyses to determine whether these strategies will, indeed, be the most effective options for recovering a threatened species (Gibbons et al. 1995). In situ management should always be evaluated as an alternative prior to

undertaking ex situ efforts. A variety of tools are available to guide the planning of an effective program. Genetic and demographic analyses, such as those typically incorporated into a **Population Viability Analysis** (PVA), can reveal how proposed ex situ activities might affect the viability of the populations involved (see Chapter 35, This Volume). Molecular genetic analyses (Ashley 1999) can inform the creation of **genetic management plans** for captive populations to ensure the long-term maintenance of genetic diversity of captive populations, as well as to minimize potential adverse effects on the genetic integrity of the wild populations (see Chapter 22, Volume 1). Evaluations of the suitability of the habitats into which introduced and reintroduced populations will be placed, using tools such as **Habitat Suitability Index** (HSI) Models, **Population and Habitat Viability Assessment** (PHVA), and **Ecological Niche Factor Analyses** (ENFA), can help predict a translocated population's fate and highlight habitat management needs to improve population viability (see Chapter 35, This Volume). HSI models provide hypotheses about the relationship between a wild-life species and the habitat(s) they rely upon. PHVA is a species-specific method to analyze risk and determine the likelihood of a population's extinction. ENFA is a modeling method that uses presence data to predict areas of key habitat based on a species' distribution.

PHVA is increasingly used to predict the likelihood of achieving recovery goals using different management strategies. Such an evaluation can clarify how best to use in situ and ex situ strategies in an overall recovery plan. For planning purposes, PVA can allow managers to evaluate the likely trade-offs of key decisions, such as how to subdivide a threatened population between a wild subpopulation and a captive subpopulation, or how many individuals to release to the wild or translocate to minimize negative effects on the captive or source population and maximize the chances for the introduced or reintroduced population to succeed (Gulve and Ebenhard 2000). For example, the endangered Puerto Rican parrot (*Amazona vittata*) has been the subject of careful planning using PVA and other tools to assess how well both in situ and ex situ management activities are affecting the species' overall viability and the chances of meeting recovery goals (Lacy et al. 1989).

TECHNIQUES INVOLVED IN CAPTIVE PROPAGATION

The execution of a successful captive propagation project depends on many factors that are associated with discrete stages through which a program progresses, from founding the captive population through release of individuals to the wild. Although many elements of a successful program are species-specific, we focus here on those general elements that are common to almost all programs.

Because captive propagation has become so important in threatened species management, there are numerous **sources**

of technical information, including the Conservation Breeding Specialist Group (CBSG), the International Species Information System (ISIS), Association of Zoos and Aquariums (AZA), Canadian Association of Zoos and Aquariums (CAZA), European Endangered Species Programme (EEP), European Association of Zoos and Aquaria (EAZA), Australasian Species Management Program (ASMP), Australasian Regional Association of Zoological Parks and Aquaria (ARAZPA), African Preservation Program (APP), African Association of Zoological Gardens and Aquaria (PAAZAB), Japanese Association of Zoos and Aquariums (JAZA), South Asian Zoo Association for Regional Cooperation (SAZARC), and South East Asian Zoo Association (SEAZA).

There are a number of **ideal goals** that most captive propagation projects should attempt to meet (Lacy 1994); common among them are

- establishing a self-sustaining captive population capable of becoming a source population for projected translocations;
- avoiding inbreeding depression by retaining a large portion (>90%) of the initial heterozygosity of founders (a measure of genetic diversity; see Chapter 22, Volume 1) over the life of the project (usually until viable wild populations are established);
- minimizing the accumulation of deleterious mutations;
- avoiding the selection of genetic traits that might jeopardize fitness of individuals released to the wild; and
- minimizing threats of demographic stochasticity (including harmful random variations in vital rates; see Chapter 35, This Volume).

Such basic guidelines address the most important biological issues that often determine the success or failure of captive propagation efforts.

Often an important prelude to a captive breeding program for an endangered species is an initial trial breeding program with a nonendangered, closely related species (Species Conservation Planning Task Force 2008). When there is little or no prior experience with the endangered species in captivity, such a warm-up exercise with a **surrogate** allows managers to perfect husbandry techniques before having to deal with individuals that may be crucial to the future of their species. Nonetheless, each species has its own unique requirements for housing, food, and other essentials, and there are few useful generalities.

Once the decision is made to launch a captive propagation program, the captive population will pass through the following successive phases (Lacy 1994):

- founding the captive population (picking the founders),
- promoting growth of the captive population (maximizing r in founder and F_x generations),
- maintaining the captive population at a target size that accommodates the demand for individuals for release

to the wild (dealing with the surplus over carrying capacity of captive facilities), and

- rearing individuals in a manner that allows for their successful translocation.

Founder Phase

An adequate founding population should be established without compromising the viability of the wild population, but this opportunity is often missed when dealing with critically endangered species. Waiting until a wild population has dropped to an extremely low population size (below approx. 1,000 individuals), as is often the case, means that many founding captive populations are less than ideal, while at the same time their removal compromises the viability of already critically small wild populations. Good preliminary planning and timely action can avoid this dilemma (Gibbons et al. 1995). When there are still options for selecting **ideal founders**, a general rule-of-thumb is they should be composed of ≥ 20 –30 “good” individuals (defined by such factors as their genetic background, their sex and age structure, and their physiological and behavioral condition). That target number is derived from theoretical population models that predict 30 such individuals could support a high proportion (>95%) of the heterozygosity and most of the more common alleles (those present at >5% frequency) in the source population (Ballou and Lacy 1995). But real threatened populations are often in worse circumstances than the “ideal” populations of geneticists’ models. An even better selection of founders might be possible if the genetic structure of the source population is known as a result of molecular genetic approaches (Haig 1998, Ivy et al. 2009), such as DNA sequencing, major histocompatibility complex, minisatellite, microsatellite, and random amplified polymorphic DNA.

When founding populations are unavoidably comprised of less than the ideal number and genetic composition, it is possible that genetic disorders will become an issue in the captive population. When that happens, there is a dilemma of whether to try to eliminate the deleterious alleles by eliminating the individuals who carry them or retaining individuals for other genetic benefits they bring to the population (Yong-Bi et al. 1998). When the founding population is small, eliminating individuals may be counterproductive because the deleterious alleles are often recessive; it is better to simply use a planned breeding strategy to avoid mating carriers of the allele.

The **founding phase** also is a time when managers must rapidly perfect the husbandry of the species. Even if there has been prior experience with a surrogate and the founders were wisely selected, unexpected idiosyncrasies frequently emerge. Common issues include individuals that do not adjust well to captivity and individuals that have difficulty forming pair bonds.

Population Growth Phase

During the growth phase, the emphasis is on stimulating rapid growth of the population and the allocation of indi-

viduals among separate facilities (to minimize the chance of a local catastrophe eliminating a single population). Initially, **demographic issues** (increasing survival and reproduction) may take precedence over genetic issues until the population has begun growing and reaches a more secure size (Lacy 1994). But it also is important to recognize and encourage those individuals that are most valuable genetically, often because their pedigrees may be underrepresented among founders. It is best if managers can impose a planned breeding strategy that minimizes loss of genetic variation while achieving rapid growth. Often such strategies are based on avoiding inbreeding, maintaining heterozygosity, and preserving any rare or unique alleles known to be present among founders (Lacy 1994). A **pedigree analysis** can be used to identify the most valuable individuals, which can be ranked on the basis of the proportion of an individual’s genome that is not represented by other founders.

Several of the previously mentioned captive breeding groups (i.e., CBSG and ISIS) offer programs and advice on how to implement planned breeding strategies. As a general rule, these strategies involve keeping the **effective population size** (N_e) as close as possible to the **actual population size** (N), which tends to maximize genetic contributions of individuals to future generations. Effective population size, in the most basic sense, is the number of individuals that contribute offspring to the next generation. The effective population size is usually lower than the actual population size. The ratio of N_e to N can generally be improved when there is a balanced sex ratio (either actual or operational), equal family sizes, and few, if any, large fluctuations in population size.

A variety of specialized husbandry techniques have been developed to encourage rapid population growth in captive populations (Seager 2005). Highly manipulative procedures such as **artificial insemination** and **embryo transfers** to surrogate mothers, sometimes of different species, can help ensure that contributions of founders are not compromised by such difficulties as problems breeding naturally, unequal family sizes, or imbalanced sex ratios (Mace 2008, Wildt 2009). **Cryopreservation** of gametes and embryos can allow founders to continue to contribute even after their death or reproductive senescence and for their gametes to be exchanged between breeding facilities. Enhancing each individual’s fecundity can be accomplished by such procedures as multiple clutching of birds, artificial incubation of unnaturally large or sequentially laid clutches of eggs, and fostering offspring in excess of natural parents’ capacity relative to surrogate parents. **Cloning** has been used with endangered species and may become more practical in the future (Holt et al. 1996, Holt and Pickard 1999).

Carrying Capacity and Release Phase

Under good management, a captive population will eventually grow until it reaches the **carrying capacity** of the holding facilities. How large that population should be is deter-

mined by both practical and theoretical considerations. Space is precious in captive breeding facilities, so it is inevitable that some limits will be imposed by availability, but there are ideals that also should be considered (Soulé et al. 2005). For captive populations that will be held at carrying capacity for multiple generations, the greater N_e can be, the lower will be the rate of loss of **genetic variation** over time. Theoretical population genetics models predict that for long-term maintenance of **heterozygosity** (say, over hundreds of generations), a N_e in the thousands would be prudent (Hedrick 1992), but in practice most captive breeding facilities can accommodate far fewer individuals. The trade-off is between smaller populations and shorter stays in captivity versus larger populations and longer stays in captivity. For most captive breeding programs, reaching a target population size quickly and accomplishing goals for translocations in a timely fashion makes sense.

How does management change when the facilities are full? Genetic issues generally become more important than demographic issues over the long haul (Ralls and Ballou 1992). **Maintaining heterozygosity** can be accomplished through careful mate selection and minimizing inbreeding. Another issue is avoiding potential problems of artificial selection for traits that enhance individuals' fitness in captivity (but not necessarily in the wild) by striving to keep the number of captive generations as low as possible (Williams and Hoffman 2009). If a captive population must be maintained for many generations, new recruits from the wild can be added to the population to maintain characteristics of the wild population that will improve the chances for a successful translocation.

Ultimately, the goal at carrying capacity is to manage for a stable breeding population in captivity by deciding what to do with surplus individuals. Deciding which individuals are really surplus is an important issue for the maintenance of the captive population and the success of individuals released to the wild (Mathews et al. 2005). As a general rule of thumb, derived from theoretical population genetics, **surplus individuals** can be regarded as those in excess of what is needed to maintain >95% of each founder's genome in captivity. In general, any offspring >5/founder/generation can be considered surplus to the captive population's viability (Lacy 1994). When pedigrees are known, surplus individuals are those individuals with the highest mean kinship and lowest genetic uniqueness.

When the time comes for releasing individuals to the wild, conflicts between what is best for the captive population and the translocated population must be addressed. **Guidelines** that are best for the captive population are often in conflict with what is best for the translocated population. For example, releasing redundant individuals (from the perspective of the captive population) and individuals with low genetic uniqueness and high similarity is not necessarily the best strategy for founding a wild population. Compromises seem unavoidable (Earnhardt 1999).

Once individuals are selected for release to the wild, it may be necessary to prepare them for the forthcoming transition. A variety of (often species-specific) **prerelease conditioning** methods have been devised. These can involve transitioning to food likely to be encountered in the wild, especially if the food in captivity has been somewhat unnatural. Teaching individuals to react appropriately to wild predators and lose any acquired tameness around human beings also is often necessary (Box 36.2).

TRANSLOCATING WILDLIFE

Soft versus Hard Release

Translocated individuals can be released into the wild using either a soft or hard release. **Soft releases** are intended to help animals acclimate to the release site by providing shelter, food, and/or water for a defined amount of time (Scott and Carpenter 1987). Soft-release protocols may confine the animals at the release site prior to release, until they become familiar with their new environment, or may release the animals and allow them to return to shelter, food, and/or water that are provided as needed. **Hard release** refers to releasing translocated animals immediately upon arrival at the release site, with no provision of shelter, food, or water (Scott and Carpenter 1987).

It has been proposed that soft releases benefit threatened or endangered species because dispersal from the release site and mortality is presumed to be low, thereby maximizing the chance that every one of the relatively few remaining individuals may contribute to the sustainability of the population (Armstrong and Seddon 2007, Teixeira et al. 2007). Species that are social and live in groups, and animals with a strong homing instinct, are thought to benefit from soft releases, with the added benefit for researchers that released individuals that stay close to the release area are easier and cheaper to monitor (Hardman and Moro 2006). Lastly, provision of food, water, and/or shelter via a soft release has been suggested to reduce stress to released animals because they have time to acclimate to the release site and find adequate resources as they are weaned off the provided resources (Hardman and Moro 2006).

Although it has been presumed that soft releases relative to hard releases improve translocation success, experimental evidence does not seem to favor one release method over the other (Armstrong and Seddon 2007, Teixeira et al. 2007). Hardman and Moro (2006) found that soft release of 2 hare-wallaby species, mala (*Lagorchestes hirsutus*) and merrnine (*Lagostrophus fasciatus*), did not improve the survival or site fidelity of either species over a hard-release protocol. Furthermore, the authors cautioned that added expenses of conducting a soft release (i.e., pen construction, water and food provision) may detract from needed resources that could be put to better use on other aspects of the translocation project.

Box 36.2. A BRIEF HISTORY OF THE CALIFORNIA CONDOR (*GYMNOGYPS CALIFORNIANUS*) RECOVERY PROGRAM

Information on the California condor was adapted from Cohn (1999) and the U.S. Fish and Wildlife Service website (<http://www.fws.gov/endangered/i/bog.html>). The California condor is a federally endangered scavenging bird currently found in California, with experimental populations established in specific areas of Arizona, Nevada, and Utah. By the time of European arrival in America, California condors were restricted to the mountains along the Pacific Coast of North America. A number of factors have been identified as possible causes for decline of the condor, including habitat modification, human development and persecution, and lead poisoning from the ingestion of bullet fragments when feeding upon carcasses shot, but not recovered, by hunters. Regardless of the reason for decline, only 25–30 condors were estimated to remain in the wild by the late 1970s.

Under the advisement of the U.S. Fish and Wildlife Service and the California Condor Recovery Team, all remaining condors in the wild were captured and brought into captivity beginning in 1985. In 1987, the last wild condor was captured and added to the captive breeding population, held at either the Los Angeles Zoo or the San Diego Wild Animal Park. A third captive propagation center was opened at the Peregrine Fund's World Center for Birds of Prey in Boise, Idaho in 1993.

Female condors in the wild normally produce one egg every other year. Removing eggs from female condors breeding in captivity, and artificially incubating the eggs,

caused female condors to lay more eggs than they would in the wild, thereby increasing the number of chicks produced annually relative to chick production in the wild. Additionally, chicks hatched by their parents were removed after hatching to induce the condors to breed every year, as compared to their biennial breeding cycle in the wild. Zoo keepers used hand puppets shaped like adult condors to raise the chicks in order to limit human contact and mimic rearing behavior that would be experienced in the wild. Results were positive; the zoos were producing as many as 20 condor chicks annually by 1998, with 90% of the chicks surviving.

Prior to releasing California condors, biologists experimented with release and monitoring techniques using Andean condors (*Vultur gryphus*) as surrogates (Wallace and Temple 1987). Following the release of the Andean condors, biologists were satisfied that they could successfully release California condors. Initial release into the wild of 13 puppet-reared condors resulted in most of the birds seeking out human-dominated areas instead of staying within the release area in the Los Padres National Forest. After 5 condors died (1 from antifreeze poisoning and 4 from collision with, or electrocution by, transmission lines), the remaining 8 condors were captured and brought back into captivity.

Following the first release, captive-rearing techniques were changed. Puppet-rearing was abandoned in favor of parent-raised chicks using captive adult condors as mentors. Prerelease conditioning included placing power-line poles in the pens holding condors and administering a mild electrical shock every time a condor landed on a pole. Anytime humans accessed the pens where condors were held, the humans harassed the condors in order to teach them to avoid humans.

The goal of the condor recovery program is to have 150 condors, plus 15 breeding pairs, in 3 distinct populations. Although that goal has not yet been achieved, there were >335 condors alive as of 2009, with more condors existing in the wild than in captivity. Furthermore, California condors released in the wild have successfully bred and fledged chicks. Despite the condor recovery program being one of the costliest, it has been deemed successful, at least in the short- to mid-term.

Prerelease conditioning was effective in making positive changes to postrelease condor behavior. Photo by Gary Kramer, U.S. Fish and Wildlife Service.

How Many Individuals to Translocate?

Regardless of type of release, the ultimate goal of any translocation is the establishment of a self-sustaining wild population (Scott and Carpenter 1987). Translocations should be conducted using proper experimental design, including controls and replication when possible, and provide methodological guidance for future reintroductions (Sarrazin and Barbault 1996). Given that conditions requiring translocations (i.e., habitat loss, predation) have been resolved, success of a translocation program often depends upon number of individuals or groups that are released, the habitat quality of the release site, and the size and location of the release area relative to the historical range of the species (Wolf et al. 1996, 1998).

The numbers of individuals and groups released are quite variable within and between wildlife taxa. Understanding the correct number of individuals to release per translocation often will determine, at least partially, the success or failure of a translocation (Wolf et al. 1996). Populations of translocated animals must become sufficiently large in numbers as soon as possible to withstand variations in the environment and population size (Gilpin and Soulé 1986, Miller et al. 1999). The number of individuals to be released may be predetermined by the source population due to the number of available individuals. If the source population is not a limiting factor, computer simulations or recommendations from a panel of experts, for example, may aid in estimating a minimum number of animals to release (prior to the initial release) in order to provide a translocation its best chance for success.

The **size of the release group** can affect population establishment, with small release groups failing to establish a population due to demographic stochasticity, or low reproduction or survival rates at low densities (Caughley 1994, Armstrong and Seddon 2007). **Postrelease dispersal** that prevents mate pairing, increased vulnerability to predation, and inbreeding or loss of genetic diversity can adversely affect small release groups more than larger release groups (Lande 1999). One exception appears to be island translocations. Taylor et al. (2005) found that reintroductions of New Zealand robins (*Petroica australis*) and saddlebacks (*Philesturnus carunculatus*) to offshore islands required as few as 5 robins and 6 saddlebacks to successfully establish populations. **Stochastic models** suggested that only 4 founders (2 males, 2 females) were required to establish a population (Taylor et al. 2005). Taylor et al. (2005) attributed population establishment from a small number of founders to a **closed system** (i.e., a small island), allowing for relatively easy mate pairing, low postrelease mortality rates, and high growth rates at low density.

Komers and Curman (2000) suggested that the initial rate of population increase (i.e., no. of individuals released) should be maximized to reduce the period during which a population may be exposed to various risks of extinction. Wolf et al. (1996) found that translocation success increased

with increasing numbers of animals released, but the general relationship between the probability of success and number of animals released was asymptotic. Beyond the asymptote, additional releases may not improve success. Komers and Curman (2000) examined ungulate translocation and found that the asymptote was reached at approximately 20 individuals/release. Wolf et al. (1996) surveyed avian and mammalian translocation managers and found that the median number of animals released per translocation was 50.5. Fischer and Lindenmayer (2000) reviewed >180 translocation case studies and theoretical papers published in scientific journals between 1979 and 1998, and supported previous authors' claims that translocation program success increased with the greater the number of individuals released. Their analysis indicated that releasing <100 total individuals increased program success versus releasing 100 individuals. However, their analysis did not discriminate between one or several releases, so it is impossible to make recommendations regarding the number of individuals per release to maximize translocation success. There are no general guidelines for reptile and amphibian translocations regarding the number of individuals translocated per release (Germano and Bishop 2008).

Release Group Demographics and Sources

Familiarity of individuals within a released group may affect the success of a translocation. Although Armstrong and Craig (1995) found that translocating North Island saddlebacks (*P. c. rufusater*) familiar with one another did not improve translocation success relative to a released group in which individuals were unfamiliar, they suggested that familiarity may result in quicker mate pairing and, therefore, greater reproductive output, when birds are released later in the breeding season or in areas where the breeding season is shortened. Among other suggestions, Armstrong and Craig (1995) proposed that translocated species that demonstrate aggression upon release and those with stronger social bonds may benefit from release groups where individuals are familiar with one another. They caution, however, that translocations using familiar founder groups may come with costs, especially the further depletion of already small, vulnerable source populations.

The **effects of age and sex** of released individuals on translocation success is not well understood because reproductive potential and value differs across individuals and age-sex classes (Miller et al. 1999, Komers and Curman 2000). Komers and Curman (2000) analyzed data from ungulate translocations and found that translocations with 20 individuals grew faster when older animals predominated because mature males seemed to induce estrus in females more effectively than young males and, therefore, were preferred as mating partners by females. Research suggests that species with a strong homing instinct should be released as eggs or younger individuals as opposed to adults that have had time to develop strong affiliation to a home site (Germano and

Bishop 2008). Egg masses of aquatic-breeding amphibians may be collected from the wild more easily, more cost effectively, and for longer collection periods relative to adult forms, and can maximize genetic diversity (Germano and Bishop 2008).

Age-related differences regarding postrelease movements are species-specific, with no general trend suggesting that juveniles versus adults should be translocated for better success rates (Letty et al. 2007). Hypotheses offered to explain age-related differences in postrelease movements include the strength of the ties between translocated individuals and their source environment, the stress and disturbance caused by the translocation, and that homing behavior may be stronger in adults because they are more capable than juveniles to return to their source environment (Letty et al. 2007). Miller et al. (1999) cites a number of studies indicating that juveniles may display greater behavioral plasticity than adults.

During translocations, replicating **sex ratios** similar to those exhibited by wild populations may facilitate reproductive encounters, thereby contributing to a self-sustaining population (Erickson and Hamilton 1988, Miller et al. 1999). Short et al. (1992) reviewed macropod (Marsupialia: Macropodidae) translocations in Australia and found that more females were translocated than males, although males demonstrated higher survival rates. Komers and Curman (2000) found no ungulate translocation that was not biased toward females due to the fact that females contribute offspring to the population. Berry (1986) suggested that desert tortoise relocations focus on adult females because they have smaller home ranges and less cohesive social structure than adult males and, therefore, are more likely to be retained at the release site. Ashton and Burke (2007), however, found that adult male gopher tortoises (*G. polyphemus*) had better retention rates at the release site than females, although they postulated that the reason may be that no gopher tortoises were present at the release site prior to the initial translocation.

Fischer and Lindenmayer (2000) identified the **source of the founder population** as being important to the success of a translocation program. Their literature review of mammal and bird translocations for conservation purposes revealed that founder populations from wild sources were more successful (29%) than if the source population was drawn from captivity (15%). Germano and Bishop (2008) found that more reptile and amphibian translocations were sourced from a wild population relative to a captive population. However, they suggested that the source of the founder group may not be as important for reptiles and amphibians as for other taxa groups because success rates did not differ between wild and captive releases.

THE RELEASE SITE

Successful translocations using either captive or wild stock require an area of habitat of suitable size and quality (Griffith

et al. 1989, Dodd and Seigel 1991, Wolf et al. 1998). It is crucially important to evaluate the condition of habitat in the proposed translocation area before releasing individuals. Otherwise, there is a risk of placing valuable animals in an environment where they will experience difficulties surviving and reproducing. Translocation sites should be evaluated for habitat characteristics like predator–prey presence and relationships, food, cover, denning sites, and water sources, among other important habitat components. **Spatial relationships** of the release site should be examined, with characteristics like degree of isolation, size, shape, and site location kept in mind (Miller et al. 1999). A species-specific habitat evaluation (i.e., HSI, PHVA, or ENFA) can identify potential limiting factors in the environment that might need to be corrected before releases are made. In a PHVA, for example, detailed data on a species' life history, genetics, and ecology are integrated with information on current and projected habitat conditions (Seal 1993). Computer models use this information to evaluate the risk of wildlife population decline or extinction under alternative future management scenarios. These PHVA exercises have been promoted by the Conservation Breeding Specialist Group (CBSG), which is part of the Species Survival Commission of the IUCN. Examples of these analyses are available on the CBSG website (<http://www.cbsg.org/cbsg/>).

Translocation success tends to be low when releases occur in less than quality habitat (Germano and Bishop 2008), with release sites being species-specific. For example, nest-site availability has been proposed as an important feature when selecting release sites for translocated female Columbian sharp-tailed grouse (*Tympanuchus phasianellus columbianus*; Coates et al. 2006). Elk (*Cervus canadensis*) released in areas with low abundance of forage resources had higher movement rates. Greater movement led to lower survival due to increased encounters with predators and humans (Frair et al. 2007).

Fidelity to the release site seems to hinge upon habitat quality (Wolf et al. 1998, Letty et al. 2007). For example, adult females often represent the habitat needs of **polygynous** (a male mates with >1 female/breeding season) carnivore species because females with young will focus their activities where necessary resources are concentrated and easy to obtain (Miller et al. 1999). It is assumed that an individual perceives itself to be in unsuitable habitat if it embarks on long-distance movement away from the release site shortly after release (Stamps and Swaisgood 2007). Rapid departure from the release site reduces an individual's fitness during the critical postrelease period, with mortality and depressed reproduction increasing as travel distance away from the release site increases (Stamps and Swaisgood 2007). Although movement away from the release site is not ideal, dispersals away from release sites can guide future release-site selections (Coates et al. 2006).

The best choice of a release site is the one that is most closely related to the environment in which the source pop-

ulation originated because long-distance dispersals away from the release site and poor survivability seem to be correlated in many instances to the difference between source and release habitats (Letty et al. 2007, Stamps and Swaisgood 2007). Animals reared in conditions similar to those found at release sites demonstrated shorter distance movements relative to individuals raised in habitats substantially different than those found at release sites. Released individuals reared in habitat similar to the release area also demonstrated more natural behaviors (Rodriguez et al. 1995, Miller et al. 1999).

In contrast to **dispersal**, which is a random movement away from the release site, **migration** and **homing** are more specific types of dispersal in that a released individual(s) will move away from the release site in a directed, straight-line fashion toward a given angle or compass direction in an attempt to return to their winter or summer grounds, or "home" location, respectively (Rittenhouse et al. 2007). Migratory and homing behavior can negatively affect the success of a translocation program due to dispersal from the release site being linked to mortality (Anthony and Blumstein 2000, Letty et al. 2007).

To minimize dispersal issues involving migration or homing, research should occur prior to release to understand the conditions under which translocated individuals will stay put once released. Additionally, release techniques and protocols should be tailored to the species being released (Tuberville et al. 2005). Human interventions have altered migratory patterns in young birds (Temple 1978a). Linnell et al. (1997) suggested holding individuals at the release site for a period of time prior to release. Tuberville et al. (2005) translocated gopher tortoises and found that holding individuals in pens at the release site for 12 months prior to release significantly increased site fidelity. Other suggestions by Tuberville et al. (2005) to improve translocation success for homing species like gopher tortoises included translocating an entire, intact population, including all size classes, and providing opportunity for translocated individuals to associate with familiar individuals, thereby encouraging social interactions. Translocating large carnivores far from their capture site to reduce postrelease dispersal may be effective, with distance between release site and home being species-specific (Linnell et al. 1997).

Releases into the **core historical range** were identified as an important variable to predict translocation success (Wolf et al. 1998). The core may be the geographical center of the species' historical range, or it may refer to the area where a species occurs at its highest density (Short et al. 1992). It is expected the core of a species' range would be more favorable to local population dynamics because, as the center of a species' range is approached, population abundance increases and variance in abundance decreases (Wolf et al. 1996). Wolf et al. (1996) recommended that translocation be considered on the periphery of a species' range relative to the core only when factors that caused the initial species de-

cline remain in place in the core of the range, but not at the periphery.

In addition to the habitat quality of the release site, the presence or absence of similar animals (i.e., **congeners, conspecifics**), competitors, and/or predators at the release site can affect the success of a translocation. Species that lack territorial behaviors or other intraspecific competitive relationships can cause like individuals to be attracted to an area and facilitate their settlement (Letty et al. 2007). Allen et al. (1993) discovered that red-cockaded woodpecker (*Picoides borealis*) translocations were more successful with regard to nesting attempts where red-cockaded woodpeckers already existed, compared to release sites devoid of red-cockaded woodpeckers, given the bird's cooperative family social structure. **Interspecific competition, namely predation**, can have severe effects on recently translocated individuals trying to get their bearings in a new and sometimes foreign environment. Predation has been the single cause of translocation failures. Moorhouse et al. (2009) identified mink (*Mustela vison*) predation as the primary cause of failure for the translocation of water voles (*Arvicola terrestris*). Thus, predator management in and around the release site may be required in the short term, and in some cases, long term.

TIMING OF RELEASE

The time of the year individuals are released can affect the success of the translocation. Predator abundance, food and cover availability, weather, and a species' life cycle are examples of factors that require consideration when determining the best season to release individuals (Letty et al. 2007). Translocating prey species seems to be more successful when individuals are released in summer months compared to winter months due to season-dependent predation risk (Letty et al. 2007). Other translocation timings appear to be species-specific. Black bears (*Ursus americanus*) translocated during winter months demonstrated advantages over summer translocations regarding site fidelity, homing, and postrelease movement and survival (Eastridge and Clark 2001). Moorhouse et al. (2009) released water voles during the first 2 weeks of May to ensure that adequate vegetative cover was available. Snyder et al. (1999) found that prairie grouse (*Tympanuchus* spp.) translocated in spring were more likely to be successful in population restoration than other times of the year, presumably due to reduced male movement due to males remaining near display grounds that were in close proximity to release sites. Gopher tortoises released in September had better site fidelity than those released between late March–early May and July–August, possibly due to the onset of the winter inactivity period (Tuberville et al. 2005).

EVALUATING SUCCESS

Some consider a translocation program successful only if a self-sustaining population has been established (Griffith et al.

1989, Dodd and Seigel 1991). Dodd and Seigel (1991) placed the burden of proof for success on the principle investigator or translocation program manager. Translocation projects that tend to fail have in common the lack of clearly defined and measurable objectives, clearly defined and logical methods, a priori and quantifiable measures of success that are linked to project objectives, and provisions for long-term follow-up studies (Dodd and Seigel 1991). **Long-term studies** are especially necessary for long-lived species like some reptiles that arrive at sexual maturity relatively later in life. Dodd and Seigel (1991) suggested long-term monitoring for certain herptile species may involve a minimum 10–15-year commitment. Griffiths and Pavajeau (2008) reviewed literature describing global amphibian translocations and discovered that successful amphibian translocation programs were conducted for ≥ 10 years before success could be declared. Dodd and Seigel (1991) recommended translocation projects not be implemented if long-term and scientifically based monitoring studies cannot be conducted. Germano and Bishop (2008) suggested that a translocated species needs to be monitored for at least as long as it takes the species to reach sexual maturation.

Evans et al. (1999) based the success of the red kite (*Milvus milvus*) translocation on whether the population could grow and expand. The authors suggested that releases should cease only when a translocated population is established and when additional releases contribute nominally to the population's

growth rate. Evans et al. (1999) stated that knowing when further releases should be suspended can only occur with long-term monitoring of basic survival and breeding parameters.

Fischer and Lindenmeyer (2000) found that translocation programs did not clearly define how they would **measure success**. They suggested that translocation programs develop a long-term monitoring program relative to the translocated species upon which key parameters are evaluated at previously specified time intervals. Examples of key parameters include number of animals, sex ratios, adult:juvenile ratios, population change, and a constant reassessment of the threatening process (Fischer and Lindenmeyer 2000).

Monitoring animals (i.e., radiocollaring) is critical to understanding postrelease events and survival of the translocated population (Short et al. 1992). Not being able to determine mortality causes after release will not allow adaptive management to occur in order to effectively and efficiently correct problems that may permanently cause the translocation to fail.

Realistically, there needs to be a **defined end-point** upon which a translocation can be deemed a success or failure, if for no other reason than the fact that resources available to devote to it are finite (Box 36.3). However, Seddon (1999) suggested that caution needs to be demonstrated when declaring a translocation successful because success implies an end-point upon which no further effort (i.e., additional releases or monitoring) is warranted. Seddon (1999) argued

BOX 36.3. A BRIEF HISTORY OF THE HOUSTON TOAD (*BUFO HOUSTONENSIS*) RECOVERY PROGRAM

Once ranging throughout most of southeastern Texas, the Houston toad is one of the rarest and most endangered amphibians in the United States (U.S. Fish and Wildlife Service 1978). In 1970, the Houston toad was the first species in Texas to be placed on the Endangered Species List (Peterson et al. 2004). Urbanization, agricultural expansion, red imported fire ants (*Solenopsis invicta*), timber harvests, and roads from increased urbanization causing mortality and barriers to movement have contributed to the endangered status of the toad (Peterson et al. 2004).

Bastrop County, Texas was thought to contain the largest remaining Houston toad population (Hatfield et al. 2004). Despite rapid and large-scale development within Bastrop County, 2 breeding populations of Houston toads remained in separate tracts of private land (Hatfield et al. 2004). In 1978, the Houston Zoo began identifying remaining populations, supplemented existing populations, and started new populations with wild adults, naturally deposited eggs, or captive-reared juveniles and adults (Dodd and Seigel 1991). Since 1982, 500,000 tadpoles or juveniles have been released at 10 sites at the Attwater Prairie Chicken National Wildlife Refuge, but it has been determined through postrelease monitoring that no population has been established at the Refuge (Dodd and Seigel 1991). Extensive knowledge was developed on the natural populations and captive propagation of the Houston toad (Dodd and Seigel 1991), but conservation of the Houston toad via captive propagation and translocation failed, primarily because of the lack of support from private landowners and delayed conservation efforts (Peterson et al. 2004).

Postrelease monitoring of Houston toads indicated that no translocated populations have become established in the wild. Photo by T. Swannack.

that a self-sustaining population is not a criterion for success. Instead, he suggested a 3-tiered approach to defining **translocation success** that included short-, medium-, and long-term measures of success: **first** is the survival of the release population; **second** is breeding by the release population and their offspring; and **finally**, persistence of the released population without human intervention.

When **evaluating the success** of a translocation program, the focus absolutely needs to be on the translocated wildlife species. Wolf et al. (1996) found that the success or failure of a translocation program rested solely on the intrinsic nature of the species being translocated or on the translocation methodology, as opposed to factors related to humans. A secondary measure of success, however, should not be overlooked, and that is the raised awareness and knowledge of the public relative to habitat and wildlife conservation. **Pre- and posttranslocation surveys of the public** in a defined geographical area are one method to assess a shift in awareness and knowledge. Increased awareness and knowledge can not only increase the support and, therefore, success, of a current translocation program (Wolf et al. 1996), but also may help to proactively fund and manage species and associated habitats prior to a crisis that requires expensive and risky translocations.

SUMMARY

Captive propagation and translocation can be a valuable and necessary tool in the conservation of threatened and endangered species. Captive propagation entails breeding and rearing animals in captivity for translocation to the wild. Translocation is a universal term and means moving animals from one area to another. Depending on the context, translocation can imply introduction (releasing captive or wild animals to areas where they have not previously existed), reintroduction (releasing animals in places where they previously existed), or restocking (movement of animals to supplement an existing population). The goal of any captive propagation and translocation project should be a self-sustaining wild population. Thoughtful and analytical consideration should occur prior to embarking on a captive propagation and translocation program due to expense, logistics, and low success rates.

There are a number of situations when captive propagation may be warranted, but the most obvious is when a species seems to be on a course for extinction, and in situ management is not possible. However, translocations from wild source populations are preferred over captive source populations because they are less expensive and labor-intensive, and translocated individuals may be more successful at surviving and reproducing due to the fact that wild populations are already used to living without assistance from managers. The objectives of captive propagation programs include establishing a self-sustaining captive population capable of offering a source population for translocations, avoiding inbreeding depressions, and avoiding the selection of genetic traits that might jeopardize fitness of individuals released to the wild. A captive propagation program involves identifying and bringing into captivity the founders, growing the captive population, and maintaining and rearing the captive population to retain wildness and provide a source population for translocations. A number of computer programs and models are available to help determine the best genetic pairings in captivity and to provide guidance for translocations.

Once translocations occur, decisions must be made about whether to hard- or soft-release individuals and how many individuals to release. Other considerations about release groups include whether familiarity of released individuals is important, as well as sex and age composition. The success of a translocation program also can be influenced by the decision of where and when to release animals. As with most decisions about captive propagation and translocation, they are often species specific.

Finally, evaluating the success of a captive propagation and translocation program is critical in order to allow for adaptive management. Prior to starting a propagation and translocation effort, the necessary resources should be committed to monitoring and evaluation, sometimes for decades. The ultimate success of any captive propagation and translocation effort has to be the establishment of a self-sustaining population in the wild. However, an important secondary success may include increasing public awareness and knowledge that may prevent the need for future captive propagation and translocation efforts.

Habitat Conservation Planning

INTRODUCTION

THIS CHAPTER INTRODUCES the process and development of **Environmental Impact Assessments** (EIAs) and **Habitat Conservation Plans** (HCPs). Developing an EIA or HCP requires in-depth knowledge of the environmental statutes, including (1) the National **Environmental Policy Act** of 1969 (NEPA; 42 USC § 4321 *et seq.*), (2) **State Environmental Policy Acts** (SEPA), where applicable, (3) the **Federal Endangered Species Act** of 1973, as amended in 1982 (ESA; 16 USC § 1531 *et seq.*), and many other federal and state statutes, as well as regulations promulgated pursuant to these statutes. In addition to knowledge of federal, state, and local environmental statutes, regulations, and policies, knowledge of the biotic and abiotic conditions present within the proposed project or impact area is required. During the development of EIAs and HCPs, consultation with federal and state regulatory agencies should occur (U.S. Fish and Wildlife Service 1996). **Consultation** with the U.S. Fish and Wildlife Service and/or the National Oceanic and Atmospheric Administration (NOAA) Fisheries Service, state wildlife agencies, and recognized experts in fields related to potentially affected project elements, will result in an easier process and enhance the viability of a plan (U.S. Fish and Wildlife Service 1996). This chapter focuses on the development of EIAs under the **National Environmental Policy Act** (NEPA), with an overview of SEPAs, and HCPs under the ESA.

STATUTES

To understand EIAs and HCPs, one must consider the statute under which each is developed: NEPA–SEPA and ESA, respectively. Most developed nations have enacted **environmental statutes** requiring an evaluation of potential environmental effects resulting from projects or policies within their jurisdiction (Truett et al. 1994; Table 37.1). Most environmental statutes mandating EIAs were patterned to some extent on NEPA (Eccleston 2008), which will serve as the basis of discussion for this chapter. In the United States, EIAs are required of all federal agencies proposing an action or policy that may have an adverse effect on the environment by NEPA. **HCPs are required for proposed actions** or policies of federal, state, and private organizations where a proposed action or policy may result in the incidental take of any species listed as endangered (defined as a species in danger of extinction throughout all or a significant portion of its range [16 USC § 1532(6)]), or threatened (defined as a species likely to become endangered within the foreseeable fu-

ture [16 USC § 1532(20)] under the ESA (ESA § 4). We provide an overview and discussion of both NEPA and relevant sections of the ESA on which the development of EIAs and HCPs are required by law, and the types of documents prepared.

National Environmental Policy Act

The **National Environmental Policy Act** of 1969 was enacted on 1 January 1970 to provide guidance to federal agencies on the evaluation of their actions and subsequent effects on the environment (NEPA § 102 *et seq.*, 42 USC § 4332). Typically, the NEPA decision-making process begins

when a federal action is proposed (Eccleston 2008). Upon proposing a federal action, the regulatory agency will conduct an internal scoping to determine whether there are (1) **No Significant Environmental Effects**, (2) **Significance of Environmental Effects of an Uncertain Degree**, or (3) **Significant Environmental Effects** (Eccleston 2008). Once a determination of the potential effect of a proposed action or policy has been identified, a NEPA-compliant document (e.g., Finding of No Significant Impact, Biological or Environmental Assessment, Environmental Impact Statement) can be prepared following adequate studies (Eccleston 2008).

Table 37.2. States (USA) with statutes similar to the National Environmental Policy Act

State	Statute
CA	California Environmental Quality Act
CT	Connecticut Environmental Policy Act
GA	Georgia Environmental Policy Act
HI	Hawaii Environmental Policy Act
IN	Indiana Environmental Policy Act

NY	State Environmental Quality Review Act
SD	South Dakota Environmental Policy Act
VA	Virginia Code sections 10.1-1188 et seq.
WA	State Environmental Policy Act
WI	Wisconsin Environmental Policy Act

State Environmental Policy Acts

Fifteen states currently have a SEPA (Table 37.2). All SEPAs are similar to NEPA, with regulatory oversight authority given to a state agency (e.g., **state wildlife agency or state EPA**) for proposed state actions potentially affecting the environment, with some states exercising additional authority over local projects (Box 37.1). The process of EIA development and review under SEPAs is similar to the NEPA process; those persons working in states with SEPA statutes (see Table 37.2) needing guidance to develop environmental documents should consult their state statute to determine specific requirements of study and document development, environmental review, and project permitting.

Federal Endangered Species Act

The ESA is administered by both the U.S. Fish and Wildlife Service and NOAA Fisheries Service, with **NOAA Fisheries Service primarily responsible for marine species**, and **U.S. Fish and Wildlife Service responsible for all other species**. The purpose of the ESA is to (1) conserve ecosystems on which endangered and threatened species depend, (2) take appropriate steps to provide programs for the conservation of endangered and threatened species (ESA § 2[b]), and mandate all federal departments seek to conserve endangered and threatened species and utilize their authorities to further the purpose of the ESA (ESA § 2[c]). Three sections (Sections 9, 7, and 10) of the ESA have specific relevance to requirements and development of HCPs.

Section 9

Section 9 of the ESA provides the basis on which HCPs are founded, specifically the restriction on “take” of any species

listed as threatened or endangered under the ESA. “**Take**” is defined as “to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or to attempt to engage in any such conduct” (ESA § 3[18]).

Section 7

Section 7 of the ESA requires federal agencies proposing any action or policy potentially affecting a listed species or a defined critical habitat to consult with the U.S. Fish and Wildlife Service. Consultation between federal agencies and the U.S. Fish and Wildlife Service is initiated in what is termed “**Informal Consultation**” where the U.S. Fish and Wildlife Service provides the federal agency with information on the potential presence of a listed species or critical habitat for listed species within the action or policy area (50 CFR § 402.02). When the U.S. Fish and Wildlife Service determines that no listed species or critical habitat occurs or may occur within the proposed action or policy area, Informal Consultation is concluded and the policy or action does not require further consultation with the U.S. Fish and Wildlife Service (1996). In this case, a letter stating that no listed species or critical habitats will be affected is prepared by the U.S. Fish and Wildlife Service within 90 days from the date on which consultation was initiated (ESA § 7[b]).

However, when the U.S. Fish and Wildlife Service determines that a listed species or critical habitat may be affected as a result of implementation of the proposed action or policy, “**Formal Consultation**” (ESA § 7[a][2]) procedures are initiated. During formal consultation the federal agency proposing the action or policy is required to submit a **Biological Assessment** (BA) to determine the potential effect of the action or policy on the listed species for submittal to the U.S. Fish and Wildlife Service (ESA § 7[c]). Once a BA has been completed by the federal agency or designated representative, and submitted, the U.S. Fish and Wildlife Service will review the BA and prepare a **Biological Opinion** (BO) within 180 days after the initiation date (ESA § 7[c]). ESA § 7(2) states that each agency action shall insure the action is “not likely to jeopardize the continued existence of any endangered species or threatened species or result in the destruction or adverse modification of habitat of such species.” When a BO results in a “no-jeopardy” opinion, the action may proceed with specific measures incorporated to mitigate potential effects. Measures or mitigation may include, but are not limited to the following: construction monitoring, habitat restoration or mitigation, and in-lieu fees paid to the U.S. Fish and Wildlife Service.

Section 10

Section 10 of the ESA is for proposed private projects or actions lacking a **federal nexus** (a determination of federal agency involved in a project through either permitting actions or authorization of federal funds), and it allows for

BOX 37.1. STATE ENVIRONMENTAL POLICY ACT, CALIFORNIA ENVIRONMENTAL POLICY ACT— BIOLOGICAL RESOURCES

The California Environmental Quality Act (CEQA) serves as an example of a SEPA statute. The CEQA was incorporated into the California Public Resources Code 21000–21177 in 1970, with the purpose to

1. inform governmental decisions-makers about potentially significant environmental effects of proposed activities;
2. identify ways to avoid or significantly reduce environmental damage;
3. require changes in projects through the use of alternatives or mitigation measures when feasible; and
4. disclose to the public the reason a project was approved if significant environmental effects were involved.

All projects proposed in California requiring issuance of a permit by a public agency are subject to CEQA. Sixteen issue areas, including biological resources, are subject to evaluation during the CEQA process. The Biological Resources category has 6 questions that must be addressed during the CEQA process. Would the proposed project

1. have a substantial adverse effect, either directly or through habitat modifications, on any species identified as a candidate, sensitive, or special status species in local or regional plans, policies, or regulations, or by the California Department of Fish and Game or U.S. Fish and Wildlife Service?;
2. have a substantial adverse effect on any riparian habitat or other sensitive natural community identified in local or regional plans, policies, regulation, or by the California Department of Fish and Game or U.S. Fish and Wildlife Service?;
3. have substantial adverse effect on federally protected wetlands as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrological interruption, or other means?;
4. interfere substantially with the movement of any native resident or migratory fish or wildlife species or with established native resident or migratory wildlife corridors, or impede the use of native wildlife nursery site?;
5. conflict with any local policies or ordinances protecting biological resources, such as tree preservation policy or ordinance?; and
6. conflict with the provisions of an adopted Habitat Conservation Plan, Natural Community Conservation Plan, or other approved local, regional, or state habitat conservation plan?

The 6 questions outlined in Appendix G of CEQA have 4 possible categories (Association of Environmental Professionals 2009):

1. Potentially Significant Impact,
2. Less than Significant with Mitigation Incorporated,
3. Less than Significant Impact, or
4. No Impact.

issuance of “**incidental take permits**” for actions prohibited under Section 9 for scientific purposes, or to enhance the propagation or survival of the affected species (ESA § 10[a][1]). Actions resulting in “take” must be incidental to an otherwise legal activity; one example of an otherwise legal activity is site grading that results in habitat destruction or alteration (ESA § 10[B]). In this example, the grading of the site is a legal activity that may result in “take,” but is not specifically intended to result in “take” as defined in Section 9.

An **incidental take permit** may not be issued unless the project applicant submits a HCP (ESA § 10[a][1][B], 50 CFR

§ 17.3). The HCP must specify (1) what effects are likely to result in “take,” (2) steps to minimize and mitigate effects, (3) funding available to implement minimization and mitigation, (4) alternative actions considered, and (5) reason for not implementing other alternatives. After a U.S. Fish and Wildlife Service review of, and public comment period on, the HCP, the U.S. Fish and Wildlife Service may issue the incidental take permit and authorize the HCP if it is determined that (1) “take” is incidental, (2) the applicant will maximize minimization and mitigation measures, (3) sufficient funding is available, and (4) “take” will not reduce the

likelihood of the survival or recovery of the species in the wild (ESA § 10[2][B]).

ENVIRONMENTAL IMPACT ASSESSMENT

Environmental Impact Assessment is the process of identification and evaluation of the consequences of human actions on the environment, and mitigation for those consequences, when necessary (Erickson 1994). EIAs require a project proponent or agency, state or federal, to view the environment as an aggregation of biotic and abiotic conditions present where the project or policy will be implemented (NEPA § 102[2][c]; Hildebrand and Cannon 1993). Several types of EIAs are prepared in the United States, including **Environmental Impact Statements** (EIS, 40 CFR § 1502, NEPA § 102[2][c]), **Environmental Assessments** (EA, § 1508.9), **Categorical Exclusions** (40 CFR § 1508.4), and **Findings of No Significant Impacts** (40 CFR § 1504). When the environmental effect is uncertain, the regulatory agency has the option of conducting a public scoping period to receive input from interested parties (e.g., private citizens, conservation organizations, and other public entities). **Public scoping** (if conducted) is followed by the preparation of an EA.

Pursuant to NEPA, federal agencies are responsible for the preparation and certification of EIAs. Although a project applicant may prepare an EA in support of a proposed project, they may not prepare an EIS due to potential conflicts of interest. In many instances the responsible federal agency may solicit a third-party preparation of an EIS under their supervision (Yost 2003).

A survey of 52 federal agencies in 1991 reported they prepared >1,000 EAs to each EIS prepared (Bass et al. 2001). Therefore, EAs are the most prevalent document prepared to evaluate environmental effects under NEPA.

In an ideal situation, project proponents would incorporate specific evaluations at each project phase, identifying specific effects that may result from project implementation (Erickson 1994, Truett et al. 1994). **In most situations, however**, EIAs are not considered until later in project development phase. Two scenarios that are common when project proponents solicit EIAs include incomplete biological studies, or biological studies have been completed but need to be incorporated into the EIA.

Document Purpose and Development

EAs are meant to be succinct public documents prepared by a federal agency, project applicant, consultant, or another agency when a proposed action has the potential to have significant environmental effects (40 CFR § 1502.1). EAs also may be prepared by an agency in the planning and decision-making process (40 CFR § 1501.3).

NEPA requirements for preparations of EAs can vary between federal agencies, with each agency having their own EA

procedures and guidance processes. Regardless of agency, **each EA prepared must include** (1) need for the proposed action (40 CFR § 1502.13), (2) description of the proposed action and alternatives (40 CFR § 1502.14 *et seq.*), (3) anticipated effects of the proposed action (40 CFR § 1502.15, 40 CFR § 1502.16) and alternatives (40 CFR § 1502.14 *et seq.*), and (4) agency and expert consultation conducted (40 CFR § 1502.25).

Need for the Proposed Action

Need for the proposed action statement establishes why the project proponent is proposing an action or project that may cause significant environmental effects (40 CFR § 1502.13). A properly framed statement will limit the number of alternatives to the proposed action or project that can be considered reasonable, prudent, and practicable, and demonstrates the potential effect of not implementing the proposed action or project (Bass et al. 2001).

Description of the Proposed Action and Alternatives

Prior to preparing EIAs project proponents should **define proposed actions** thoroughly and accurately (40 CFR § 1502.14 *et seq.*). At a minimum, proposed actions should include names and types of project, locations (including regional, local, and site maps), project features, construction schedule and activities, and features or measures taken to reduce potential effects (Bass et al. 2001).

Descriptions of alternatives considered should include an evaluation and comparison of reasonable proposed alternative actions, including no-action alternatives, and reasons for not implementing each alternative. Descriptions of each alternative should provide sufficient information to allow readers to evaluate relative merits of each alternative and suitable justification as to why the alternative was not preferred (Bass et al. 2001).

Agency and Expert Consultation

Agency and expert consultation is an integral component to developments of EIAs. Agency consultation provides project proponents with necessary guidance to ensure compliance with specific environmental statutes and discuss potential implementation effects (Truett et al. 2005). Expert consultation is beneficial, although not required, during the EIA process. Consulting with recognized experts will, in many cases, provide greater detail on potential project effects and comprehensive alternative-action analysis, particularly mitigation measures that would reduce potentially adverse effects (Truett et al. 1994).

Public Review and Notification

When an internal review of a proposed federal action is determined to have a significant environmental effect, the lead agency must publish a **Notice of Intent** (40 CFR § 1508.22) in the federal register and conduct public scoping to receive input from interested parties (40 CFR § 1506.6). Once **pub-**

lic scoping is completed, the lead agency will prepare an internal **Draft Environmental Impact Statement** (DEIS; typically, qualified outside consultants are contracted to prepare EISs). DEIS drafting typically take 1–2 years and must be followed by a public comment period (U.S. Fish and Wildlife Service 1996). A **Notice of Availability** will be published in the *Federal Register*, formally opening the public comment (40 CFR § 1503 *et seq.*) period (60 days), where the public can review the DEIS and provide comments. Once the public comment period ends, all received comments are addressed during the preparation of the Final EIS (FEIS). The final step in the EIS is adoption (40 CFR § 1506.3) and publishing a Record of Decision (ROD; 40 CFR § 1505.2) in the *Federal Register* and subsequent implementation of the proposed action (40 CFR § 1505.3).

HABITAT CONSERVATION PLAN

The concept and process of HCPs were modeled after the San Bruno Mountain HCP developed in the mid-1970s in the San Francisco Bay region of California (Beatley 1994). A proposal to excavate San Bruno Mountain over a 20-year period to provide fill for the San Francisco Airport was produced in 1965, resulting in the formation of the San Francisco Bay Conservation and Development Commission, Save the Bay Committee, Committee to Save San Bruno Mountain, and many local citizen groups opposing the proposed project and preventing the proposed development. Subsequent to the 1965 San Bruno Mountain project, a proposal to develop approximately 18,581 m² (200,000 square feet) of office and commercial space and 8,500 residential units was begun. The project was initiated to **mediate conflicts between development activities and endangered species** protection and, when completed, ended with issuance of an incidental take permit in 1983; the HCP was developed through the coordinated efforts of the U.S. Fish and Wildlife Service, the State of California, local municipal governments (including San Mateo County, the City of Brisbane, Daly City, and South San Francisco), private landowners, and non-government organizations (e.g., Committee to Save San Bruno Mountain). The approach taken by the creators of the San Bruno Mountain HCP has become the model on which all HCPs are developed (Beatley 1994).

HCPs are variable in size of area and number of species covered, and duration of agreement. For example, of 430 approved HCPs, size of area ranges of 0.07 ha to >6,475 km², number of listed species from 1 to 29, number of total species covered from 1 to 165, and duration of agreements from 1 year to 100 years (http://ecos.fws.gov/conserv_plans/).

HCP complexity ranges from the relatively simple (e.g., HCPs for the Alabama beach mouse [*Peromyscus polionotus ammobates*] with typical areas of 0.8 ha and durations of 50 yr) to highly complex, with numerous stakeholders, species, and large spatial and temporal extents. One of the more complex HCPs approved to date is the Western River-

side Multiple Species HCP (Riverside County, CA), which covers 25 listed and 140 nonlisted species over 5,261 km² and 75 years. The East Contra Costa County is more typical of HCPs, covering 28 species over 704.2 km² for a 30-year period (East Contra Costa County Habitat Conservation Plan Association 2006; Box 37.2).

Regardless of the number of species, area, or duration covered by an HCP, all documents **must specify the following**: (1) effects likely to result from the proposed taking, (2) measures undertaken to monitor, minimize, and mitigate effects, and funding to undertake such measures, (3) alternative actions considered resulting in no “take” and justification for not implementing said actions, and (4) additional measures the U.S. Fish and Wildlife Service or NOAA Fisheries Service may require as necessary or appropriate. We discuss each separately as they relate to development of HCP (U.S. Fish and Wildlife Service 1996).

Purpose

The **purposes of the HCP** process and issuance of incidental take permits are to authorize incidental take of a threatened or endangered species, not to address the underlying activities resulting in “take.” Processes of developing HCPs ensure that, to the maximum extent possible, minimization and mitigation for effects authorized in the incidental take permit is addressed (U.S. Fish and Wildlife Service 1996).

Assessing Take

Before a HCP can be written, coordination with the U.S. Fish and Wildlife Service or NOAA Fisheries Service should be conducted in order to determine whether or not “take” is the likely outcome of a proposed action or policy. During the evaluation of the proposed action or policy, consultation with the U.S. Fish and Wildlife Service or NOAA Fisheries Service must be conducted to assess whether the proposed action or policy can reasonably **avoid “take” by one of the following**: (1) relocation of the proposed action or policy area, (2) relocation of project facilities, (3) seasonal changes in timing of initiation of the action or policy (typical for projects affecting breeding birds and amphibians), or (4) similar actions. When “take” cannot be avoided, the U.S. Fish and Wildlife Service or NOAA Fisheries Service will recommend the project proponent apply for an incidental take permit (U.S. Fish and Wildlife Service 1996).

Species and Effect Determination

Once a project applicant identifies which species are likely to be adversely affected by the proposed action or policy, the project proponent must develop an HCP. The U.S. Fish and Wildlife Service recommends that all potentially occurring threatened or endangered species that may be affected by the proposed action or policy be addressed in the HCP to reduce **potential violation** of ESA § 7(a)(2). Such violations would result in project delays, work stoppage, and/or fines levied upon the project proponents (U.S. Fish and Wildlife Service 1996). In

addition to species listed under the ESA, it is strongly recommended that the project applicant include additional species that may become listed while the incidental take permit is authorized (U.S. Fish and Wildlife Service 1996). **Species not afforded protection** under the ESA that have been included in development of HCPs include (1) federal candidate species, (2) federally sensitive species (including those on the U.S. Forest Service and U.S. Bureau of Land Management [BLM] lists), (3) state endangered or threatened species, and occasionally, (4) species of local importance. After a species list and effect determinations have been prepared by the project applicant, consultation with the U.S. Fish and Wildlife Service or NOAA Fisheries Service should be conducted to ensure the adequacy and obtain concurrence of the species list and effect determinations (U.S. Fish and Wildlife Service 1996).

Likely Effects

An adequate development of a **HCP includes 4 tasks**: (1) delineation of the HCP boundary or plan area, (2) biological data collection and synthesis for species covered by the HCP, (3) identification of activities proposed that are likely to result in incidental take, and (4) quantification of anticipated levels of “take” (U.S. Fish and Wildlife Service 1996).

HCP Delineation

Delineation of the proposed HCP boundary or plan area should include the applicant’s project, land use area, or jurisdictional area for which the proposed action is likely to result in incidental take. Under the ESA, there are no regulations concerning an HCP’s required coverage area; as previously discussed, current HCPs may range from 0.004 km² to nearly 6,500 km². A clearly defined boundary is critical to successful application of HCPs and reduces the potential for uncertainty during the HCP’s duration (U.S. Fish and Wildlife Service 1996).

Biological Data Collection and Synthesis

In most cases a project applicant will require outside assistance, typically from an ecological consultant, to guide the applicant through the HCP process, including literature and database reviews and **research of species covered** by an HCP. At a minimum, these efforts require an understanding of the current distribution, ecology, occurrence data, and applicable regulations for each species covered (Truett et al. 2005). Availability of current and complete data may be limited for some taxonomic groups (e.g., invertebrates and herpetofauna); in such cases, consultants use professional knowledge and judgment to make reasonable inferences based on similar species or scenarios to estimate potential project effects (U.S. Fish and Wildlife Service 1996).

Proposed Activities

The U.S. Fish and Wildlife Service recommends project applicants provide a detailed description of all **proposed activ-**

ities within the HCP boundary likely to result in incidental take over the HCP’s duration (U.S. Fish and Wildlife Service 1996). Specific project descriptions of likely effects results in an easier evaluation of incidental take. For example, in regard to specific details describing grading and excavation activities required for a construction project, verbiage such as the following might be included:

Construction activities will include site grading at 6 locations (Exhibit 1) totaling 4.9 ha. Grading will be conducted outside of the known breeding bird season (20 Sep to 14 Feb) with a D-9 bulldozer. Topsoil will be skimmed and stockpiled at 6 preidentified locations (Exhibit 1) during construction activities and reclamation of 4 locations will be accomplished by spreading stockpiled topsoil to a depth of not 30.5 cm (12 inches) upon completion of the project (Exhibit 2).

Anticipated Incidental Take Levels

The project applicant must provide a **determination of the amount of incidental take anticipated** due to the proposed action. The project applicant must inform the U.S. Fish and Wildlife Service of how incidental take will be calculated, the level of “take” and related effects resulting from proposed actions, and level of incidental take actually authorized (U.S. Fish and Wildlife Service 1996).

To accurately assess potential incidental take levels the project applicant should make a “**good faith**” effort to determine the number of each species covered by the incidental take permit and HCP. Complete counts may be possible for small projects, whereas regional-scale projects may require population modeling or density estimates, when appropriate. There are 2 possible scenarios for providing the level of anticipated incidental take: the first is the actual number of each species anticipated to be killed, harmed, or harassed as a result of the proposed action, and the second scenario is based on the amount of habitat affected either directly or indirectly from a proposed project element when numbers of individuals are unknown or cannot be determined (U.S. Fish and Wildlife Service 1996).

Mitigation

Due to the variable nature of HCPs, species, and associated habitats that may be affected as a result of project implementation, the U.S. Fish and Wildlife Service does not provide standard regulatory guidelines for specific **mitigation measures** to be used by a project proponent. Regardless of the proposed mitigation, each proposed measure must be based on a sound biological basis and should be feasible and proportional with the effects they are designed to address (U.S. Fish and Wildlife Service 1996). **Mitigation approaches** commonly employed for HCPs can include any or all of the following: (1) avoidance, (2) minimization of effects, (3) habitat restoration, and (4) habitat preservation (U.S. Fish and Wildlife Service 1996).

BOX 37.2. EAST CONTRA COSTA COUNTY HABITAT CONSERVATION PLAN AND NATURAL COMMUNITY CONSERVATION PLAN, CONTRA COSTA COUNTY, CALIFORNIA

The East Contra Costa County Habitat Conservation Plan (HCP) and Natural Community Conservation Plan (NCCP) is a 30-year plan with a plan area of 704.2 km², initiated in 1995 and adopted in 2006, and was created to provide a framework for protection of natural resources in eastern Contra Costa County, California and improve and streamline the environmental permitting process for potential effects to endangered species within the HCP and NCCP area. The primary objective of the HCP was to obtain authorization for take of covered species under the ESA for proposed urban development in the cities of Brentwood, Clayton, Oakley, and Pittsburg, and specified areas in unincorporated Contra Costa County. Activities covered under the HCP include all ground-disturbing activities, rural infrastructure projects supporting growth (e.g., road and flood-control projects and maintenance), ongoing management, restoration, and monitoring activities by the preserve manager, and limited public access. The estimated financial commitment to the HCP is between US\$297–350 mil-

San Joaquin kit fox in native habitat, Lokern Natural Area, Kern County, California. *Photo by C. L. Van Horn Job.*

lion for the 30-year plan period and will be available from various sources, including fees on covered activities (new development fees, wetland impact fees, rural infrastructure fees) and nonfee public funding (East Contra Costa County Habitat Conservation Plan Association 2006).

The HCP requested authorization of incidental take of 28 listed and nonlisted species occurring within the plan

Avoidance can be accomplished through project designs or timing of proposed activities (e.g., including bridge designs that completely span potential habitat, or limiting certain construction activities outside the breeding bird season). When proper coordination occurs between project proponents and the U.S. Fish and Wildlife Service, impact or effect avoidance is possible. Coordinated avoidance efforts typically include relocating proposed elements from suitable habitat for an identified species to areas containing no potential

habitat. An avoidance example for projects potentially affecting the desert tortoise (*Gopherus agassizii*; Fig. 37.1) may include relocating a project impact site within suitable habitat (e.g., Mojave Creosote Bush Scrub; Holland 1986) to areas lacking desert tortoise habitat (e.g., pinyon-juniper woodland; Holland 1986).

When avoidance is not possible, through design or timing of the proposed action, minimization measures must be implemented and approved by the U.S. Fish and Wildlife

area, including Townsend's western big-eared bat (*Plecotus townsendii townsendii*), San Joaquin kit fox (*Vulpes macrotis mutica*), tricolored blackbird (*Agelaius tricolor*; nesting colony), golden eagle (*Aquila chrysaetos*; nesting and wintering), western burrowing owl (*Athene cunicularia hypugaea*), Swainson's hawk (*Buteo swainsoni*; nesting), silver legless lizard (*Anniella pulchra pulchra*), western pond turtle (*Actinemys marmorata*), Alameda whipsnake (*Masticophis lateralis euryxanthus*), giant garter snake (*Thamnophis gigas*), California tiger salamander (*Ambystoma californiense*), California red-legged frog (*Rana draytonii*), foothill yellow-legged frog (*R. boylei*), longhorn fairy shrimp (*Branchinecta longiantenna*), vernal pool fairy shrimp (*B. lynchi*), midvalley fairy shrimp (*B. mesoatlantica*), vernal pool tadpole shrimp (*Lepidurus packardii*), Mount Diablo manzanita (*Arctostaphylos auriculata*), brittlescale (*Atriplex depressa*), San Joaquin spearscale (*A. joaquiniana*), big tarplant (*Vlepharizonia plumosa*), Mount Diablo fairy lantern (*Calochortus pulchellus*), recurved larkspur (*Delphinium recurvatum*), round-leaved filaree (*Erodium macrophyllum*), diablo helianthella (*Helianthella castanea*), Brewer's dwarf flax (*Hesperolinon breweri*), showy madia (*Madia radiata*), and adobe navarretia (*Navarretia nigelliformis* ssp. *nigelliformis*).

The California tiger salamander is listed as threatened by the U.S. Fish and Wildlife Service throughout California (excluding Santa Barbara and Sonoma counties), where it is endangered due to loss and fragmentation of habitat and to nonnative predators. Photo by N. R. Sisk.

The California red-legged frog is listed as threatened by the U.S. Fish and Wildlife Service due to conversion of habitat, water diversion, and predation. Photo by N. R. Sisk.

The conservation strategy provided in the HCP is designed to mitigate effects to covered species and contribute to the recovery of each species through a set of 33 conservation measures and 91 biological objectives.

The goal of the HCP is to preserve from 105.4 km² to 139 km² of land to benefit the covered species, preserve and enhance existing habitat corridors, manage habitats to enhance populations of the covered species, and compensate for habitat loss through restoration efforts (East Contra Costa County Habitat Conservation Plan Association 2006).

The HCP established a monitoring and adaptive management program to facilitate meeting the goals outlined for the HCP. The monitoring and adaptive management program established a framework and decision-making process to evaluate monitoring, research, and data management, which allow the project proponent to adapt measures through the term of the plan. Monitoring activities are supposed to provide data that can be incorporated into conceptual models, allowing the project proponent to evaluate specific actions and adjust as necessary to meet the objectives of the HCP (East Contra Costa County Habitat Conservation Plan Association 2006).

Service. **Minimization measure could include** (1) the use of the most degraded habitat, (2) reducing the size of the permanent impact area, (3) reduced construction or maintenance during key biological periods, (4) habitat manipulation, (5) best management practices, (6) and access control (e.g., reduced public or livestock access).

Rectification of effects may include habitat restoration (e.g., removal of invasive exotics, plantings or other vegetation manipulations, creation of new habitat, or habitat preserva-

tion where the project proponent purchases land containing suitable or occupied habitat and donates to a nongovernmental organization [NGO], agency, etc., for preservation in perpetuity [U.S. Fish and Wildlife Service 1996]).

Restoration activities are most frequently conducted in HCPs as a means for offsetting temporary effects as a result of the proposed activity (ESA § 10[B][ii]). Temporary effects are those effects include staging areas, temporary access roads, etc. Depending on the size, affected habitat, and du-

Fig. 37.1. The desert tortoise is listed under the Endangered Species Act as “threatened.” Human development activities have reduced its populations in many areas. *Photo by R. A. Fridell.*

ration of temporary effects, restoration may or may not be viable mitigation. Restoration activities can be as simple as reseeded grassland areas or top-soil reclamation or as complex as restoring tidal wetland systems.

Compensation can be accomplished through the purchase of land of comparable habitat, both in size and quality. Most compensation for effects to habitats suitable to support threatened and endangered species is based on the habitat “value” and requires mitigation ratios. A simple example of habitat “value” is the qualitative scoring system used by the Natural Resources Conservation Service (NRCS) in range assessments. Under the NRCS scoring system, range sites are qualitatively scored from 5 to 1 (excellent to poor) based on species composition, habitat functioning, and site degradation (NRCS 2003).

An example of **compensation as a mitigation tool** can be found in the West Mojave Plan (BLM 2005). The BLM identified areas with specific compensation requirements, based on estimated habitat quality, for projects potentially affecting desert tortoise and their associated habitats. Mitigation ratios for effects to suitable habitat range from 0.5:1 (low-quality habitat) to 5:1 (exceptional habitat). With clear definitions of mitigation ratios already identified for the area, project proponents can identify the amount of in lieu mitigation or land purchase for habitat preservation that may be required based on the location within the West Mojave Plan area.

Conservation banking is another form of HCP-related habitat impact-mitigation approaches. Mitigation or conservation banks are permanently protected lands managed for threatened, endangered, or candidate species that intend to offset adverse effects resulting from a project implemented elsewhere (Endangered Species Program 2009). The Balcones Canyonlands Conservation Plan (BCP) is an example of mitigation banking (Beatley 1994). Development and other projects near Austin, Texas (particularly areas over Edwards

Limestone geology) that could affect several endemic, federally listed species (e.g., black-capped vireos [*Vireo atricapilla*], golden-cheeked warblers [*Dendroica chrysoparia*], several salamanders, cave invertebrates, and 27 species of concern) are offset through purchase credits within the BCP. Over time, mitigation purchase credits are used to purchase contiguous land containing suitable habitat for a variety of species. This **mitigation banking** effort includes joint management of the BCP by a variety of primary stakeholders, including the Lower Colorado River Authority, U.S. Fish and Wildlife Service, Texas Parks and Wildlife Department, Travis County, City of Austin, private landowners, developers, and several NGOs (U.S. Fish and Wildlife Service 2005b).

Available Funding

All HCPs, regardless of species, size, or duration, must have **sufficient funding available** to ensure proper implementation of the agreement. The ESA required detailed accounting of available funding to implement mitigation measures proposed under the HCP (ESA § 10[a][2][B][iii]; U.S. Fish and Wildlife Service 1996).

The implementation agreement always contains provisional funding language. **Federal funding** that may be used during the implementation of the HCP is subject to the requirements of the **Anti-Deficiency Act** and subject to availability of appropriate funds. Failure to meet requisite funding levels prior to approval of the HCP and incidental take permit, are grounds for suspension, revocation, or denial of existing permits (ESA § 10[a][C]; U.S. Fish and Wildlife Service 1996).

Alternative Actions Considered

Alternative actions are those actions that were considered during the HCP process and are determined to be infeasible during project implementation. Alternative actions considered will always include the preferred alternative, a “no-build” alternative, and numerous alternative project scenarios. Examples of alternative actions include modification of construction schedules to reduce incidental take during key biological periods (e.g., during breeding or migration periods), relocation of project elements to avoid potential effects to sensitive habitats or wetlands, or land purchase agreements (U.S. Fish and Wildlife Service 1996).

Coordination and Planning

The HCP process was created by Congress as a method to reduce issues and conflicts between species with a federal listing and nonfederal development projects (U.S. Fish and Wildlife Service 1996). The U.S. Fish and Wildlife Service and NOAA Fisheries Service are active participants in the HCP process, not just regulatory overseers, and **early coordination is essential** for a successful HCP. The HCP must adequately address state-listed species as well, and coordination with the state’s habitat conservation planning branch is

critical; otherwise, failing to coordinate with the state will result in a delayed HCP. Some states have their own permitting process, and further planning and coordination is required on this level. The crux is to ensure that the HCP complies with Sections 7, 9, and 10 of the ESA (U.S. Fish and Wildlife Service 1996).

Permit Processing

The **final permitting process** varies depending on completeness and complexity of submitted applications and supporting documents (e.g., EIS, EA, or Categorical Exclusion). For proposed actions having minimal or low effects on listed or candidate species and their associated habitats, the target processing time is 3 months. HCPs that do not have minimal or low effect on listed species and their associated habitats require submittal of either an EA or EIS, and have a target processing time of 4–12 months. In most cases the target processing times are the minimum time it will take to process the application and, in most instances, actual permitting will require longer periods of time due to available staff and higher priority projects. After permit processing, the U.S. Fish and Wildlife Service will publish a Notice of Availability in the *Federal Register*, opening a 30-day public comment period, with an option to extend the period to 60 days. Interested parties can review the document and provide comments to the U.S. Fish and Wildlife Service (ESA § 10[3][c]). At the closing of the public comment period, the U.S. Fish and Wildlife Service or a designated representative of the project applicant will compile, address, and evaluate comments prior to issuance of the incidental take permit and HCP implementation (U.S. Fish and Wildlife Service 1996).

Implementation

Once the U.S. Fish and Wildlife Service approves an HCP and issues the incidental take permit, the HCP may be **implemented** by the project proponent. **Monitoring** is a key component to the implementation of an HCP to ensure the applicant is proceeding with project activities as agreed. If monitoring is conducted by an entity other than the U.S. Fish and Wildlife Service, periodic reports would be required by the U.S. Fish and Wildlife Service, documenting progress, as well as compliance and noncompliance, with the issued permit (ESA § 10[b][v]; U.S. Fish and Wildlife Service 1996).

“No Surprises” Rule

The “**No Surprises**” rule (63 CFR § 8859) provides project applicants with an incidental take permit with long-term certainty that the U.S. Fish and Wildlife Service or NOAA Fisheries Service will not require additional commitments of land or finances beyond the level stipulated for the term of the **Incidental Take Permit** except under “extraordinary circumstances.” The “No Surprises” rule ensures the gov-

ernment honors agreements outlined within the HCP (43 CFR § 17.22[c][5], 43 CFR § 17.32[c][5]).

SAFE HARBOR AGREEMENTS

Safe Harbor Agreements (63 CFR § 32,180) are voluntary agreements in which the U.S. Fish and Wildlife Service works with nonfederal landowners to develop management actions contributing to the recovery of a listed species for a predetermined time period (64 CFR § 32.717). **Management actions can include** (1) habitat maintenance, and (2) reintroduction of threatened or endangered species to private lands. The U.S. Fish and Wildlife Service provides regulatory assurances to the nonfederal landowner with an enhancement of survival permit (ESA § 10[a][1][A]) in exchange for implementation of management actions. The enhancement of survival permit provides the subject property that is enrolled in a safe harbor agreement can be altered and returned to an agreed-upon baseline condition at the end of the agreed time period, even if take of a threatened or endangered species is involved (64 CFR § 32.171 *et seq.*). The enhancement of survival permit may include “no surprises” assurances (43 CFR § 17.22[c][5], 43 CFR § 17.32[c][5]; Box 37.3).

CANDIDATE CONSERVATION AGREEMENTS

Candidate Conservation Agreements (CCA) are formal agreements between the U.S. Fish and Wildlife Service and nonfederal landowners addressing conservation needs of candidate or at-risk species (50 CFR § 17.22[d], 50 CFR § 17.32[d]). **Candidate species** are those species for which there exists enough information on their biological status and threats to their long-term survival that the species can be listed as threatened or endangered under the ESA (ESA § 4[b][3][c][iii]), but that are precluded from listing by higher priority listing activities. Enrolled landowners typically receive regulatory assurances from the U.S. Fish and Wildlife Service, providing incentives to voluntarily implement conservation measures for candidate or at-risk species. Similar to safe harbor agreements, an **enhancement or survival permit** (ESA § 10[a][1][A]) will be issued by the U.S. Fish and Wildlife Service, providing that no additional conservation measures will be required if the species becomes listed in the future, even if “take” is involved (64 CFR § 32726–32736). This permit also allows permit holders to “take” wildlife species and modify habitat conditions to those agreed upon and specified in the CCA (64 CFR § 32726–32736).

SUMMARY

The environmental movement of the 1960s and early 1970s established key environmental statutes (e.g., NEPA and ESA) on which EIAs and HCPs are based. Under NEPA, federal

BOX 37.3. GULF COAST PRAIRIES OF TEXAS SAFE HARBOR AGREEMENT

The Safe Harbor was developed as a provision of the Habitat Conservation Plan for the Gulf Coast of Texas and adopted to promote restoration, conservation, and/or enhancement of prairie habitats supporting endangered species (specifically the Attwater's prairie-chicken [*Tympanuchus cupido attwateri*], Houston toad [*Anaxyrus houstonensis*], and Texas prairie dawn flower [*Hymenoxys texana*]) on private lands, and protect individuals entering into this voluntary agreement from future liabilities under the ESA (U.S. Fish and Wildlife Service [USFWS] 1995). There are 2 key differences between a Safe Harbor and a HCP: (1) Safe Harbor is voluntary, and (2) Safe Harbor is proactive.

The Safe Harbor encourages private landowners to restore and/or enhance degraded habitat and conserve existing habitat to promote the recovery of the 3 listed species. Once a private landowner has agreed to enter the Safe Harbor, the USFWS will establish baseline habitat improvements (e.g., brush clearing, prescribed burning, and native vegetation reestablishment) or responsibilities. Earmarked funds for habitat improvements and responsibilities are made available for enrolled landowners to encourage participation and offset costs associated with voluntary conservation measures. Landowners may continue to conduct any lawful action at the enrolled property so long as they do not go below the baseline established in conjunction with the USFWS (USFWS 1995).

At present, 12 landowners have entered into the Gulf Coast Prairies of Texas Safe Harbor with total land enrolled at >89.03 km². Should a participating landowner decide to opt out of the Safe Harbor Agreement, they are required to notify the USFWS and allow the USFWS to relocate any endangered species from the property. Landowners also may sell land enrolled in the Safe Harbor with the buyer given the option to continue or decline further participation (USFWS 1995).

agencies are required to assess potential effects a proposed project or action may have on the environment. Several types of EIAs are prepared in the United States, including EIS (40 CFR § 1502, NEPA § 102[2][c]), EA (40 CFR § 1508.9), Categorical Exclusions (40 CFR § 1508.4), and Findings of No Significant Impacts (40 CFR § 1504). The most commonly prepared EIA in the NEPA is the EA.

Preparation time of individual EIAs is related to the complexity of the proposed project or action and the number of potential environmental effects resulting for each component of the proposed project or action. SEPA documents closely parallel the format, structure, and development time of NEPA documents.

Section 10 of ESA as amended in 1982 allowed for the issuance of incidental take permits for private projects potentially resulting in "take," as defined in Section 9 of the ESA, through otherwise lawful activities. In order for the U.S. Fish and Wildlife Service or NOAA Fisheries Service to issue an incidental take under Section 10, project proponents must prepare an HCP for review. HCPs must include (1) a purpose statement, (2) assessment of potential "take," (3) listed and nonlisted species considered for coverage, (4) likely effects, (5) delineation of the HCP boundary and time the HCP will be in effect, (6) mitigation of "take," (7) available funding, (8) alternative actions considered, and (9) coordination and planning.

The U.S. Fish and Wildlife Service offers voluntary alternatives to HCPs for individuals, including Safe Harbor Agreements (63 CFR § 32,180), and CCAs (50 CFR § 17.22[d], 50 CFR § 17.32[d]). Safe Harbor Agreements allow private landowners to enter agreements with the U.S. Fish and Wildlife Service to conduct voluntary conservation measures assisting in the conservation and recovery of listed species on private lands. Private landowners participating in Safe Harbor Agreements allow the individual to continue lawful activities on their land as long as the baseline habitat remains intact. CCAs are proactive agreements with U.S. Fish and Wildlife Service to enhance existing habitat for candidate species to reduce the likelihood of a candidate species receiving a higher listing under the ESA (e.g., federally listed as threatened or endangered).

Both EIAs and HCPs are environmental documents designed to evaluate and remediate the potential effect of a proposed policy or action to the environment or listed species, respectively. The development of EIAs and HCPs have similar processes where a project proponent discloses the potential effects of the proposed project or action on the environment and how those potential effects will be avoided, reduced, or mitigated to below the level of significance.
